<b>Brief Summary of Relevant Clinical Research Experience:</b> I have been a in the area of enveloped virus-host cell interactions for over the past 32 years. I developed the first oligomeric HIV-1 gp140 envelope glycoprotein, established a vaccinia virus-based reporter gene assay for measuring viral glycoprotein-mediated membrane fusion, and defined the membrane fusion tropism of HIV-1 followed by the discovery of the HIV-1 coreceptors (CXCR4 and CCR5). In 1999, I established an international group of experts in Hendra virus and Nipah virus research. My lab's work includes the discovery of the entry receptors for Hendra and Nipah (ephrin-B2/B3), developed the feline, ferret and African green monkey models of Hendra and Nipah pathogenesis, the structural solutions of the F glycoprotein and the G-ephrin receptor interactions; the discovery and development of antiviral human monoclonal antibodies including one having a Phase I clinical trial completed in May, 2016, known as m102.4 that has been used by compassionate emergency protocol in 15 people in Australia and one in the United States because of significant exposure risk to Hendra or Nipah infection. I also developed the Hendra/Nipah subunit vaccine based on soluble Hendra G (HeV-sG); called Equivac® HeV (Zoetis, Inc.) which is the first commercialized vaccine to a BSL-4 agent. We have developed reverse genetics platforms for Australian bat lyssavirus and Cedar henipavirus that can be utilized at BSL-2. My lab is now doing virus surveillance using multiplex assays with native-like viral membrane proteins that measure antiviral humoral responses in animals and humans

Edited by Vishva M. Dixit, Genentech, San Francisco, CA, and approved September 14, 2020 (received for review February 21, 2020)

Bats have emerged as unique mammalian vectors harboring a diverse range of highly lethal zoonotic viruses with minimal clinical disease. Despite having sustained complete genomic loss of AIM2, regulation of the downstream inflammasome response in bats is unknown. AIM2 sensing of cytoplasmic DNA triggers ASC aggregation and recruits caspase-1, the central inflammasome effector enzyme, triggering cleavage of cytokines such as IL-1 $\beta$  and inducing GSDMD-mediated pyroptotic cell death. Restoration of AIM2 in bat cells led to intact ASC speck formation, but intriguingly resulted in a lack of caspase-1 or consequent IL-1 $\beta$  activation. We further identified two residues undergoing positive selection pressures in *Pteropus alecto* caspase-1 that abrogate its enzymatic function and are crucial in human caspase-1 activity. Functional analysis of another bat lineage revealed a targeted mechanism for loss of *Myotis davidii* IL-1 $\beta$  cleavage and elucidated an inverse complementary relationship between caspase-1 and IL-1 $\beta$ , resulting in overall diminished signaling across bats of both suborders. Thus we report strategies that additionally undermine downstream inflammasome signaling in bats, limiting an overactive immune response against pathogens while potentially producing an antiinflammatory state resistant to diseases such as atherosclerosis, aging, and neurodegeneration.

bats | AIM2 | caspase-1 | inflammasome | IL-1 $\beta$

Bats are placental mammals which uniquely utilize powered flight for locomotion, harbor a diverse viral repertoire, and possess longevity exceptional to their body size. In recent years, bats have been implicated in major outbreaks caused by fatal zoonotic viruses, such as SARS-CoV and MERS-CoV, henipaviruses, filoviruses including Ebola and Marburg virus, and a high likelihood of the currently circulating SARS-CoV-2 (1–4). Ongoing outbreaks with significant mortality and morbidity in human and livestock have driven a targeted search for the originating hosts of these spillover pathogens and pivotal studies have identified bats as significant reservoir and ancestral hosts to more zoonotic diseases per species, against all other mammalian orders (2, 5). Of key interest is the bat innate and adaptive immune system, due to evolutionarily driven or yet undiscovered, altered interactions between the host–pathogen interface, leading to their tolerance of viral diseases.

Genomic and transcriptomic studies have identified disparities between bats and other mammals. Positive selection has been shown in critical innate immune, tumor suppressive, and DNA damage checkpoint genes of bats (6), including NLRP3, TP53, and ATM. Altered natural killer (NK) cell repertoires were found among *Pteropus alecto*, *Myotis davidii*, and *Rousettus aegyptiacus* bats, along with differential contraction of IFN- $\alpha$  genes and expansion of IFN- $\omega$  genes in *Pteropus*, *Myotis*, and *Rousettus* bat species (7, 8). Despite mounting genomic evidence that bats have unique alterations in innate immune pathways,

experimental confirmation is rare. We recently demonstrated that NLRP3 is dampened in bats as a result of loss-of-function bat-specific isoforms and impaired transcriptional priming (9). The stimulator of IFN genes (STING), a key adaptor to the DNA-sensing cGAS protein, is also exclusively mutated at S358 in bats, resulting in a reduced IFN response to HSV1 (10). We previously reported a complete absence of Absent in melanoma 2 (AIM2)-like receptor (ALR) genes across all available bat genomes from both Yinpterochiroptera and Yangochiroptera suborders (11). As these modifications in bats signify shifts in cell signaling and immune regulation, we thus investigated the loss of the PYHIN or ALR gene family for implications on the bat DNA-sensing inflammasome response.

The ALRs are an essential group of germline-encoded pattern recognition receptors (PRRs) comprising 5 members in humans and 14 members in mice, with the most well studied being AIM2 (12, 13). AIM2 is the prototypical member of the ALR family and was shown to mediate intracellular dsDNA-responsive inflammasome signaling, typically of invading pathogenic origin or aberrant host cytosolic DNA (14, 15). There is extensive

## Significance

Bats have been shown to dampen several key upstream pathogen and danger-associated molecular patterns, yet much of the downstream signaling is yet unknown. Here, we identify residues in caspase-1 which are critical for enzymatic activity and have been targeted for inhibition in *Pteropus* bats. Further, we discover cleavage-site flanking residues which lead to loss of IL-1 $\beta$  cleavage in *Myotis* bats. Thus, we report an inverse relationship between caspase-1 function and IL-1 $\beta$  cleavage, resulting in a consistent reduction of downstream signaling by the inflammasome across bats within the two suborders. In sum, we confirm that bats have targeted the inflammasome pathway at multiple levels and via heterogeneous strategies to reduce proinflammatory responses, thus mitigating potential immune-mediated tissue damage and disease.

diversity across mammalian ALR families and AIM2 is the only member with preserved orthology among species (12, 16). Upon recognizing exposed intracellular DNA, it binds to the major turn of the DNA helix and recruits its adaptor apoptosis-associated speck-like protein containing a CARD (ASC), which forms aggregates (ASC specks) to complex with downstream procaspase-1 (15, 17). The caspase-1 proenzyme undergoes homodimerization and autocleavage for activation, conferring it the ability to bind, cleave, and mature IL-1 $\beta$ , IL-18, and gasdermin D (GSDMD) and trigger pyroptotic cell death (18–22). The mammalian AIM2 is crucial in its role in sensing intracellular foreign DNA, accompanied by a potential for either a pathological or protective inflammatory response in the host (23–25). Yet the consequence of its absence in bats, a unique animal model shown to down-regulate components of its inflammasome pathway, is poorly understood.

Caspase-1, or cysteine aspartic protease 1, is the central inflammasome effector for pyroptosis and cytokine secretion, playing roles in diverse cellular processes, including apoptosis/necrosis, metabolism, mitophagy, and autophagy (26–29). The propeptide consists of a caspase-recruitment domain (CARD), a p20 and p10 polypeptide sequence, and undergoes sequential autoproteolysis at aspartic acid residues into p20/p10 subunits which dimerize to achieve the activated conformation for substrate binding and cleavage (18, 21, 30). It is converged upon by all canonical inflammasome receptors, including NLRP3, NAIP/NLRP4, NLRP1, AIM2, and pyrin, and many other members of the NLR family such as NLRP6, NLRP7, and NLRP12, mediating critical proinflammatory host responses against microbes or auto-immune and autoinflammatory sequelae (31). Further, it is involved in multiple age-related diseases, including amyloid  $\beta$  accumulation in Alzheimer's disease and cardiac injury during acute myocardial infarction (32, 33). While intensive study of human caspase-1 inhibitors are currently ongoing, given its therapeutic potential, still little is known about the downstream activation of caspase-1 in bats, especially given their altered immune landscape and dampened inflammasome function.

Here, we confirm that genomic loss of AIM2 in bats dismantles the inflammasome adaptor recruitment responsive to dsDNA. Additionally, reconstitution of the human gene in a bat in vitro environment is sufficient to partly restore this intracellular pathway up to ASC level. However, we discovered an absence of the downstream cytokine release or cell-death initiation despite robust ASC speck formation in bat primary macrophages. We identify key residues in the bat caspase-1 responsible for dampened IL-1 $\beta$  cleavage, or altered IL-1 $\beta$  cleavage sites which significantly reduce its processing and maturation in bats. Importantly, we have elucidated multiple levels of disengagement within the bat inflammasome pathway with key implications in their response toward cellular stress, inflammation, and pathogenic detection.

## Results

**Absence of ASC Speck Induced by DNA Stimulation in Bat Kidney and Immune Cells Is Restored by Human AIM2.** Given the ALR family members, including AIM2, are the only DNA sensors mediating the intracellular sensing of pathogenic and aberrant host DNA to activate the inflammasome, we hypothesized that absence of all ALR genes in bats would result in the inability for bats to trigger inflammasome signaling. Indeed, with exogenous dsDNA ligand PolydA:dT stimulation of bat bone-marrow-derived macrophages (BMDMs), we observed a lack of recruitment of ASC into aggregates (ASC speck), which could be seen in dsDNA-treated murine BMDMs (Fig. 1A). Further, using high-throughput image-based flow cytometry (Imagestream), we observed that the cytosolic ASC remained diffusely distributed in bat cells, unlike their aggregation into a speck-like morphology in mouse macrophages (Fig. 1B).

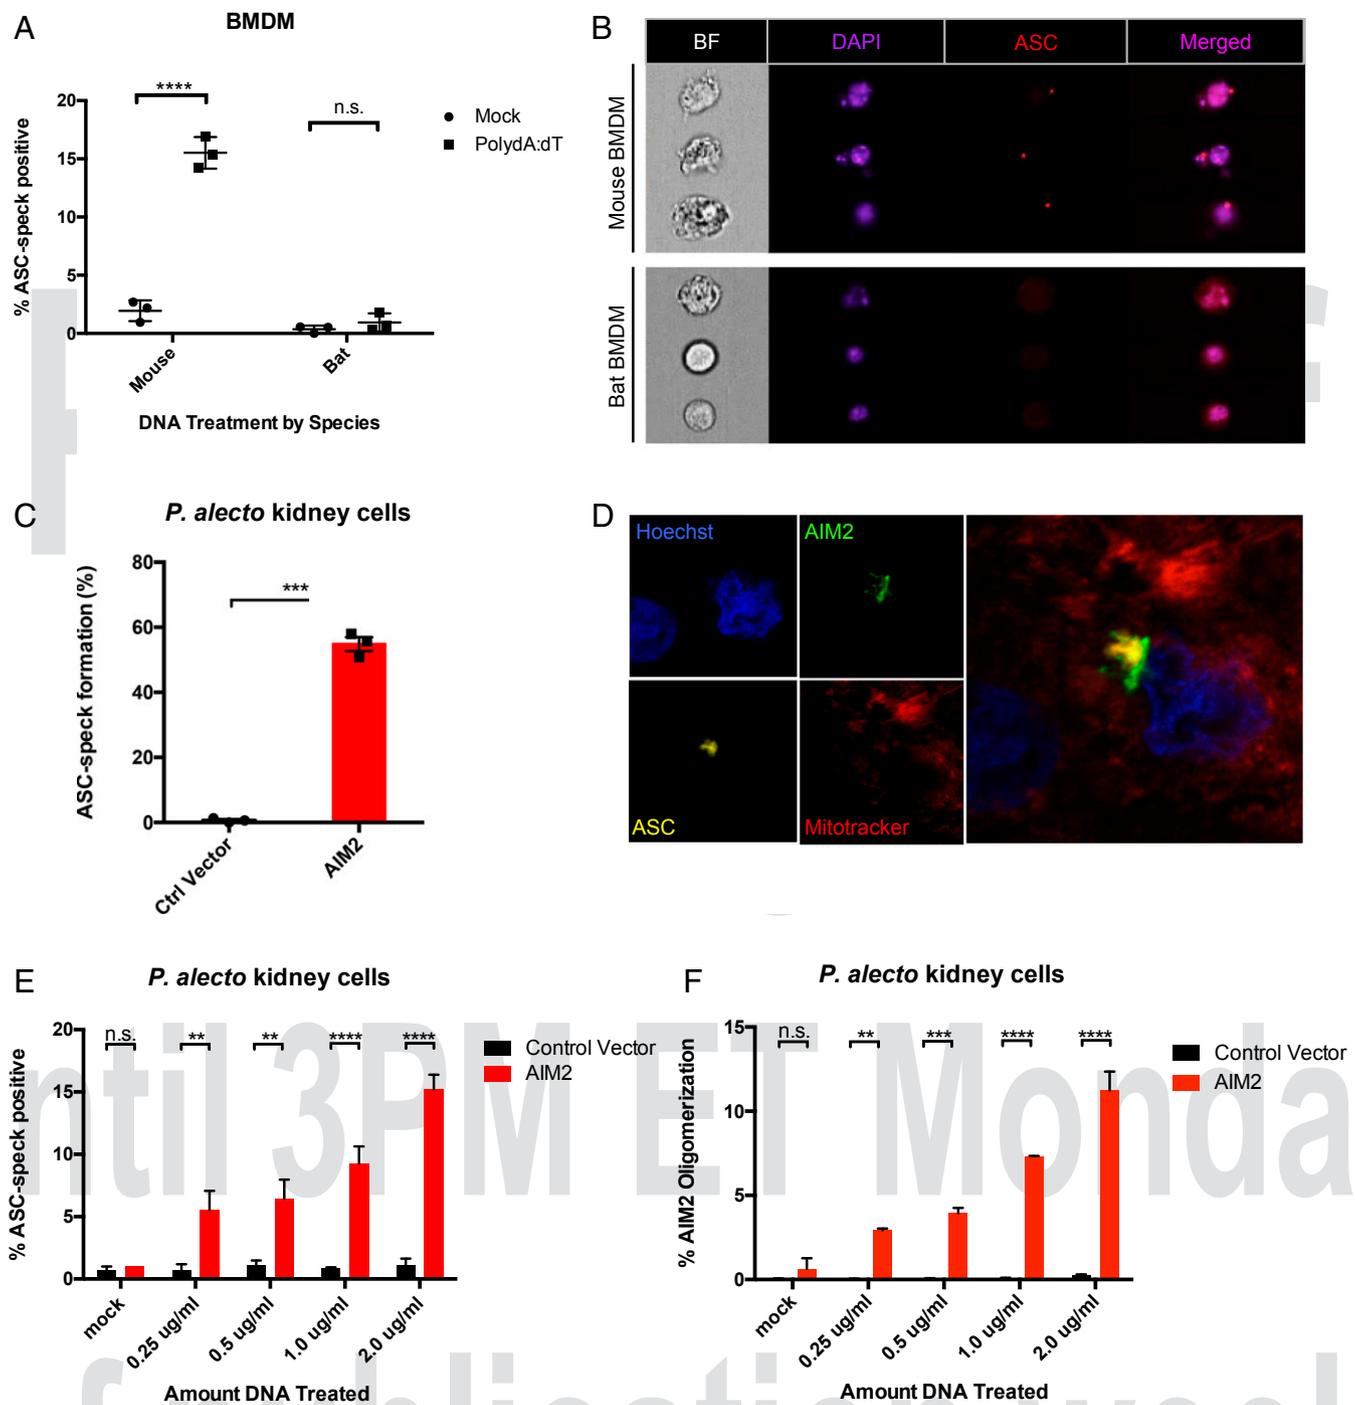

To investigate whether lack of ASC speck formation was attributable to the absence of gene and protein expression from

the ALR family, we generated a human AIM2-mCitrine fusion construct cloned into a mammalian expression vector and rescued the gene in *Pteropus alecto* kidney-derived (PaKiS) immortalized cells (34). We selected the human AIM2 protein, as AIM2 is the only ALR gene with conserved evolutionary and functional orthology across species (16) and the human ortholog is closest in homology to the only nonfunctional PYHIN peptide fragment identified in bats (*Pteronotus parvelli*) (11). Transient overexpression of human AIM2 alone was sufficient to restore ASC speck formation in PaKiS cells stably expressing bat ASC (Fig. 1C and *SI Appendix, Fig. S1 A and B*), resulting in organization into a perinuclear inflammasome complex with colocalization of AIM2 and downstream ASC (Fig. 1D). To evaluate the activation in response to intracellular DNA, lentiviral delivery was used to generate PaKiS cells stably expressing both human AIM2 and bat ASC at low copy number. ASC speck formation was induced with addition of PolydA:dT DNA ligand and increased in a dose-dependent manner in AIM2-positive cells only (12-fold increase at 2.0  $\mu$ g/mL compared to 0  $\mu$ g/mL) (Fig. 1E). This was accompanied by increasing detection of AIM2 oligomerization (15-fold), signaling intact sensing of dsDNA by AIM2 and consequent formation of the inflammasome recruitment platform (Fig. 1F). Importantly, interaction of the adaptor ASC with the AIM2 sensor demonstrates the highly conserved nature of bat ASC to retain ability for recruitment to oligomerized human AIM2. This supports our previous observation whereby bat ASC is also conserved with the human ASC in its function and speck properties, including size, density, and shape in response to NLRP3 (9).

**Human AIM2 Restores ASC Speck Formation but Not Caspase-1 Activation or IL-1 $\beta$  Release in Bat Macrophages.** As the *P. alecto* kidney in vitro immortalized cell system lacks classic inflammasome machinery, we examined primary in vitro differentiated bat BMDMs for activation of the inflammasome as a consequence of AIM2 restoration. Transduction of lentivirus carrying a control vector or human AIM2 was performed in *P. alecto* BMDMs (PaBMDMs), and ASC speck formation was similarly quantified by Imagestream. Only AIM2 reconstituted (AIM2<sup>+</sup>) bat macrophages treated with PolydA:dT were able to induce endogenous bat ASC aggregation, whereas minimal induction was observed in the mock (vehicle)-treated control vector or AIM2<sup>+</sup>, or PolydA:dT-treated control vector, conditions (Fig. 2A). Imagestream analysis supported this finding with visible ASC speck in PolydA:dT-treated AIM2<sup>+</sup> BMDMs compared to vehicle-only (mock) controls (Fig. 2B). This suggested AIM2-dependent restoration of ASC speck induction in response to the DNA ligands.

Thus, we next looked for downstream IL-1 $\beta$  cleavage or induction of pyroptosis. Unexpectedly, mature IL-1 $\beta$  was unable to be detected in the supernatant despite ASC speck induction in DNA-treated AIM2-reconstituted bat BMDMs, in contrast to the mouse BMDMs (Fig. 2C). This was accompanied by minimal lytic cell death and low lactate dehydrogenase (LDH) activity levels in the cell supernatant (Fig. 2D). To measure the caspase-1 activity specifically in bat BMDMs, we utilized the 660-YVAD-fmk fluorescent-labeled inhibitor of caspase activation (FLICA) assay with relative specificity for the caspase-1 active site. We observed lack of substrate binding even in DNA-treated and AIM2<sup>+</sup> bat BMDMs, compared to the robust activity in treated mouse BMDMs which possess endogenous AIM2 (Fig. 2E). As a previous study similarly identified minimal secretion of IL-1 $\beta$  upon NLRP3 inflammasome activation in bat primary immune cells, we decided to investigate the downstream convergence of both sensing platforms onto caspase-1.

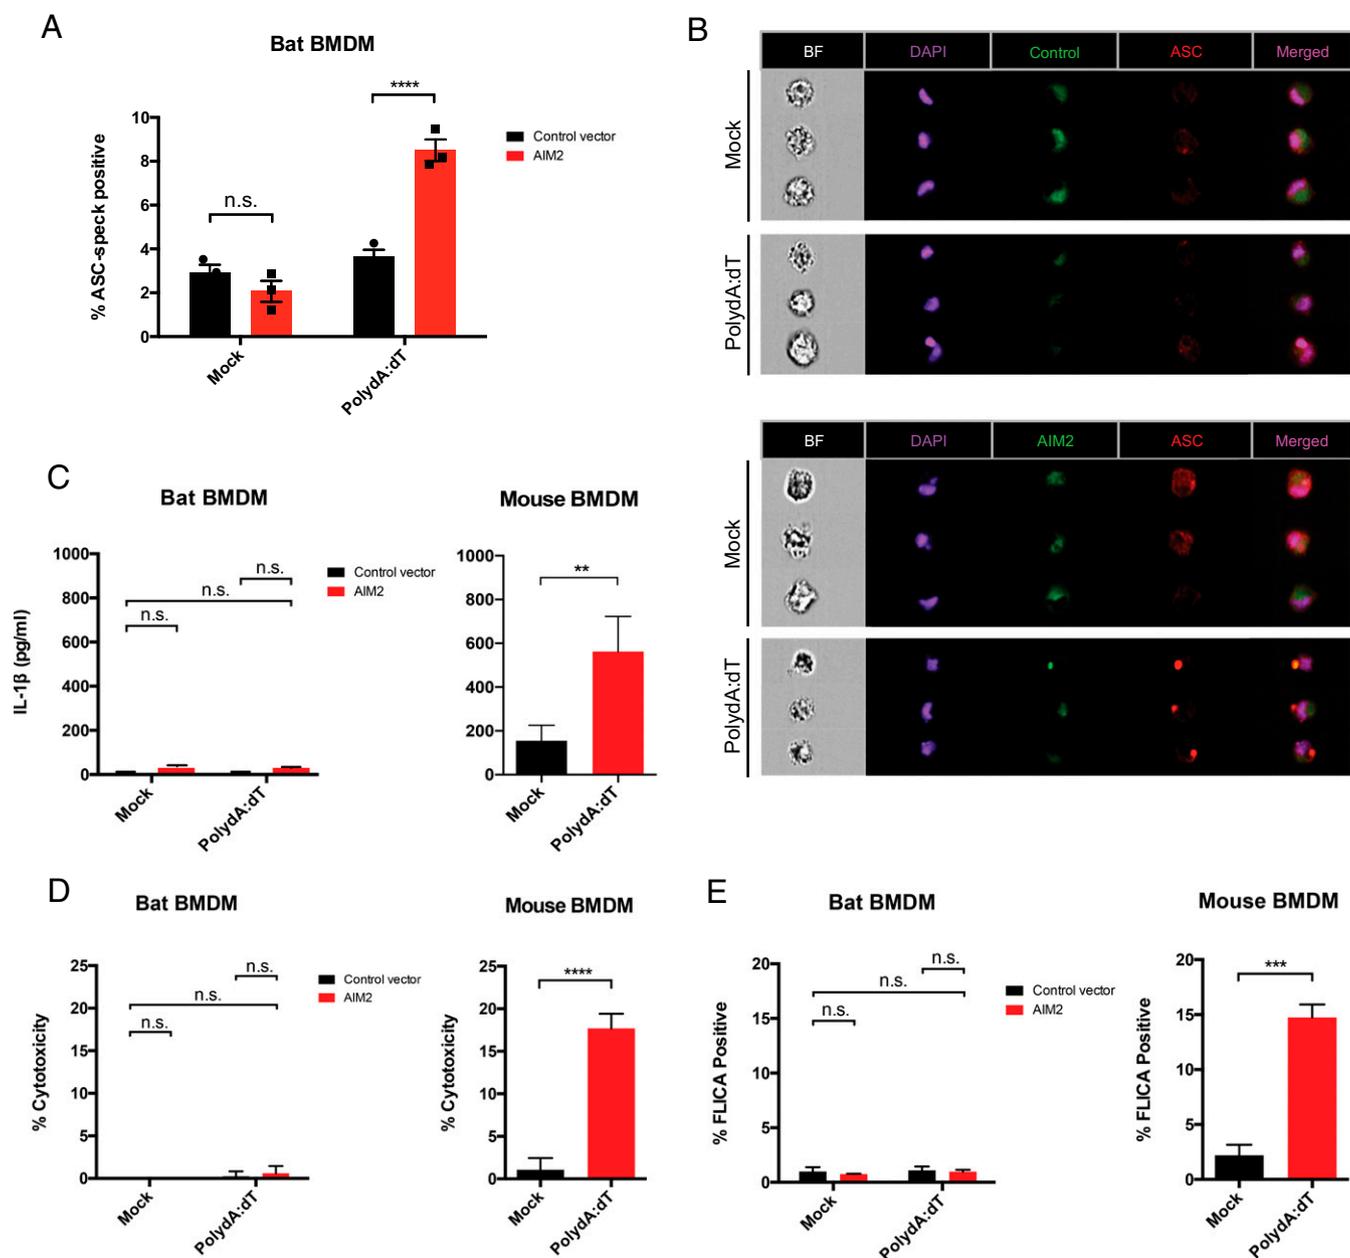

**Failure in IL-1 $\beta$  Production Is Due to Substitution of Two Residues in *P. alecto* Bat Caspase-1.** Lack of downstream activation in the presence of ASC specks can be attributed to either caspase-1, or

**Fig. 1.** Reconstitution of AIM2 restores DNA-triggered ASC speck in bat cells. (A) Measurement of ASC speck formation in mouse and bat BMDMs treated with either vehicle (mock) or transfected dsDNA (PolydA:dT, 1  $\mu$ g/mL) for 4 h after 3 h LPS (mouse) or CL264 (bat) priming. (B) Single-cell imaging of mouse or bat BMDMs collected on Imagestream to visualize ASC speck aggregation or diffuse intracellular distribution, shown as bright field (BF), DAPI, and ASC signals. (C) ASC speck formation was quantified on Imagestream flow cytometry in *P. alecto* kidney cells (PaKiS) stably expressing bat ASC-mPlum and transiently expressing human AIM2. (D) Single-plane confocal imaging of transfected PaKiS cells showing ASC speck aggregation and association with cotransfected AIM2. Hoechst 33342 nuclear staining (blue), AIM2-mCitrine (green), ASC-mPlum (yellow), and Mitotracker (red). (E) Retroviral transduction of control vector or AIM2 was performed in ASC-mPlum stably expressing PaKiS cells, and DNA transfected in a dose-curve (mock, 0.25 to 2.0  $\mu$ g/mL PolydA:dT). Imagestream flow cytometry was performed for triggered ASC speck. (F) AIM2 oligomerization induced in a dose-dependent manner quantified by Imagestream. \*\* $P < 0.01$ , \*\*\* $P < 0.001$ , \*\*\*\* $P < 0.0001$ , n.s., nonsignificant; linear regression and two-tailed unpaired  $t$  test. Data are presented as mean  $\pm$  SEM of three biological replicates (A and B) or three independent experiments (C–F).

IL-1 $\beta$ , or both. To dissect the mechanism, we reconstituted the entire AIM2 inflammasome axis in human embryonic kidney (HEK293T) cells, coexpressing AIM2, ASC, caspase-1, and IL-1 $\beta$ . Human genes were used for the upstream components

(AIM2 and ASC) to standardize the system in a human cell line. Either control (empty vector), human, or *P. alecto* caspase-1 (HsCASP1, PaCASP1) proteins were expressed in increasing concentrations and the cell lysates were immunoblotted for

**Fig. 2.** Lack of caspase-1 or IL-1 $\beta$  signaling despite ASC speck restoration in AIM2-reconstituted bat macrophages. (A) Mouse or *P. alecto* BMDMs (PaBMDM) were differentiated in CSF-1 for 5 d and transduced with AIM2 or control vector lentivirus. At 48 h posttransduction, macrophages were primed with CL264 or LPS and treated with vehicle (mock) or DNA (PolydA:dT, 1  $\mu$ g/mL) for 4 h and ASC speck was quantified via ImageStream. (B) Representative images for PaBMDMs stained for DAPI and anti-PaASC, shown is HsAIM2-mCitrine reconstitution and PaASC speck formation with either mock or PolydA:dT treatment. (C) LDH assay was performed on supernatant to measure cytolytic cell death in PolydA:dT-treated bat control or AIM2<sup>+</sup> BMDM (Left) or mouse BMDM (Right). (D) Similarly, IL-1 $\beta$  secretion was quantified in the supernatant of treated bat and mouse BMDMs using in-house bat ELISA protocol as previously published (14) and mouse IL-1 $\beta$  ELISA kit. (E) Fluorescent-labeled inhibitor of caspase activation (FLICA) assay was performed on bat and mouse BMDMs for caspase-1 activation upon DNA treatment, with staining for 1 h and flow cytometry analysis. Statistical analysis was performed using two-way ANOVA with Bonferroni's multiple comparisons test (A and C-E) and two-tailed unpaired *t* test (C-E). \*\**P* < 0.01, \*\*\**P* < 0.001, \*\*\*\**P* < 0.0001, n.s., nonsignificant. Data are representative of three biological replicates (*n* = 3) in B or mean  $\pm$  SEM of three biological replicates (*n* = 3) in (A, C, and E).

cleaved IL-1 $\beta$  p17, representing the product of inflammasome activation. Notably, there was minimal detection of mature bat IL-1 $\beta$  p17 in the cell lysates despite increasing expression of PaCASP1 (Fig. 3A). In contrast, human caspase-1 showed robust cleavage of bat IL-1 $\beta$ , suggesting intact cleavage of bat IL-1 $\beta$ . We observed an overall decrease in pro-PaCASP1 expression in contrast to human protein expression, and an absence of PaCASP1 p32 or other intermediate self-cleavage products. Importantly, a clear reduction in PaCASP1 activity compared to

HsCASP1 was observed, which suggested decreased functionality of bat caspase-1.

To confirm the loss of caspase-1 activity, we interrogated PaCASP1 for intact activation by FLICA assay with specificity to caspase-1 to detect for active site binding. Similarly, although HsCASP1 exhibited 10-fold times higher FLICA substrate retention and fluorescence (11.03%  $\pm$  0.201), PaCASP1 had minimal detection in activity (2.855%  $\pm$  0.991), with levels similar to the control vector (1.58%  $\pm$  0.218) (Fig. 3B and C). To

further confirm that loss of inflammasome signaling was at the bat caspase-1 and not IL-1 $\beta$  level, we paired expression of either HsCASP1 or PaCASP1 with human or bat IL-1 $\beta$ . Assay of the lysates for either HsIL-1 $\beta$  or PaIL-1 $\beta$  indicated that HsCASP1, but not PaCASP1, was able to successfully cleave the IL-1 $\beta$  from both species (Fig. 3D). Altogether, this indicates that caspase-1, and not IL-1 $\beta$ , is dampened in the *Pteropus* bat inflammasome pathway, resulting in failure of IL-1 $\beta$  maturation and cleavage.

Structural studies in human caspase-1 have identified C285 and H237 as essential residues for catalytic activity, among others which form the substrate-binding active site (35, 36). Additional residues within the p10 and p20 fragments have been shown to mediate crucial interactions in dimerization, and mutations result in inability to bind and cleave cytokines for secretion (37). A recent study established that homodimerization of two p20/p10 subunits forms the active conformation of caspase-1, whereby autoprocessing of the caspase-1 p10 fragment is required for GSDMD cleavage and initiation of pyroptosis (22). Given the existing understanding of caspase-1 activation, we analyzed the caspase-1 gene sequence to determine the potential mechanism of its reduced activity in bats. Sequences of available bat caspase-1 genes across Yinpterochiroptera and Yangochiroptera suborders, and 10 nonbat mammalian species were aligned, and phylogenetic analysis by maximum likelihood (PAML) performed to identify lineages and sites acted on by selection pressures (38) (SI Appendix, Fig. S2A). We found one ancestral branch of the bats to have undergone positive selection pressures, and branch-site testing identified greater positive selection pressure exerted on two residue sites in its subsequent branch (SI Appendix, Fig. S2B). Compared to human, mouse, and other included species, the *P. alecto* and *Pteropus vampyrus* caspase-1 sequence showed alterations at residue 365 from Asp to Asn, and at 371 from Arg to Gln (red boxes). Both residues are localized within the p10 polypeptide and span five amino acids apart.

To understand the consequence of these substitutions, we performed site-directed reverse mutagenesis of the specific sites, replacing either one, or both residues in the bat with the equivalent human residues, resulting in N365D-only, Q371R-only, or double-mutant (DM) PaCASP1 (Fig. 3E). Likewise, the human HsCASP1 gene was mutated to individually or simultaneously replace both residues with those of *Pteropus* bat amino acid sites (D365N-only, R371Q-only, and HsCasp1 DM). Only the PaCASP1 DM, but not the single mutants, provoked reversal of the inactive PaCASP1 phenotype to rescue cleavage of IL-1 $\beta$  (Fig. 3F). Conversely for HsCASP1, single mutation of either site to the bat residues was sufficient to abrogate its ability to cleave IL-1 $\beta$  (Fig. 3G). Further, HEK293T cells expressing either HsCASP1 WT or mutant PaCASP1 DM showed increased cellular stress and death morphologically, while HsCASP1 DM and PaCASP1 WT exhibited increased viability regardless of ASC speck formation (SI Appendix, Fig. S3).

Bats also possess the GSDMD gene with conserved pore-forming N-terminal subunits and a caspase-1 recognition site<sup>266</sup>FLSD<sup>269</sup>; yet its function and cleavage potential by bat caspase-1 are still unknown. Thus, PaGSDMD was cloned and compared with HsGSDMD for cleavage by human and *P. alecto* wild-type (WT) or mutant caspase-1 variants. Similar to the pattern of IL-1 $\beta$  processing by PaCASP1, cleavage of PaGSDMD was undetected in WT PaCASP1, while PaCASP1-DM successfully restored cleavage as observed by the 31-kDa PaGSDMD-N fragment (Fig. 3H). Conversely, HsCASP1-D365N, R371Q, or the combined HsCASP1-DM led to abrogation of GSDMD cleavage (Fig. 3I). To provide the molecular basis of the loss-of-function mutations of D365N and R371Q, we examined the structure of human caspase-1 bound to GSDMD (Protein Data Bank [PDB] code: 6VIE) (39). In the substrate-bound caspase-1 state (p20/p10 dimer), R371 participates in electrostatic interactions with E367 of the opposite p10 subunit, therefore R371Q mutation results in

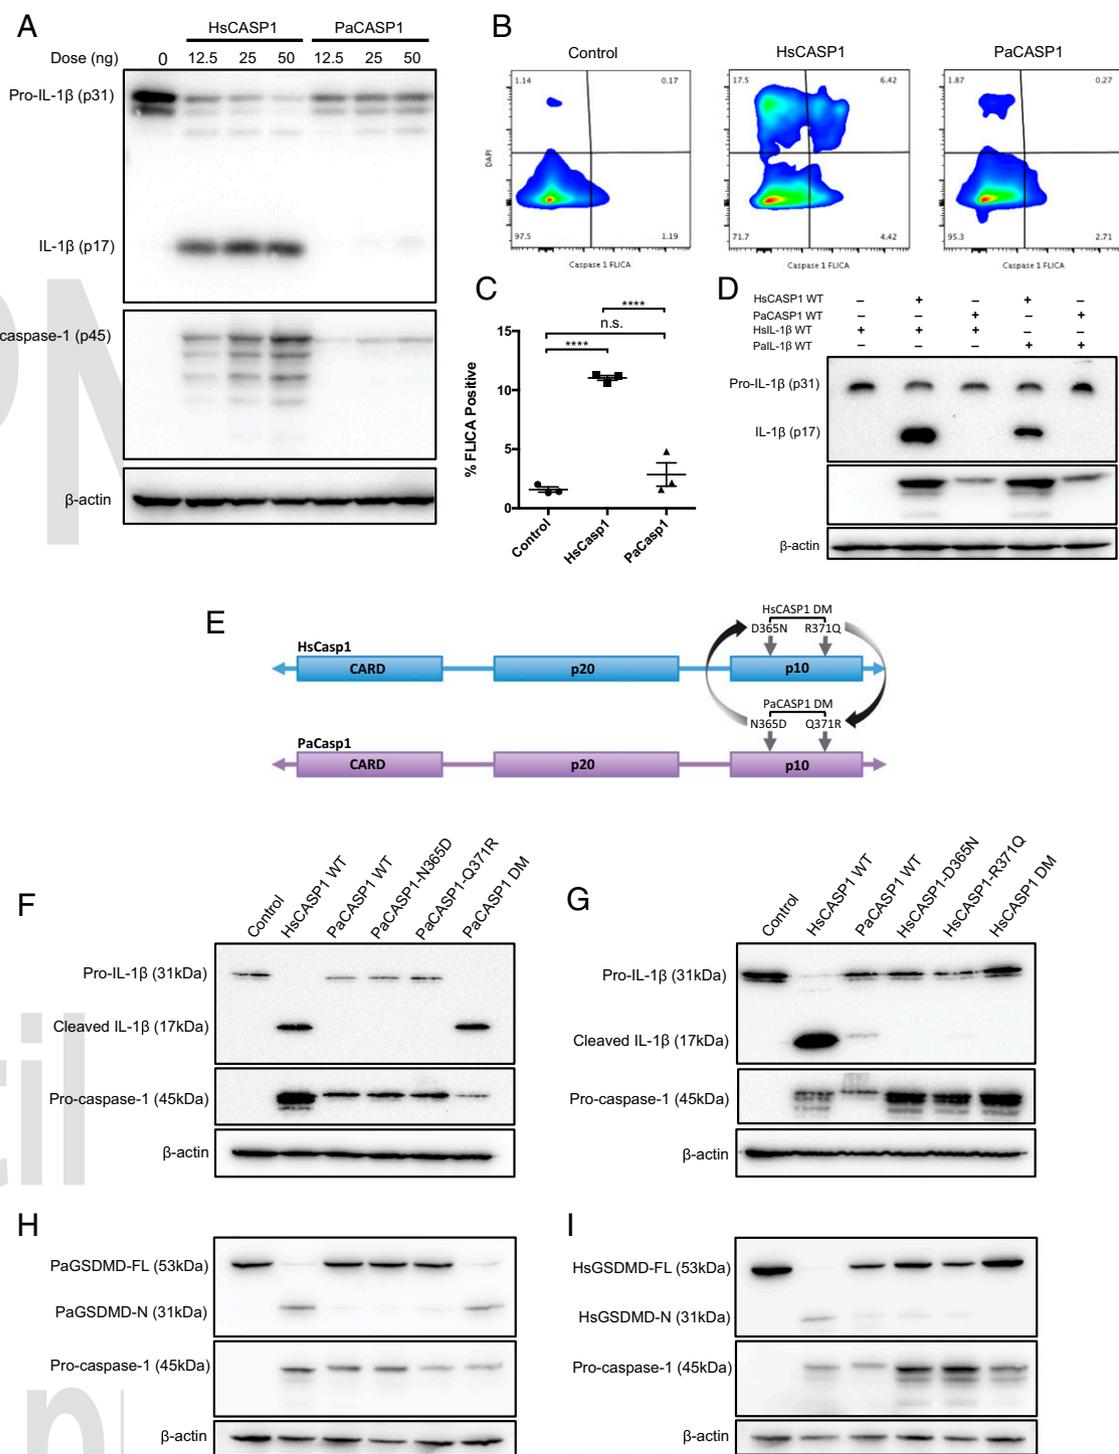

unfavorable interaction across the interface (SI Appendix, Fig. S4). D365 forms part of the dimer interface and may stabilize the homodimeric interactions. As such, similar to R371Q, D365N mutation would weaken the caspase 1 dimer-dimer coordination, leading to inactivation of the enzyme (22, 39, 40). Taken together, our findings demonstrate that both sites in the p10 fragment are necessary for caspase-1 activation by the inflammasome complex, and both IL-1 $\beta$  and GSDMD substrate maturation is dampened in *P. alecto* bats in a caspase-1-dependent manner.

#### Complementation between Caspase-1 Activity and IL-1 $\beta$ Cleavage Results in Consistent Inflammasome Dampening across Bats.

Bats, belonging to the order Chiroptera, are the second largest group of mammals with more than 1,000 species. Within the order Chiroptera, *Pteropus* bats are part of the Pteropodidae family in the suborder Yinpterochiroptera, which are distinct from the suborder Yangochiroptera, containing the rest of the microbat families (41, 42). To better understand if downstream inflammasome dampening is a consistent pattern across bats, we extended our study to include both the *Eonycteris spelaea* bat (cave nectar bat), also from Yinpterochiroptera, and the *M. davidii* (David's myotis) species from the Yangochiroptera suborder. Due to the ability of caspase-1 to signal via multiple upstream sensors, we reconstituted the NLRP3 inflammasome axis in HEK293T cells and expressed either human or relevant species of bat caspase-1 in a dose-dependent manner. We observed that *E. spelaea* caspase-1 (EsCASP1) retained the ability to cleave *P. alecto* IL-1 $\beta$  at reduced levels, and *M. davidii* caspase-1 (MdCASP1) demonstrated intact activity comparable to that of human at low-dose expression (Fig. 4A).

Next, we reconstituted the NLRP3 inflammasome axis and varied IL-1 $\beta$  of three different bat species in either a HsCASP1, EsCASP1, or MdCASP1 system (Fig. 4B and SI Appendix, Fig. S5A). Interestingly, we observed that *M. davidii* IL-1 $\beta$  possessed the least capacity for cleavage and *P. alecto* the highest, in contrast to their respective caspase-1 activity (highest in *M. davidii* and lowest in *P. alecto*). We hypothesized that efficient targeting of MdIL-1 $\beta$  for reduced cleavage may occur at or near its cleavage site. Therefore, we aligned the IL-1 $\beta$  amino acid sequence of *M. davidii* against eight other species of bats (*Myotis lucifugus*, *Eptesicus fuscus*, *Miniopterus natalensis*, *Desmodus rotundus*, *P. alecto*, and *P. vampyrus*, *R. aegyptiacus*, *Hipposideros armiger*) and six other model mammalian species (*Sus scrofa*, *Canis lupus*, *Pan troglodytes*, *Mus musculus*, and *Rattus norvegicus*) (SI Appendix, Fig. S5B). Among the 15 total species analyzed using branch site modeling in PAML, we discovered a Ser117 residue immediately adjacent to the cleavage site Asp<sup>115</sup>-Ala<sup>116</sup> which was under higher selection in the *Myotis* branch, which was a proline residue in all except three other species (*M. natalensis*, *S. scrofa*, and *C. lupus*).

We next hypothesized that residues conserved between *Homo sapiens*, *P. alecto*, and *E. spelaea* but differing in *M. davidii* may be responsible for the impaired cleavability of MdIL-1 $\beta$ . We thus additionally identified G110, S111, E113, and Q122 in MdIL-1 $\beta$  as distinct from equivalent IL-1 $\beta$  residues of the other three species. For a direct comparison of MdIL-1 $\beta$  with PaIL-1 $\beta$  (which is fully cleavable), we performed site-directed mutagenesis replacing each of the respective MdIL-1 $\beta$  residues into their *P. alecto* counterparts, along with a combined mutation containing all amino acid site substitutions (Fig. 4C). Notably, the MdIL-1 $\beta$  mutant S117P was able to strongly restore IL-1 $\beta$  cleavage, along with a partial restoration by a double mutant GS110/111DG; however, the combined mutant demonstrated strongest cleavage ability (Md > Pa 110 to 112) (Fig. 4D). Conversely, the PaIL-1 $\beta$  mutants DG110/111GS and P117S resulted in defective IL-1 $\beta$  cleavage (Fig. 4E). Further, both residues appear to have a partial effect either in restoration (MdIL-1 $\beta$ ) or abrogation (PaIL-1 $\beta$ ) of function, whereby the

**Fig. 3.** Inactive PaCasp1 is rescued by substitution of N365D and Q371R in the p10 domain. (A) The AIM2 inflammasome axis was reconstituted in HEK293T cells using either HsCASP1 or PaCASP1 in a dose-curve. Cell lysates were stained for pro-IL-1 $\beta$  (p31) or mature IL-1 $\beta$  (p17). Procaspase-1 (p45) was assayed to compare expression, and lysates were normalized by  $\beta$ -actin. (B) Cells were reconstituted with the AIM2 inflammasome axis genes and incubated for 48 h, and stained with 660-YVAD-fmk caspase-1 FLICA substrate (Immunocytochemistry). Flow cytometry was performed to detect caspase-1 activation in control vector, HsCASP1 or PaCASP1 expressing cells, and data analyzed in FlowJo. (C) Quantification of FLICA-positive cells measured via flow cytometry. (D) Immunoblot of cell lysates crossing HsCASP1-3XFLAG with HsIL-1 $\beta$ -HA or PaIL-1 $\beta$ -HA, and PaCasp1-3XFLAG with HsIL-1 $\beta$ -HA or PaIL-1 $\beta$ -HA, coexpressed with human AIM2 and ASC. Cleaved human or bat IL-1 $\beta$  was measured with anti-HA antibody. (E) Schematic of site-derived reverse mutagenesis conducted in the p10 domain of PaCASP1 or HsCASP1. Targeted residues are shown, either single bat N365D or Q371R mutation, or containing both mutations (PaCASP1 DM); and D365N, R371Q, or HsCASP1 DM for the human gene. (F) AIM2 inflammasome axis was reconstituted in HEK283T cells, varying the PaCASP1 for WT, single-mutant N365D, Q371R, or double mutant DM. Cleaved IL-1 $\beta$  p17 was assayed via immunoblotting 48 h posttransfection. (G) Similarly, HsCASP1 WT, D365N, R371Q, or DM was reconstituted, and cleavage of IL-1 $\beta$  was analyzed by immunoblot. Shown are the pro-IL-1 $\beta$  (31 kDa), cleaved IL-1 $\beta$  (17 kDa), and human or bat procaspase-1 (45 kDa). (H and I) Similarly, PaGSDMD was coexpressed with PaCASP1 (H) and HsGSDMD with cognate HsCASP1 (I) WT, single-mutants or double-mutant variants, in conjunction with upstream AIM2 inflammasome axis. Cleavage of GSDMD was detected by immunoblotting for the GSDMD-N-2xMyc domain after 48 h incubation in vitro as per D. Data are representative of three independent experiments in A–G. \*\*\*\* $P < 0.0001$ , n.s., nonsignificant. Statistics were performed using unpaired Student's  $t$  test and presented as mean  $\pm$  SEM of three independent replicates (C).

effect was strongest in the combined mutants. Thus, we observe that given a certain level of caspase-1 activity in any of the bat species (*P. alecto* low, *E. spelaea* medium, and *M. davidii* high), the cleavage potential of IL-1 $\beta$  occurs in opposite direction (*P. alecto* high, *E. spelaea* medium, and *M. davidii* low) (Fig. 4F). Taken together, this demonstrates a complementary mechanism whereby full caspase-1 activity is balanced by diminished cleavage potential of IL-1 $\beta$ , and vice versa, resulting in an overall, equivalent dampening of inflammasome signaling across multiple bat species from both suborders.

## Discussion

We have confirmed that loss of AIM2/ALRs in bats results in inactive initiation of the inflammasome cascade in response to cytosolic DNA *in vitro*. Crucially, we reveal another layer of dampening through bat caspase-1, the principal cysteine protease responsible for cleaving inflammatory cytokines such as IL-1 $\beta$  and IL-18. We identified two inactivating alterations N365D and Q371R localized in the p10 sequence of wild-type *P. alecto* bat caspase-1 which when rescued by substitution of the human residues at equivalent sites, restored caspase-1 enzyme functionality. Simultaneously, when human caspase-1 was replaced with the equivalent bat amino acids, either residue change resulted in abrogation of IL-1 $\beta$  cleavage. Despite retention of caspase-1 activity in other bat species, corresponding reduction in IL-1 $\beta$  cleavage mitigated downstream inflammasome signaling. Thus, we have experimentally validated two additional residues of mammalian caspase-1, which are integral to its activity for substrate maturation, and demonstrated a proof of concept whereby downstream inflammasome activation in bats is dampened through a unique inverse relationship involving bat caspase-1 and IL-1 $\beta$ .

The discovery of dampened caspase-1 in bats has particular significance in their response to infection and immunity. As the classical inflammatory effector of the inflammasome complex, caspase-1 is converged upon by multiple upstream sensors, including NLRP3, NLRP1, AIM2, NLRC4, and others (43–47). These sensors are activated by a diverse array of cell- and pathogen-derived stimuli, including viral and bacterial nucleic acids, flagellin, ATP, and MSU crystals, and reactive oxidative species (ROS). Such signals trigger a systemic activation of alert and defense mechanisms, including pyroptosis, cytokine signaling, and the recruitment of neutrophils and macrophages into the affected tissue area (17, 48, 49). As caspase-1 cleaves cGMP-AMP (cGAMP) synthase (cGAS) to enhance host resistance to DNA viruses, and MAVS and TRIF to abolish IFN signaling (50), it is possible that bats may have evolved other compensatory mechanisms to resist viral pathogenesis by biasing cross-regulation of these pathways (7). Indeed, there is increasing evidence that AIM2 and other inflammasomes oppose type I IFN sensors, including cGAS, STING, and MyD88/IRF7 (51–54). As such, constitutive IFN expression in bats may, in part, be both an outcome and compensatory mechanism of inflammasome dampening, allowing them to mitigate viral pathogenesis. Further, as non-canonical caspase-1 substrates range from cytoskeletal components, enzymes in cell metabolism, and diverse other proteins involved in cellular stress responses and cell death pathway, it is possible that caspase-1 may retain residual baseline activity for regulation of these processes, thus conserving its expression in bats albeit at reduced function. Thus the effect of our findings on these nonimmune substrates would also warrant investigation.

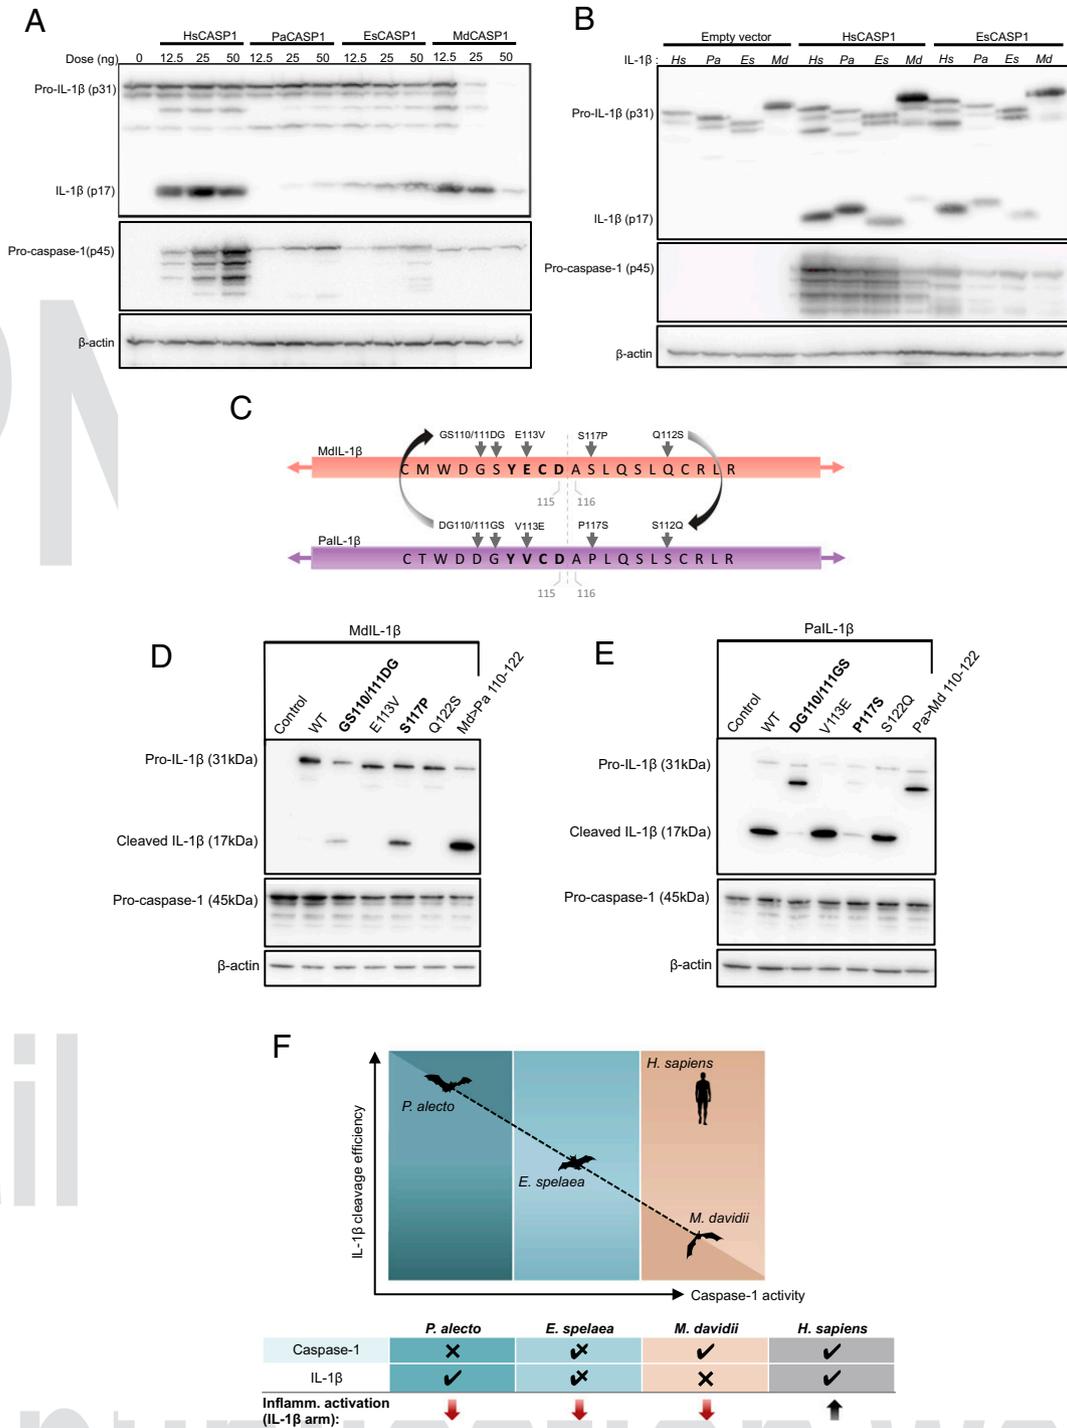

It is notable that both identified caspase-1 residues acted on by high positive selection pressures possess noncharged (Asn, Gln) instead of charged (Asp, Arg) side chains, representing a substantial decrease in capacity for ionic bond formation. Both amino acids are situated within the p10-p10 interface of the caspase-1 (p20p10)<sub>2</sub> homodimer and are shown to participate in critical electrostatic interactions across the interface of the active conformation of caspase-1 (SI Appendix, Fig. S4). Loss of these

charged residues likely results in weakened caspase-1 dimerization, preventing robust autoprocessing and substrate cleavage. To our knowledge, no prior study has identified either D365 and R371 in  $\alpha 6$  as essential for caspase-1 activity in humans or other mammalian species, with early structural studies reporting the interface to only consist of residues 318 to 322 and 386 to 396 (35). Two noncompetitive inhibitors discovered decades earlier, gold thiomalate and auranofin, closely mimic this interface-disruptive mechanism but differ in residue specificity (35). While most widely used caspase-1 inhibitors to date utilize active site-specific mechanisms to impede function (18, 32, 35, 55–57), none of the marketable inhibitors yet allosterically perturb caspase-1 at the p10 dimer-dimer interface despite efforts (58, 59). Thus, our findings may prove to facilitate additional specificity in inhibitor design. Importantly, our findings provide evidence of evolutionary drivers of inhibitory mechanisms in nature informing insight into human caspase-1 and suggest another potential alternative strategy for caspase-1 targeting in human therapeutics.

Positive selection pressure occurred in both caspase-1 residues of the *Pteropus* bat genus but not in any other bat species. We observed retention of caspase-1 activity by *E. spelaea* and *M. davidii* bats from both bat suborders Yinpterochiroptera and Yangochiroptera, which may be explained by a lack of D365 and R371 substitutions in caspase-1 of both bats. Intriguingly, further downstream investigation for IL-1 $\beta$  maturation elucidated an inverse relationship between bat caspase-1 activity and IL-1 $\beta$  cleavage potential, whereby the cleavage of IL-1 $\beta$  within a bat species occurs in the opposite direction to its caspase-1 activity (e.g., in *M. davidii*, caspase-1 high and IL-1 $\beta$  low). The mechanism by which MdIL-1 $\beta$  cleavage is diminished was shown to occur through the S117 site immediately adjacent to the <sup>115</sup>Asp-Ala<sup>116</sup> cleavage site, which when restored by mutation to S117P permitted cleavage of the MdIL-1 $\beta$  mutant into its 17-kDa fragment. This was followed to a smaller extent by the double mutant GS110-111DG of MdIL-1 $\beta$ , suggesting that all three residues might play a role in dampening maturation of the cytokine in *Myotis* bats. We demonstrate that by targeting either caspase-1 or IL-1 $\beta$ , bat species of both suborders possess dampening of important downstream inflammasome components.

Therefore, it is clear that differing strategies have been co-opted by bats to dampen either caspase-1 activation, IL-1 $\beta$  cleavage, or both in a complementary manner, highlighting the importance of this phenotype across bats. Indeed, previous genomic or functional studies have found that different bat species exhibited varying or independent genomic strategies to dampen the AIM2 or NLRP3 inflammasome sensors, which culminated in an equivalent level of loss or reduction of activity (9, 11). However, cleavage of IL-1 $\beta$  alone is not sufficient to generate biological inflammasome functioning, and recent studies have demonstrated requirement of GSDMD for IL-1 $\beta$  and IL-18 secretion and activation of pyroptotic cell death (60–62). Thus, in bat species with intact caspase-1 activity, other significant functions may be retained such as GSDMD-mediated pyroptosis and secretion of IL-18, or activation of IL-37 and inactivation of IL-33, which may confer higher regulatory control of pro/antiinflammatory responses (63–65). As such, multiple other indicators of inflammasome functioning in bats remain unknown and require further investigation in the context of these findings.

In conclusion, we find strong experimental evidence pointing to diminished multisensor inflammasome signaling in bats, suggesting high selection pressures acting not only on single, but multiple levels in this pathway. Given the inflammasome functions at the forefront of innate immune signaling, such alteration of inflammasome signaling in bats has a critical role in viral disease tolerance and asymptomaticity (66). Inflammasome activation has been implicated in multiple coronavirus infections, including MERS-CoV, SARS-CoV, and SARS-CoV-2 (67), possibly

**Fig. 4.** Complementary relationship between *M. davidii*, *E. spelaea*, and *P. alecto* caspase-1 and IL-1 $\beta$ . (A) HEK293T cells were transfected with human NLRP3, ASC, pro-IL-1 $\beta$  for inflammasome axis reconstitution, and coexpressed with either *H. sapiens*, *P. alecto*, *E. spelaea*, or *M. davidii* caspase-1 in increasing concentrations (12.5 to 50 ng/well). Cells were incubated for 48 h and the cell lysate was harvested for Western blot. The amount of mature/cleaved IL-1 $\beta$  (p17) was compared between HsCASP1 and the three bat species and normalized by  $\beta$ -actin. (B) Coexpression of human, *P. alecto*, *E. spelaea*, or *M. davidii* IL-1 $\beta$  in HEK293T with reconstituted human NLRP3 and ASC. Cells were transfected with either empty vector, HsCASP1, or EsCASP1 (as indicated). Cell lysate was immunoblotted for pro-IL-1 $\beta$  (p31) and cleaved IL-1 $\beta$  (p17) with anti-HA, procaspase-1 (p45) with anti-FLAG, and normalized by  $\beta$ -actin. Figures are representative of three independent experiments (A and B). (C) Alignment of full-length IL-1 $\beta$  sequences was performed for *H. sapiens*, *P. alecto*, *E. spelaea*, and *M. davidii*, and site-directed mutagenesis was performed substituting identified MdlIL-1 $\beta$  amino acid residues with equivalent sites from PalL-1 $\beta$  near the Asp-Ala cleavage site (gray arrows). In bold, cleavage sites YECD and YVCD for MdlIL-1 $\beta$  and PalL-1 $\beta$ , respectively. (D) Full-length WT or mutant MdlIL-1 $\beta$  was coexpressed with HsCASP1, AIM2, and ASC and incubated for 48 h; and lysates were assayed for successful cleavage of 17 kDa IL-1 $\beta$  via staining of C-terminal HA-tag. Md  $\rightarrow$  Pa 110 to 122 denotes combined introduction of all identified *P. alecto* residues expressed by the MdlIL-1 $\beta$  mutant protein. (E) Various mutant PalL-1 $\beta$  was similarly expressed within the AIM2 inflammasome axis and incubated in vitro for 48 h, and various levels of cleaved PalL-1 $\beta$  were detected by Western blot. (F) Diagram of inverse reciprocal relationship between *P. alecto*, *E. spelaea*, and *M. davidii* caspase-1 activity and IL-1 $\beta$  cleavage efficiency, displayed on the x axis and (Left) y axis, respectively. Top showing increasing pattern of caspase-1 activity (*P. alecto* < *E. spelaea* < *M. davidii* < *H. sapiens*) is countered by decreasing IL-1 $\beta$  cleavability (*M. davidii* < *E. spelaea* < *P. alecto* < *H. sapiens*). Table shows vertical summation of either caspase-1 or IL-1 $\beta$  cleavage and resultant function of the downstream inflammasome axis (IL-1 $\beta$  arm).

affecting the ability of bats to function as a reservoir host. With unique capacity for metabolically costly flight, bats could have adapted to elevated metabolic states by dispensing with this inflammatory arm (68–70). Further, inflammasome suppression improves longevity or prevents age-related decline in mice and promotes longevity in humans (71–75), which is in line with bats' long-lived mammalian phenotype. Taken together, our study contributes significant mechanistic understanding for strategies targeting inflammasome dampening in bats, offers potential insight in regulation of human inflammation, and further elucidates the ability of bats to harbor and transmit zoonotic pathogens without sustaining detrimental costs of immune activation.

## Materials and Methods

**Reagents.** Reagents are as previously described (9). Ultrapure LPS-B5, CL264, and Hygromycin B Gold were obtained from InvivoGen. *P. alecto* ASC-specific monoclonal antibody (mouse IgG2b) was generated by GenScript's monoclonal antibody service. Rabbit polyclonal anti-ASC (AL177) (human/mouse) was purchased from Adipogen. Goat polyclonal anti-dog IL-1 $\beta$  (ab193852) (cross-reactive to *P. alecto*) and rabbit polyclonal anti-mouse IL-1 $\beta$  (ab9722) were from Abcam. mAb to  $\beta$ -actin (A2228) was from Sigma-Aldrich and mAb to GFP and variants (including mCitrine) were from Roche (11814460001). Anti-mouse/rabbit/goat horseradish peroxidase (HRP)-conjugated secondary antibodies were from Santa Cruz.

**Plasmids.** Generation of expression constructs for NLRP3, ASC-mPlum, IL-1 $\beta$ -HA, and empty vectors (control vectors) are as previously described (34, 76). Human AIM2 was cloned from human peripheral blood mononuclear cells (PBMC) cDNA using Q5 Polymerase (NEB) with *Agel* and *NotI* flanking primers (NUS-IRB reference code H-18-029). AIM2 was digested and ligated into pQCXIH (Clontech) vector containing C-terminal mCitrine or 3 $\times$  FLAG. Procaspase-1 was cloned from the human pCl-caspase-1 construct (Addgene plasmid 41552) or Omniscript (Qiagen)-generated cDNA of *P. alecto* spleen. Caspase-1 was inserted into pQCXIH-mCitrine and pQCXIH-3 $\times$  FLAG vectors. *P. alecto* or human caspase-1 mutants were generated by overlap extension PCR with primers containing the respective mutations. Similarly, *P. alecto*, *E. spelaea*, and *M. davidii* IL-1 $\beta$  were cloned by PCR of bat spleen cDNA into pQCXIH (Clontech) backbones containing C-terminal HA-tag. *P. alecto* and *M. davidii* IL-1 $\beta$  mutants were also generated by overlap extension PCR. Gasdermin D was cloned from human PBMC cDNA and *P. alecto* spleen cDNA with 2 $\times$  MYC-tag on the N terminus into pQCXIH (Clontech) backbones containing C-terminal HA-tag. Primer sequences are listed in [SI Appendix, Tables S1 and S2](#). All constructs were prepared with endotoxin-free plasmid maxi-prep kits (Omega Bio-tek).

**Cells.** All procedures utilizing animal samples in this study were performed in compliance with all relevant ethical regulations. Capturing and processing of bats (*P. alecto*) in Australia was approved by the Queensland Animal Science Precinct and University of Queensland Animal Ethics Committee (AEC#SVS/073/16/USGMS) and the Australian Animal Health Laboratory Animal Ethics Committee (AEC#1389 and AEC#1557). Where possible, wild bats with irreparable physical damage (torn wings) already scheduled to be killed were utilized. Processing of bats has been described previously (9, 69). Wild-type C57BL/6 mice were obtained with permission from the Singhealth institutional animal care and use committee. Harvesting and differentiation of bone marrow from *P. alecto* bats has been described previously and performed according to identical protocols (76, 77). Mouse bone marrow was harvested from C57BL/6 mice and frozen once in liquid nitrogen, thawed, and differentiated over 7 d in 10 ng/mL macrophage colony-stimulating factor (M-CSF) as described previously (34). GP2-293 retroviral packaging cells were obtained from Clontech. GP2-293, HEK293T, and PaK15 cells were cultured in Dulbecco's modified Eagle medium (DMEM) (Gibco 11965092) medium supplemented with 10% fetal bovine serum (FBS). PaK15 (CVCL\_YM14) is a spontaneous-immortalized kidney epithelial cell line with identical origin from the parental primary cells of PaK1T03 (RRID: CVCL\_DR89) (34). GP2-293 cell culture medium was supplemented with sodium pyruvate and nonessential amino acid (NEAA) cell culture supplement (Life Technologies) during retroviral packaging.

**Reconstitution of AIM2 in Bat Macrophages.** Retrovirus was generated by cotransfecting pVSV-G envelope protein with the plasmid containing the gene of interest (AIM2-mCitrine or mCitrine-only) at 1:1 ratio in GP293 cells grown at 70% confluency. Cells were incubated for 48 to 72 h in DMEM

containing 10% FBS at 37 °C, and supernatant centrifuged and filtered through 0.45- $\mu$ m PVDF sterile filters (Millipore). To further concentrate the retrovirus, either 100,000 MW Vivaspin columns (Sartorius) in a benchtop centrifuge or ultracentrifugation at 125,000  $\times$  g for 90 min (Optima X, Beckman Coulter) in a SW41-TI rotor was performed to 75 to 100 $\times$  dilution. Retrovirus was titrated on HEK293T cells and added at multiplicity of infection 5 into PaBMDM media at day 5 of differentiation. Cells were incubated for 48 h, supernatant was removed, and cells were recovered in additional 24 h of PaCSF-1 RPMI with 10% FBS before treatment.

**In Vitro dsDNA Stimulation.** *P. alecto* immortalized kidney cells have been described previously (9). Cells stably expressing *P. alecto* ASC were transduced with mCitrine-only or AIM2-mCitrine retrovirus generated from GP2-293 cells. Cells were selected with puromycin for 5 d and recovered in 10% FBS DMEM media. AIM2-mCitrine/ASC double-positive cells were sorted by fluorescence activated cell sorting (FACS) using BD FACSAria for medium-to-low expression. Cells were grown to 70% confluency and transfected with increasing doses of PolyA:dT (Invivogen). For BMDM stimulation, differentiated cells were primed with 1  $\mu$ g/mL CL264 (PaBMDM) or LPS B5 (MmBMDM) (Invivogen) for 3 h, washed with FBS-free RPMI (Gibco), and transfected with 1 mg/mL PolyA:dT using Lipofectamine 3000 (Thermo Fisher) in RPMI for 4 h. Supernatant was collected for LDH assay, IL-1 $\beta$  ELISA, and cells were stained for flow cytometry by Imagestream of FACS.

**Imagestream Imaging Flow Cytometry.** Cells were harvested for Imagestream imaging flow cytometry as previously described (9). Briefly, BMDM cells were harvested with 5 mM ethylenediaminetetraacetic acid (EDTA), washed once with phosphate-buffered saline (PBS), fixed in 4% paraformaldehyde, and permeabilized with 0.3% Triton-X + 2% FBS for 10 min at 4 °C. Cells were stained with primary ASC and prelabeled fluorescent anti-mouse antibodies for 1 h at room temperature, with DAPI for 15 min, and then washed twice with PBS and resuspended in FACS buffer. PaK15 were harvested by trypsinization and resuspended in FACS buffer directly. Events on the Imagestream X were acquired using using INSPIRE software on an Amnis ImageStreamX Mk II imaging flow cytometer using 40 $\times$  magnification. At least 5,000 events were acquired per sample and analyzed with the inbuilt IDEAS software. Cells in focus were gated by brightfield r.m.s. values, single cells by aspect ratio by area values, and intact nuclei using DAPI staining. Double positive cells (AIM2-mCitrine, ASC-mPlum) were gated and analyzed for ASC speck formation plotted via mean fluorescence intensity by max-pixel intensity.

**Confocal Microscopy.** PaK15 cells were seeded into 24-well plates containing coverslips (#1.5 thickness). Cells stably expressing *P. alecto* ASC-mPlum were transiently transfected with human AIM2-mCitrine for 4 h, washed, and incubated for 48 h. Cells were stained for 30 min at 37 °C incubation with working concentration of Mitotracker according to manufacturer's instructions (Thermo Fisher). Mitotracker probe solution was removed and cells were washed with PBS 2 $\times$  before fixing with 4% paraformaldehyde. Nuclear staining was performed with DAPI. Coverslips were mounted onto glass slides with Mowiol 4.88 and images acquired on a Leica TCS SP8 machine at 100 $\times$  resolution. Images were processed using ImageJ 2.0.0 software.

**IL-1 $\beta$  ELISA and LDH Release Assay.** Supernatant collected from DNA-treated PaBMDMs was centrifuged to remove debris and frozen once at  $-80$  °C. The supernatant was then measured by a sandwich ELISA protocol as previously described (9). Briefly, purified recombinant PaIL-1 $\beta$  protein was utilized for the standard curve, with goat anti-canine IL-1 $\beta$  primary antibody and rabbit anti-mouse IL-1 $\beta$  antibody used as capture and detection antibodies, respectively. IL-1 $\beta$  in mBMDM supernatants was detected using the BioLegend IL-1 $\beta$  Standard ELISA kit. LDH release assay was performed as previously described using a Cytotoxicity Detection Kit PLUS (LDH) from Roche (9). Calculations were performed as per manufacturer's instructions, with low and high controls included for normalization of individual biological replicates.

**Evolutionary Analysis of Mammalian Caspase-1 and IL-1 $\beta$ .** Caspase-1 coding sequences (CDs) were retrieved from National Center for Biotechnology Information (NCBI) for one armadillo (*Dasypus novemcinctus*) and many Boreoeutheria species, including Euarhontoglires and Laurasiatheria. Euarhontoglires species include two primates (human and *Pan troglodytes*), two rodents (rat and mouse), and one tree shrew (Chinese tree shrew, *Tupaia belangeri chinensis*) ([SI Appendix, Table S3](#)). Homologs of caspase-1 in the 15 bat genomes were identified by discontinuous MegaBLAST (BLAST + 2.7.1) with max e-value of 1e-5 and word size of 11. Similarly, IL-1 $\beta$  sequences for *M. davidii* and eight other species of bats (*M. lucifugus*, *E. fuscus*, *M. natalensis*,

*D. rotundus*, *P. alecto*, and *P. vampyrus*, *R. aegyptiacus*, and *H. armiger*) and six other model mammalian species (*S. scrofa*, *C. lupus*, *P. troglodytes*, *M. musculus*, *R. norvegicus*) were retrieved from NCBI or PCR-cloning and gene sequencing performed on bat cDNA (SI Appendix, Table S4). Alignment of the CDSs was generated by MAFFT (78) and used to plot the phylogeny tree by the maximum-likelihood method with the general-time-reversible (GTR) model and 1,000 bootstrap replicates in PHYML 3.0 software (38). The phylogeny tree and alignment file then served as input for performance of positive selection analysis on CodeML from the PAML package (version 4.9) (79), and branch-site models with relevant branches were marked on the tree. LRTs were performed in different substitution models, including 1) M0 (one-ratio), M1a (nearly neutral), M2a (positive selection), M3 (discrete), M7 (beta), M8 (beta and  $\omega > 1$ ), and M8a (beta and  $\omega = 1$  in site mod); 2) M0 (one-ratio) and two-ratio model assuming different  $\omega$  for background and foreground branches in branch mode; and 3) positive selection along specified branches (model A) against a null model (model A null) that allows neutral evolution and negative selection for branch-site mode. Positive selection sites were scored by the Bayes empirical Bayes (BEB) method (80).

**Caspase-1 Western Blot and FLICA Assay.** The AIM2 inflammasome axis (HsAIM2, HsASC, human caspase-1, and IL-1 $\beta$ ) was reconstituted into HEK293T cells at increasing doses using Eugene 6 (Promega) at 3:1 ratio with total DNA. Cells seeded into 96-well plates (Corning) were incubated for 48 h posttransfection and lysed in lysis buffer (79). cOmplete ULTRA protease inhibitor mixture and PhosSTOP phosphatase inhibitors (Roche) were added to lysis buffer before use. Proteins were separated on 12 to 15% SDS/PAGE gels and transferred onto 0.45- $\mu$ m polyvinylidene difluoride (PVDF) membrane with a Trans-Blot Turbo transfer system (Biorad). Membranes were

blocked in 5% bovine serum albumin (BSA) for 1 h and stained with primary antibody followed by HRP-conjugated secondary antibody. Membranes were developed with Amersham ECL Prime Western blotting detection reagent (GE Healthcare) on a myECL Imager (Thermo Scientific). For FLICA detection, cells were trypsinized, washed once in PBS, and stained with 660-Caspase-1 FLICA substrate (Immunochemistry) with occasional agitation for 1 h. Cells were washed three times with cellular wash buffer (provided), resuspended in PBS with 2% BSA, and analyzed via flow cytometry (LSRFortessa Cell Analyzer, BD Biosciences). Live/dead gating was performed using DAPI and subgated for AIM2-mCitrine and ASC-mPlum positivity, before gated for FLICA-660 positive staining (SI Appendix, Fig. S6). At least 10,000 cell events were collected per replicate and independently analyzed on FlowJo.

**Data Availability.** All study data are included in the article text and SI Appendix.

**ACKNOWLEDGMENTS.** This work was funded by the Singapore National Research Foundation (Grants NRF2012NRF-CRP001-056 to L.-F.W. and NRF2016NRF-NSFC002-013 to L.-F.W.), and a New Investigator's Grant (to A.T.I.) from the National Medical Research Council of Singapore (NMRC/BNIG/2040/2015). We thank Cramer Research Consulting, J. Meers, H. Field, and Duke-NUS team members for help with collection of bat samples; D. Anderson and M. Wirawan for the critical reading of the manuscript; and P. Rozario for assistance with experiments. We thank A. Bertoletti and A. T. Tan for use of the Amnis ImageStream. We also acknowledge the facilities and technical assistance of the Advanced Bioimaging Core and Flow Cytometry Core at SingHealth Duke-NUS Academic Medical Centre.

---

Hello, my name is Charles Choi, and I'm a science reporter in New York writing for science news service Inside Science, which is syndicated by MSNBC, Fox News and Discovery News, among others.

I'm interested in interviewing you about Linfa Wang et al.'s research on bats and viruses appearing in the next issue of the Proceedings of the National Academy of Sciences. I've spoken with several of you before regarding bats and viruses — good to contact you again.

My deadline is 2 p.m. ET on Sunday. Could you contact me via email to set up an appointment as soon as possible or call me at 1-917-328-7810?

I understand when the embargo on your research is -- my deadline allows my editor time to actually work on the story, as opposed to doing a rush job that can introduce inaccuracies into the piece. The story naturally will not get published until after the embargo lifts.

It would really help me out if you could answer a few questions:

x) What do you personally find most surprising or exciting about these results? What do you feel is the most important implication of these findings?

x) What specific potential clinical applications might this research hold? Perhaps by helping bodies not react in potentially harmful way to infections and other disorders?

x) Obviously COVID-19 is of concern right now. Might you talk about how we might think about these findings in relation to the current pandemic?

x) Are there any specific questions or criticisms you have about these findings?

x) What specific directions do you think research might or should go from here? What obstacles do you foresee in future research or development?

x) This shouldn't have to be asked, but can you for a lay audience talk about how the discovery that bats are reservoirs for so many diseases shouldn't mean that people should go out of their way to cull bats?

x) Are there any questions you would have liked to answer that I didn't ask you? Is there anything we didn't cover that you feel is important?

x) Since editorial style says I not refer to people by their institutional title (e.g. assistant professor of chemical engineering), what specialty might I refer to you by (e.g. virologist)?

x) Is there any research of yours that journalists have not reported on yet that might be interesting for a story?

Hope to hear from you soon! Thanks --

Charles Choi

## **Biosurveillance for Viral Zoonoses around Bat-Livestock-Human interfaces in Southern Africa**

### **TECHNICAL PROPOSAL**

#### **I. ABSTRACT**

Bat species, which are widespread in the Southern African region and beyond, have been identified as hosts of a number of viral agents, including filo- and viruses related to the Middle East respiratory syndrome (MERS) corona- and paramyxo- such as the henipaviruses. These viruses have proven to cause substantial human morbidity and mortality, threaten livestock and wildlife health and have pandemic potential. However, their distribution and potential to infect people and livestock in Southern Africa are unknown. This project will focus on building capacity and enhancing surveillance, including early detection programs for henipa-, filo- and zoonotic coronaviruses in Southern Africa. The project will specifically address the following: 1) regional training, including biosafety, bat capturing techniques, clinical sampling, viral detection and serological techniques, developing standardized protocols, ecological data collection and human behavioral studies; 2) establishment of serological and nucleic acid detection technologies in South Africa to develop sustainable regional diagnostic capacity that can be shared; 3) targeted serological and molecular surveillance in bats as well as serological surveillance in potential spillover hosts (livestock and humans); 4) assessing human behavioral risk for exposure to these agents; and 5) multi-stakeholder workshops to develop a sustainable regional biosurveillance strategy, analyze results and develop mitigation strategies and threat reduction policies for the region. Planning, training, execution and reporting will use an interdisciplinary One Health approach involving local government agencies of the respective countries including the Departments of Health, Agriculture, Environment, Veterinary and Wildlife Services to ensure long-term sustainability and stakeholder preparedness. The proposed project closely aligns with the aims of the Cooperative Biological Engagement Program with regards to support for biosurveillance, capacity building and threat reduction.

#### **II. SCOPE**

##### **A. OBJECTIVE:**

The overall objective is to detect filo-, henipa- and zoonotic coronaviruses in bat populations in Southern Africa and evidence of spillover in humans and livestock.

Specific objectives to achieve this are:

- 1) Regional training and establishment of networks in Southern Africa [Southern Africa Bat Research Network (SABRENET)] focused on biosafety, bat capturing techniques, bat taxonomy, virological sampling, viral detection techniques, developing standardized protocols, ecological and environmental data collection and observational and human behaviour studies.
- 2) Establishment of serological and nucleic acid detection platforms in key partner laboratories in human and animal health in South Africa that will sustainably build and enhance regional diagnostic capacity and will generate comparable data across the region.
- 3) Targeted serological and molecular surveillance and screening of samples in bats, as well as additional serological surveillance in potential spillover hosts (livestock and humans) at selected bat-human-animal interphases.
- 4) Assessing human behavioral risk for exposure to these agents at selected bat-human-animal interphases.
- 5) Multi-stakeholder workshops to develop a sustainable regional biosurveillance strategy, analyze results and develop mitigation strategies and threat reduction policies for the region.

We propose to test the following **hypothesis**: A diversity of potentially zoonotic henipa-, filo- and coronaviruses circulate in bats in South Africa and neighboring Mozambique and Zimbabwe, and may previously have infected livestock and people in areas where interactions between bats and such

hosts occur. Enhancing biosurveillance and building regional capacity will reduce biothreats by improving the ability to detect, diagnose and report emerging and re-emerging pathogens of biosecurity concern.

## **B. BACKGROUND:**

Over the past four decades, approximately 75% of important emerging and re-emerging diseases were of zoonotic origin and most of these originating from Africa (Chan et al., 2010) and from a wildlife origin (Daszak et al., 2000; Olival et al., 2017). This includes paramyxoviruses in the genus *Henipavirus* such as Hendra (HeV) and Nipah virus (NiV), filoviruses that include Ebola (EBOV) and Marburg virus (MARV), as well as coronaviruses like severe acute respiratory syndrome coronavirus (SARS-CoV), all select agents, causing outbreaks with high mortality in humans. Fatal zoonoses have significant financial implications, with the World Bank estimating economic losses between 1997 to 2009 of US\$80 billion, and that US\$6.7 billion per year could be saved globally by preventing emerging disease outbreaks (Mazet et al., 2015). International agencies such as CDC, USDA, WHO and OIE have identified zoonotic diseases as a threat to global health security with pathogens not adhering to international borders and the ability to spread extensively and rapidly.

**Filoviruses:** The family *Filoviridae* are negative-sense, single-stranded RNA viruses represented by six genera of which two, *Ebolavirus* and *Marburgvirus* (Kuhn et al., 2019), cause fatal hemorrhagic fever outbreaks in humans. The diversity of filoviruses have also expanded in recent years with several novel viral detections in bats including Lloviu virus (LLOV) in Schreibers' long-fingered bats (*Miniopterus cf schreibersii*) in Spain and Hungary (Kemenesi et al., 2018), Mengla virus from China in rousette fruit bats (*Rousettus* spp.) and cave nectar bats (*Eonycteris* spp.) (Yang et al., 2019), as well as Bombali virus from Sierra Leone and Kenya associated with molossid bats [Angolan free-tailed bat (*Mops condylurus*) and the little free-tailed bat (*Chaerephon pumilus*)] (Goldstein et al., 2018; Forbes et al., 2019). MARV was first identified in 1967 in green monkeys imported into Europe from Uganda after laboratory workers became infected (Olival and Hayman, 2014) and has since been detected and isolated in several African countries. Substantial evidence now exists that the Egyptian rousette fruit bat (*Rousettus aegyptiacus*) is a reservoir of MARV (Towner et al., 2009; Amman et al., 2012), and this species is widespread throughout Africa and into the Middle East. Historically, detections have been from central and eastern Africa, but recently MARV was also detected in *R. aegyptiacus* in the northern regions of South Africa (Paweska et al., 2018) and Sierra Leone. Detections have been opportunistic and sporadic, and not always corresponding to where human outbreaks have been identified or representative of the geographic range of the reservoir, which highlights a lack of surveillance. Longitudinal studies identified distinct viral pulses in juvenile bats that corresponded to the timing of human outbreaks, implicating birthing pulses as a driver of infection (Amman et al., 2012). Experimental infection studies of MARV virus in captive-bred Egyptian fruit bats reported viral RNA in oral and vaginal secretions, as well as excreta implicating these as potential routes of transmission (Swanepoel et al., 1996; Leroy et al., 2005; Amman et al., 2015). The first *Ebolavirus* spp. was discovered in 1976 and the genus now consists of six species: *Zaire ebolavirus*, Ebola virus (EBOV), *Bundibugyo ebolavirus*, Bundibugyo virus (BDBV), *Sudan ebolavirus*, Sudan virus (SUDV), *Tai Forest ebolavirus*, Tai Forest virus (TAFV), *Bombali ebolavirus*, Bombali virus (BOMV) and *Reston ebolavirus*, Reston virus (RESTV) (Kuhn et al., 2019) with potentially unique ecological niches. More than 25 human outbreaks have occurred with the most significant being the 2013-2016 outbreak in Guinea, Sierra Leone and Liberia where more than 11000 people died (Spengler et al., 2016). Index cases were reported to have had contact with dead wildlife including non-human primates and antelope, however, these species are not considered viral reservoirs since they also succumbed to the disease. Viral RNA for EBOV has only been detected in bat species with distributions restricted to West Africa and not occurring in Southern Africa, including the hammer-headed bat (*Hypsignathus monstrosus*), Franquet's epauletted fruit bat (*Epomops franqueti*) and little collared fruit bat (*Myonycteris torquata*) (Leroy et al., 2005). However, a recent detection of EBOV has been reported in a Greater long-fingered bat (*Miniopterus*

*cf inflatus*) in Liberia (Epstein personal communication) expanding the potential geographic range for EBOV. Ebolavirus reactive antibodies are present in an even wider range of bat species, including *Epomophorus*, *Rousettus* and *Mops* spp. that do occur in Southern Africa (Olival and Hayman, 2014). RESTV had been detected in *Miniopterus cf schreibersii* in the Philippines (Jayme et al., 2015) again implicating the *Miniopterus* genus. Pigs are currently the only species of livestock known to be at risk of infection by an ebolavirus species as demonstrated by studies in the Philippines and China indicating that they are naturally infected with RESTV (Marsh et al., 2011). The reservoir and geographical distribution of EBOV and other Ebola virus species are still not clear with limited surveillance performed in the Southern African region in wildlife species due to the historical absence of human outbreaks.

**Paramyxoviruses:** This is negative-sense single-stranded RNA viruses capable of infecting a diverse host range including mammals, birds, reptiles and fish (Virtue et al., 2009). HeV and NiV were first detected in the 1990s following outbreaks of fatal respiratory and encephalitic illness in Australia and Malaysia, respectively (Murray et al., 1995; Chua et al., 1999). During the initial emergence, both viruses spilled over into the human population from pteropid bats by means of intermediate hosts, i.e. horses and pigs respectively. Multiple NiV outbreaks have subsequently been reported from Bangladesh and India linked to repeated spillover events from flying foxes of the *Pteropus* genus directly to humans followed by a high rate of human-to-human transmission and high mortality (Gurley et al., 2007a; Chadha et al., 2006; Arunkumar et al., 2018). These viruses have been shown to be excreted in bat urine, saliva and feces (Chua et al., 2002; Smith et al., 2011). In Bangladesh, contamination of date palm sap by bats while feeding overnight, is the primary route of spillover, though other mechanisms of spillover may exist elsewhere (Gurley et al., 2007b). In Malaysia, pigs were infected by pteropid bats after eating dropped fruit contaminated with saliva, and subsequently infected farmers and abattoir workers (Chua et al., 1999; Paton et al., 1999). Initially, the distribution of henipaviruses was believed to be restricted to the geographical distribution of *Pteropus* spp. in Australia and South-East Asia, however, detections of henipavirus-related virus antibodies and nucleic acids in African fruit bat species has expanded the geographical range (Hayman et al., 2008; Drexler et al., 2009). Serological evidence of these viruses in bat populations in several African counties including Zambia, Tanzania, Malawi, Madagascar, and Cameroon, as well as several islands in the Gulf of Guinea were reported (Peel et al., 2012; Peel et al., 2013; Brook et al., 2019). In addition, serological evidence in pigs (Hayman et al., 2011) and antibodies in Cameroonian locals were also identified (Pernet et al., 2014), highlighting the potential of spillover. A number of studies also reported the detection of henipa- and rubulavirus-related viral RNA in several bat species on the African continent (Drexler et al., 2012; Baker et al., 2012; Mortlock et al., 2015) including *Rousettus* and the Straw-coloured fruit bat (*Eidolon helvum*) (Peel et al., 2013). Sosuga virus (*Pararubulavirus* genus) has been the only paramyxovirus associated with human disease on the African continent, following the identification of the virus as the causative agent of a non-fatal febrile disease in a single human infection (Albarino et al., 2014), believed to have spilled over from *R. aegyptiacus* in Uganda (Amman et al., 2015). Various research studies, mostly targeted towards HeV and NiV, have reported strong seasonality associated with dry winters, correlations with bat densities, nutritional stress, and various events during the bat reproductive period (Plowright et al., 2008; Dietrich et al., 2015; Paez et al., 2017; Mortlock et al., 2019) as drivers of infection. The diversity and viral dynamics of henipa- and other potentially zoonotic paramyxoviruses in African bat species are poorly understood with only limited sporadic surveillance.

**Coronaviruses:** These are positive-sense RNA viruses divided into four genera, namely, *Alphacoronavirus*, *Betacoronavirus*, *Gammacoronavirus*, and *Deltacoronavirus*. A number of subgenera were recently assigned to each of these genera (Wong et al., 2019) due to an expansion of global diversity. These viruses can undergo recombination, creating new variants that may result in spillover infections and manifest as respiratory pathogens in humans that are transmitted through aerosols. Bat coronaviruses are predominantly excreted in faecal material, though oral swabs, and

urine have also tested positive implicating several routes of transmission. Severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) coronaviruses emerged in 2002 and 2012 respectively, and both pandemics resulted in significant morbidity and mortality (10% and 35%, respectively) in humans, which was exacerbated by global travel (Berry et al., 2015). Global coronavirus surveillance increased significantly after the detection of SARS. In the subsequent search for the reservoir, serological and partial nucleic acid detection in 2005 linked SARS-CoV to horseshoe bats (*Rhinolophus*) in China by identifying a closely related virus. Subsequent studies identified an even larger diversity of SARS-CoV-related viruses in horseshoe bats worldwide (Hu et al., 2017; Lau et al., 2010), however, the virus protein responsible for receptor-binding that mediates cellular entry (spike protein) (Li et al., 2005) was unable to interact with the SARS-CoV virus receptor. Thus, it is unlikely that any of these identified SARS-CoV related viruses were the source of the SARS-CoV human outbreak (Li et al., 2005). Recently a bat SARS-related CoV was found to possess a spike protein that facilitated binding to the same virus receptor as SARS-CoV (Ge et al. 2013; Yang et al., 2016), indicating the potential to cross species barriers and infect humans directly. In 2012, Middle East Respiratory syndrome virus (MERS) was identified in the Arabian Peninsula (Zaki et al., 2012), and a partial nucleic acid sequence was detected in an Egyptian tomb bat (*Taphozous perforates*) from Saudi Arabia (Memish et al., 2013). It has subsequently been shown that detected bat MERS-related CoVs are only distantly related to MERS-CoV and dromedary camels are considered the reservoir species transmitting the virus to people. Diverse coronavirus sequences were found in many different bat species worldwide, leading to the hypothesis that bats host the genetic diversity of the *Alphacoronavirus* and *Betacoronavirus* mammalian infecting genera (Woo et al., 2012), however, the risks and factors important to spillover is unknown (Hu et al., 2017; Anthony et al., 2017a). The diverse SARS-related coronaviruses circulating within the horseshoe bat (*Rhinolophus*) genus throughout their Asian, European or African distribution make this an important host genus to monitor for viral diversity and novel emergences.

**Surveillance data for the Southern African region** has been limited, with mostly opportunistic, once off sampling events focused on restricted geographical regions and selected bat species (Geldenhuys et al., 2013; Ithete et al., 2013; Cronje 2017; Bourgarel et al., 2018; Paweska et al., 2018; Mortlock et al., 2019). Southern Africa possesses a rich diversity of bat fauna including both frugivorous and insectivorous bat species (Monadjem et al., 2010) distributed across several biotic zones, but mostly concentrated in the eastern region of the continent, including areas in South Africa, Mozambique, Zimbabwe, Malawi and Zambia (Cooper-Bohannon et al., 2016). In addition to the taxonomic diversity, these bat species also exemplify a diversity of roosting behavior and site selection including trees, rock crevices and man-made structures. This include *Rousettus*, *Rhinolophus* and *Miniopterus* spp. as well as several free-tail bat species (Molossidae) implicated as potential hosts for high consequence pathogens in other studies. If pathogens are present, several factors play a role in spillover to other species and very few studies investigated this. This include host ecology, movement of bats (both foraging and long term movement), viral shedding and routes of transmission. These factors may be seasonal, emphasizing the need for longitudinal studies. Livestock such as cattle, goats, and pigs, are also present throughout Southern Africa and overlaps with bat diversity hotspots (Robinson et al., 2014; StatsSA2016). People with frequent close contact with bats due to religious, cultural or sociological reasons (Markotter, personal communication) also inhabit the same areas. This bat-human-animal interphase and risk for spillover has not been studied in the region. Habitat loss, primarily through deforestation has been increasing in the Southern African region (Brink and Eva, 2009), and there is evidence of increased bushmeat consumption (Regan et al., 2015; Lindsey et al., 2013). Understanding contact between bats, humans and other animals, including behavior analysis, are needed to understand risk in areas where these viral pathogens are present.

Several factors need to be considered when designing biosurveillance strategies in bats. Individuals do not generally exhibit signs of disease, populations can be large with low viral

prevalence and seasonality affect prevalence and transmission. Detection of viral nucleic acids can therefore be challenging and should be paired with **serological surveys**, which take advantage of long-term antibody persistence. Serology has some limitations including inherent antibody cross reactivity between target and related viruses, statistical interpretation of seropositive cut-offs, limited bat specific assays and control sera, and not being able to directly characterize the infectious agent involved. As a result, greater value can be achieved when combining serological surveys with molecular detection assays and subsequent viral characterization. When investigating potential spillover in non-bat hosts, such as domestic animals and humans, serology can be a more comprehensive strategy given the commercially available reagents that can be used to detect both past/convalescent (immunoglobulin G) and recent/acute (immunoglobulin M) infections. Serological assays for emerging zoonotic pathogens are limited and mostly based on in-house assays using different methodologies including virus neutralization, ELISA, western blots and indirect fluorescent assays (IFAs) and can only detect evidence of exposure to a single virus target. Multiplex serological assays using Luminex xMAP-based technology offer the advantage to simultaneously detect virus specific and cross-reactive antibodies in a single test, saving time, resources and cost. Since the volume of bat sera collected in surveillance is limited, this is a major advantage. The Luminex system is based on the principles of flow cytometry, allows for multiplexing at least 100 analytes in a single microplate well and uses very small sample volumes (2 µl). This assay uses inactivated serum and recombinant reagents, which means the analysis can be performed in a Biosafety Level 2 laboratory. This technology has been successfully used in surveillance studies in bats and spillover hosts including detection of antibodies against paramyxoviruses and filoviruses (Brook et al., 2019; Laing et al. 2018; Hayman et al., 2011; Peel et al., 2012; Chowdhury et al., 2014;) (See preliminary results for more detail). Broadly reactive **molecular RT-PCR assays** based on the conserved regions of viral genomes at family or genus level have been successfully used in surveillance studies for the viral families targeted in this proposal (See work plan for detail). These assays target short genomic regions that can be sufficient for determining phylogenetic relationships, but not formal genus or viral species demarcation that requires longer gene and/or genome sequences. For this, additional sequencing data is needed including targeting regions that may be important in spillover potential such as the receptor-binding and virulence factor encoding regions.

### **C. RELEVANCE; SCIENTIFIC AND THREAT REDUCTION IMPACT:**

South Africa plays a prominent role in the Southern African region with laboratory capacity that can be expanded and shared to strengthen sustainable biosurveillance in the region. These pathogens can easily affect any country and therefore biosurveillance capacity must include regional networks and engagement with neighboring countries. Surveillance data will identify presence but also shedding of high consequence viruses in different seasons, bat species and biomes. Serological investigations will identify if spillover in livestock and humans occurred in the past and behavioral analysis will investigate risk factors for potential spillovers that may happen in the future. This project will strengthen South Africa's, and the region's, capacity to develop and implement surveillance strategies with appropriate biosafety and biosecurity principles, detect pathogens (both molecular and serological) in bats before outbreaks occur, recognize and diagnose outbreaks if they do occur and develop appropriate reporting strategies for the region. All this information can be used collectively to assess risk, predict potential outbreaks, and develop risk mitigation strategies that can be used throughout the region. It follows a One Health approach involving multi-sectoral stakeholders including government engagement and local communities to enhance communication and threat reduction activities. A regional network, Southern African Bat Research Network (SABRENET), will be established to improve communication and collaboration between countries and between disciplines. Sustainability and threat reduction will be specifically addressed by workshops involving all stakeholders from multiple Southern African countries and to align with the Global Health Security Agenda, and comply with the International Health Regulations (IHR) and other reporting guidelines. This project is closely aligned with the goals of the Cooperative Biological Engagement

Program (CBEP) and align with several of the Biological Threat Reduction Programme (BTRP) Lines of effort (LOE) including National Regulatory Frameworks (LOE3), Disease detection (LOE4), Laboratory diagnosis (LOE5), Epidemiological Analysis and investigation (LOE6) and Reporting and Communication (LOE7).

**D. PRELIMINARY WORK AND ESTABLISHED COLLABORATIONS (See table 1 for explanation of abbreviations for institutions):**

The two major partners, UP, South Africa (Markotter) and EHA, USA (Epstein) will combine their expertise in implementing surveillance programs and diagnostic sample testing. The major partners will also establish regional networks, and link with international networks including the Bat One Health Network (BOHRN), EcoHealthNet (an NSF-funded disease ecology research training program led by EHA), and the Western Asia Bat Research Network (WABNet). UP and EHA initiated discussions about possible collaborations five years ago and both UP and EHA currently collaborate with CEZPD-NICD. UP also collaborated with AfricanBats NPC (Seamark) and DNMNH (Kearney) since 2004. This includes training activities, joint fieldwork, co-supervision of students, as well as several joint publications. UP already has DAFF section 20 approval to research zoonotic pathogens in bats in Southern Africa and regularly communicate surveillance data to DAFF and NDoH. UP has been collaborating with USU (Broder) since 2017, and has initiated acquisition of Luminex reagents for filo- and henipavirus testing including a signed Material transfer agreement. EHA also have a successful collaboration with USU. EHA and CEZPD-NICD have a joint DTRA project on Rift Valley fever virus since 2014. UP has previously collaborated with the CVL laboratories in Mozambique and Zimbabwe, with joint publications on rabies as an output. Preliminary surveillance activities in small mammals were also conducted in Mozambique in 2017, and a preliminary visit to the CVL laboratory in Zimbabwe was conducted in 2018 to discuss future collaborations. Previous studies led by the South African team, including UP, CEZPD-NICD, DNMNH and AfricanBats have reported detections of several potential zoonotic pathogens in bats (Figure 1). This work was performed under the South African Research Chair of Prof. Markotter funded by the South African Department of Science and Innovation (ongoing) and the Global Disease Detection Programme of the Centers for Disease Control and Prevention (USA) 2016-2019. Biosurveillance on select agents in bats was only a small part of these projects, and therefore surveillance studies were sporadic and limited in scope to only specific bat species and limited

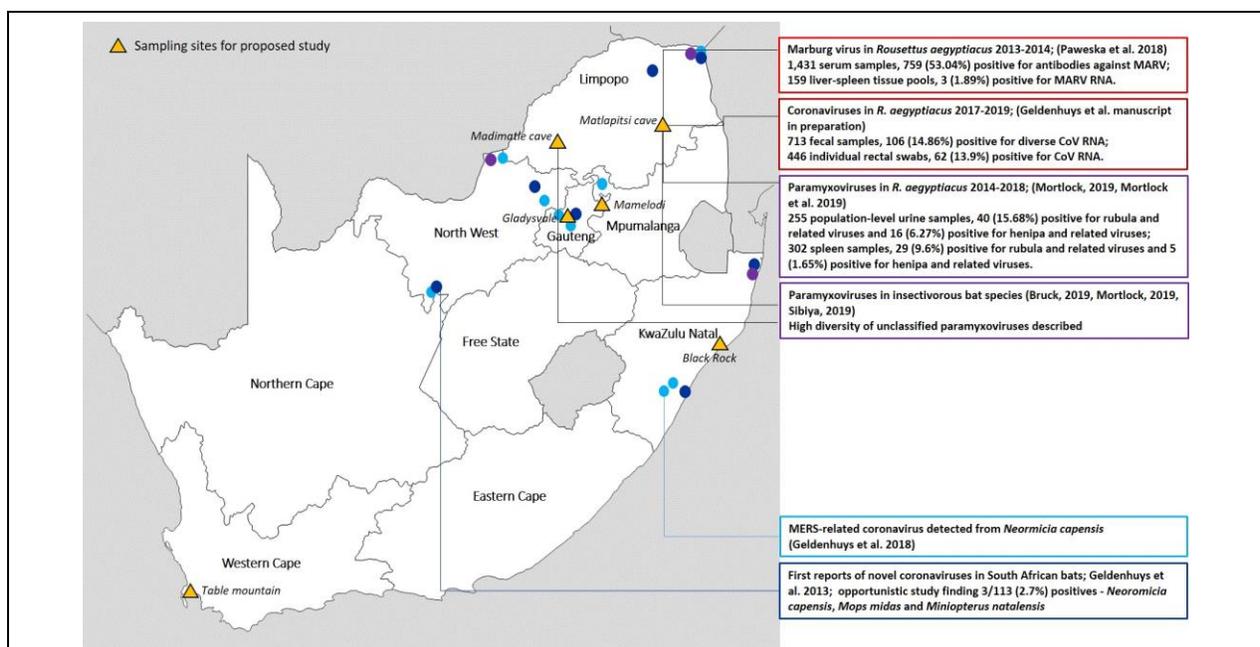

Fig 1: Summary of filo, corona and paramyxovirus nucleic acid detections in South Africa. Previous and proposed samples sites for this project are indicated (Unpublished).

geographical locations in South Africa. In addition, this surveillance only included molecular detection of pathogens and very limited serological investigations in bat species and none in potential spillover hosts. Preliminary studies indicate that seasonal reproduction of *R. aegyptiacus* drives viral infection dynamics, and that gradual loss of passive immunity among juveniles in this bat population increases the number of susceptible individuals, creating favorable conditions for viral spread (Figure 2).

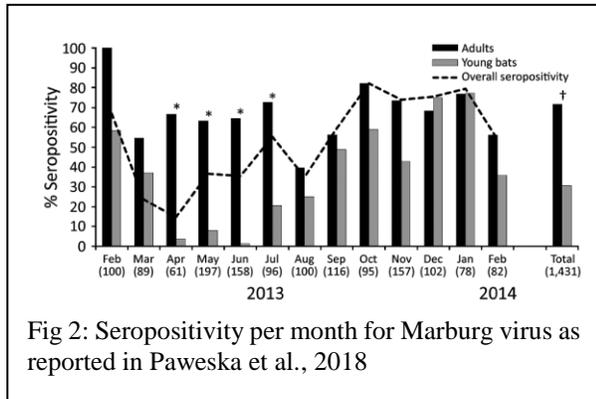

Fig 2: Seropositivity per month for Marburg virus as reported in Paweska et al., 2018

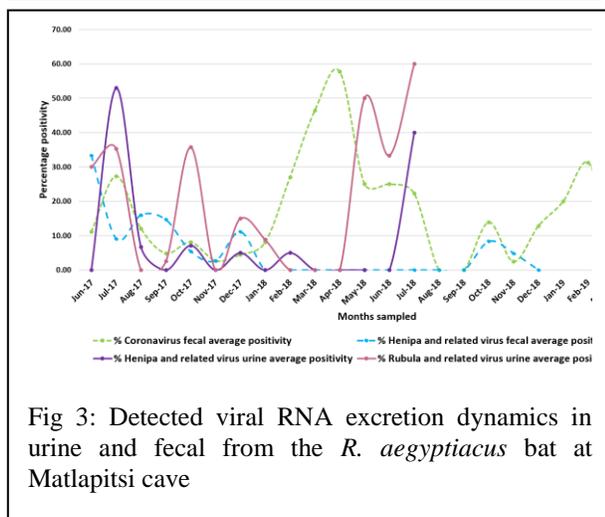

Fig 3: Detected viral RNA excretion dynamics in urine and fecal from the *R. aegyptiacus* bat at Matlapitsi cave

It also results in changes in virus shedding and seroconversion patterns, which are driven by sex, age and reproductive condition of female bats (Figure 2 and 3). Molecular assays to detect paramyxo-, corona- and filoviruses are established in the South African laboratories (UP and NICD) with some improvements needed (see detail under Work plan). Serology was not part of previous studies, with the exception of targeted Marburg virus serological studies. At the time, we had no feasible serological option available that could accommodate a multiplex platform suitable for low amounts of sera collected from bats and we initiated discussions to obtain luminex reagents from USU. Purified oligomeric, receptor-binding protein (G) of henipaviruses (e.g. HeV and NiV) have been used by the USU lab and collaborators for several years in antigen-based immunoassays to differentiate antibodies specific to HeV or NiV (Bossart et al., 2007), and in biosurveillance studies to examine exposure to these high priority viruses (Chowdhury et al., 2014; Peel et al., 2012) (Figure 4). With the isolation of new viruses including Cedar virus (CedV), Ghana virus (GhV) and Mojiang virus (MojV), the lab has continued to generate tetrameric henipavirus G for all presently described henipaviruses, and expand the HeV/NiV

immunoassay into a pan- henipavirus multiplex assay capable of simultaneously

detecting and differentiating henipavirus-specific antibodies. Furthermore, USU constructed native-

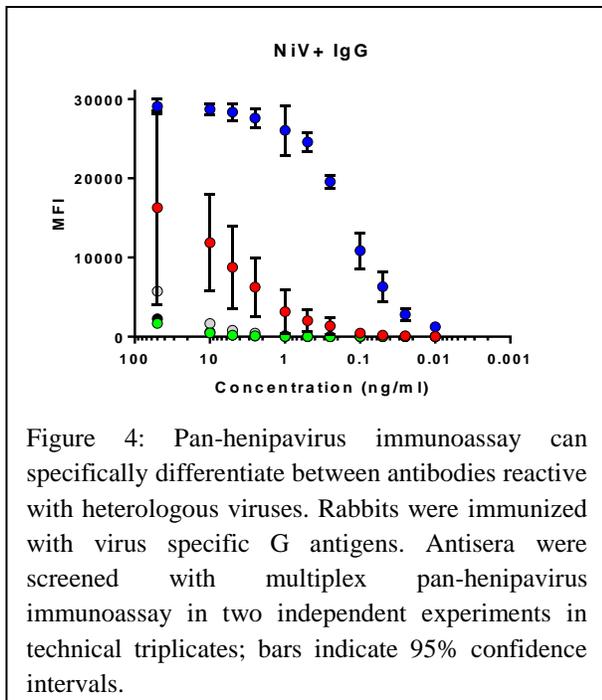

Figure 4: Pan-henipavirus immunoassay can specifically differentiate between antibodies reactive with heterologous viruses. Rabbits were immunized with virus specific G antigens. Antisera were screened with multiplex pan-henipavirus immunoassay in two independent experiments in technical triplicates; bars indicate 95% confidence intervals.

like glycoprotein antigens of all presently described filoviruses to generate a pan-filovirus antigen-based immunoassay that can be simultaneously used with the pan-henipavirus immunoassay to detect antibodies reactive with four of the WHO priority pathogens with pandemic potential. This pan-filovirus immunoassay was used by Laing et al. to detect serologic evidence of Asiatic filoviruses, antigenically-like ebolaviruses, in three fruit bat species collected in Singapore (Laing et al., 2018) (Figure 5).

This assay was also used at the National Centre for Biological Sciences, Bangalore, India in a DTRA BTRP supported project to Duke-NUS researcher Dr. Ian Mendenhall, to detect exposure to Asiatic filoviruses in bats and humans hunting these bats for food, implicating likely cross-species transmission of novel filoviruses at this wildlife-human interface (Figure 6) (Dovich et al., 2019).

This pan-filovirus/henipavirus immunoassay has

been transferred to three laboratories in Peninsular Malaysia where it is being utilized in serology-based biosurveillance of wildlife (e.g. bats), livestock and indigenous human communities, funded by DTRA BTRP to Co-PI J. Epstein and contributed further evidence that a diversity of novel Asiatic

filoviruses, distantly related to Reston virus, but with unknown pathogenesis, circulate in certain species of bats.

In collaboration with DNMNH, a taxonomic database for bat species, including voucher specimens with morphological classification and genetic sequence confirmation, has been generated for most South African bat species, and for some species in Zimbabwe and Mozambique. UP, USU and EHA have developed several standard operation procedures and training material for past studies including

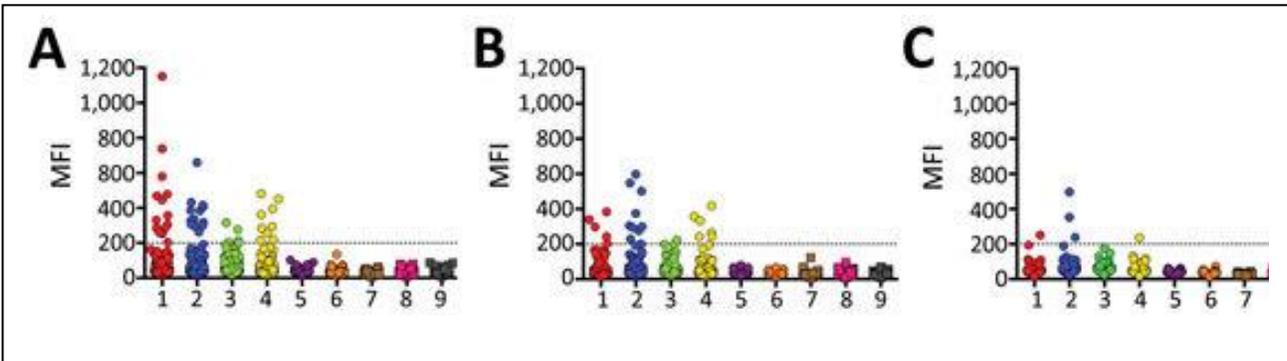

Figure 5. Serologic evidence of exposure to Asiatic filoviruses in 3 fruit bat species. (A) *Eonycteris spelaea* (B) *Cynopterus brachyotis* (C) *Penthetor lucasi*. Mean fluorescence intensity (MFI) values obtained from Bio-Plex assay (Bio-Rad, Hercules, CA, USA) screening of individual serum samples from bats of 3 species with soluble filovirus glycoproteins. Dashed line indicates the cutoff value at 200 MFI. 1, *Zaire ebolavirus*; 2, *Bundibugyo ebolavirus*; 3, *Tai Forest ebolavirus*; 4, *Sudan ebolavirus*; 5, *Reston ebolavirus*–monkey; 6, *Reston ebolavirus*–pig; 7, *Marburg virus*–Musoke; 8, *Marburg virus*–Angola; 9, *Ravn virus*.

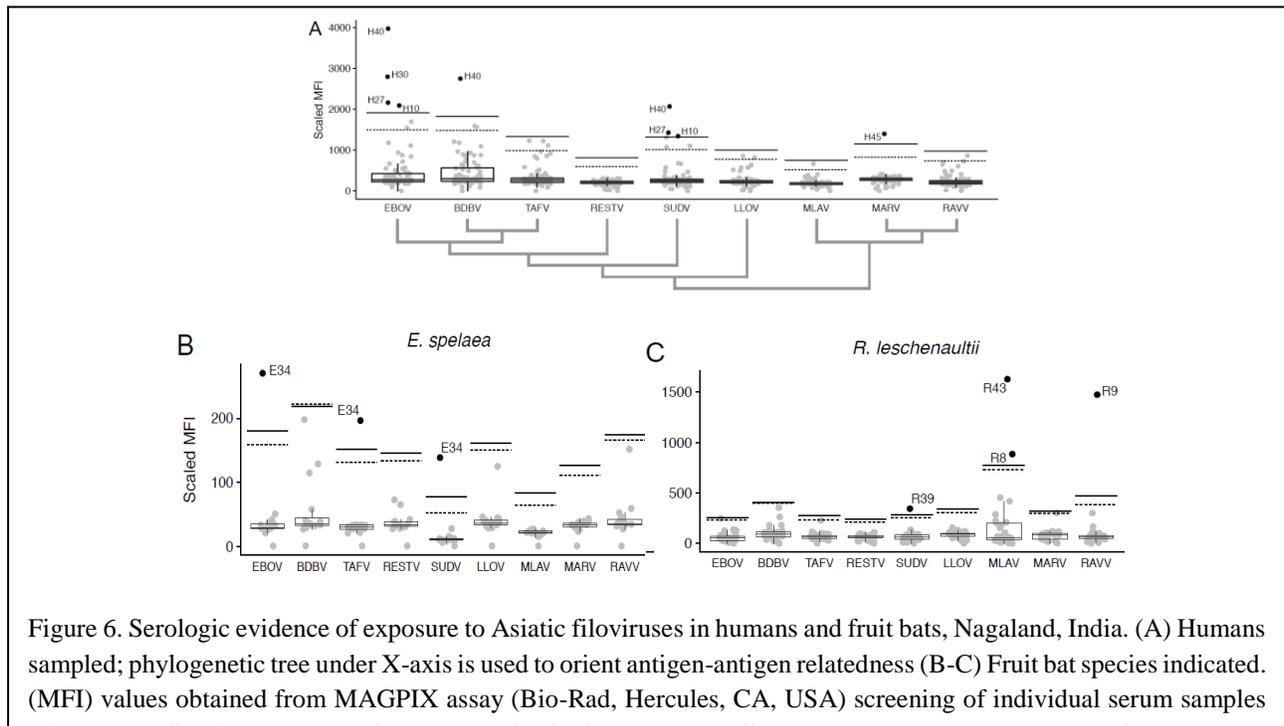

Figure 6. Serologic evidence of exposure to Asiatic filoviruses in humans and fruit bats, Nagaland, India. (MFI) values obtained from MAGPIX assay (Bio-Rad, Hercules, CA, USA) screening of individual serum samples

biosafety, collection of bat samples, RT-PCR testing, DNA sequencing, bioinformatics analysis, luminex serological testing and behavioral risk assessment tools. This will be revised in Y1 and improved where necessary.

#### E. INSTITUTIONS AND ROLES (Summarized in table 1):

**University of Pretoria (UP; prime (PI)), Pretoria RSA,** Will finalize and implement the study design, coordinate overall project, coordinate and present training and workshops, develop and finalize SOPs, supervise Hons, MSc, PhD and post-doctoral students, obtain relevant regulatory and

ethical approvals in coordination with relevant government departments; coordinate and perform all field work, coordinate sample testing and testing of all animal samples, coordinate behavioural studies in coordination with relevant government agencies and partners; build diagnostic capacity in the UP laboratory (focused on animal sample testing) that can be shared including hosting and training of partners from neighbouring countries; data analyses, report and publish data; disease modelling and assessing risk mitigation strategies; and development of threat reduction policies. UP will be responsible for all contractual obligations with DTRA including reporting. **Staff:** Wanda Markotter (PI, Overall coordination – involved in all activities listed above), Jessica Coertse (Postdoctoral fellow, Bat filovirus surveillance), Marike Geldenhuys (Postdoctoral fellow, Bat coronavirus surveillance), Marinda Mortlock (Postdoctoral fellow, Bat paramyxovirus surveillance), Liz Basson (Grant administrator), Research assistants x 4 (fieldwork, processing and testing of samples (molecular and serology), database management) (To be hired), students to be identified (PhD, MSc and Honours),

**EcoHealth Alliance (EHA; sub (Co-PI), NY USA,** Will co-develop and implement the study design, coordinate and present training workshops, develop and finalize SOPs, co-supervise students, develop and implement human behavioural studies in coordination with relevant government agencies; fieldwork training and sampling (limited), data analyses, report and publish data; disease modelling and assess risk mitigation strategies; and development of threat reduction policies, develop awareness material. **Staff:** Jonathan Epstein (Co-PI – Involved in all activities listed above), Noam Ross (Disease modelling), Kendra Phelps (Fieldwork training and finalizing SOPs), Kevin Olival (Risk mapping, Developing SOPs & participating in training workshops, linkage with other bat networks e.g. WABNet), Emily Hagan (Develop and direct behavioural risk tools and analysis, assist in developing and implementing risk reduction strategies, community engagement and outreach material development), 1 postdoc and 1 PhD student who will work on disease modelling in bats and spatial analysis of movement data, respectively (To be identified).

**Uniformed Services University (USU, sub CO-I), Maryland USA,** Will develop and transfer Luminex reagents and SOPs to UP and NICD; train laboratory staff; co-supervise MSc and PhD students involved in serological projects; analysis and interpretation of filo-, henipa-, and coronavirus serological data; standardization of multiplex immunoassay and data interpretation. Assess risk mitigation strategies and development of threat reduction policies. **Staff:** Eric Laing (Co-investigator – Involved in all activities listed above), Christopher Broder (Head of the research group, scientific expertise and guidance), Laboratory technicians x 3 (Preparation of Luminex reagents at USU and assistance with training and data analysis).

**National Institute for Communicable Diseases (NICD) Centre for Emerging Zoonotic and Parasitic Diseases (CEZPD) (CO-I), RSA,** Develop SOPs specifically for laboratory diagnostics, fieldwork and reporting, co-supervise Hons, MSc, PhD and post-doctoral students, obtain relevant regulatory and ethical approvals pertaining to human studies in coordination with relevant government departments; coordinate and perform field work, involved in human behavioural and serological studies in coordination with relevant government agencies; build diagnostic capacity in the NICD laboratory that can be shared including hosting and training of partners, provide serological positive and negative serum panels, verify positive serology results obtained from the luminex, analyse results, report and publish data. Assess risk mitigation strategies; and development of threat reduction policies **Staff:** Jacqueline Weyer (Co-investigator – Involved in all of the above), Janusz Paweska (Head of the research group, scientific expertise and guidance), Naazneen Moolla (Medical scientist – Assistance and verification of luminex serological results), Postdoctoral fellow (Human and livestock serology) to be identified.

**Table 1: Prime and partner institutions and summarized roles**

	Study design and coordination	Contractual obligation with DTRA and in-country lead	Regulatory and ethical requirements	Coordinate and/or attend training	Development of SOPs	Collection of bat samples	Collection of host, environmental and ecological data	Collection of livestock samples	Collection of human samples	Molecular testing of samples	Transfer of Luminex technology and testing of samples	Human behavioral studies	Disease modelling	Co-analyze and reporting of data. Risk mitigation strategies and development of threat reduction policies
University of Pretoria (UP), Centre for Viral Zoonoses, South Africa (PI: Prof. Markotter)														
EcoHealth Alliance (EHA), USA (Co-PI: Dr Epstein)														
Uniformed Services University (USU), USA (CO-I: Dr Laing)														
National Institute for Communicable Diseases (NICD), Centre for Emerging Zoonotic and Parasitic Diseases (CEZPD), South Africa (Co-I: Dr. Weyer)														
Department of Agriculture, Land Reform and Rural development (DALRRD previously DAFF), South Africa together with KwaZulu-Natal, Limpopo and Western Cape Department of Agriculture and Rural Development														
National Department of Health (NDoH), South Africa														
National Department of Environment, Forestry and Fisheries (DEFF), South Africa														
Central Veterinary laboratories (CVL), Agrarian Research Institute of Mozambique, Ministry of Agriculture and Food Security, Department of Veterinary Services and Wildlife services, National Ministries of Health, Mozambique and Zimbabwe														
AfricanBats NPC, South Africa, Mr. Seamark														
Ditsong National Museum of Natural History (DNMNH), South Africa: Dr Kearney														

**Department of Agriculture, Land Reform and Rural Development (DALRRD previously DAFF) together with KwaZulu, Limpopo and Western Cape Departments of Agriculture and Rural development, RSA,** Identify representatives and attend training, meetings and workshops from the animal health sector, assistance with obtaining local regulatory documents and import permits, take part in and assist with field studies for collection of bat and livestock samples in South Africa, co-analyze data, report and publish, assess risk mitigation strategies and development of threat reduction policies. **Staff:** Grietjie de Klerk, DVM (Director - Involve in all of the above), Alicia Cloete (Epidemiologist, Involve in all of the above), State veterinarians for sampling areas; Limpopo, Western Cape and KwaZulu Natal RSA (assist and facilitate collection of bat and livestock samples and reporting).

**National Department of Health (nDoH), RSA,** Identify representatives and attend training, meetings and workshops from the human health sector, assist with collection of human samples and behavioral questionnaires in South Africa, co-analyze data, report and publish. Assess risk mitigation strategies and development of threat reduction policies. **Staff:** Wayne Ramkrishna (Epidemiologist - Involve in all of the above)

**National Department of Environment, Forestry and Fishery (DEFF) RSA**, Identify representatives and attend training, meetings and workshops from the environmental health sector, co-analyze data, report and publish, assess risk mitigation strategies and development of threat reduction policies. **Staff:** Abednego Baker - Involve in all of the above.

**Central Veterinary laboratories (CVL), Agrarian Research Institute of Mozambique, Ministry of Agriculture and Food Security, Mozambique**, Identify relevant trainees in animal health, attend training and workshops, coordinate field studies in Mozambique, collect and test samples collected in Mozambique in South Africa, assistance with obtaining local regulatory documents, co-analyze data, report and publish, assess risk mitigation strategies and development of threat reduction policies. **Staff:** Sara Achá (Veterinarian and researcher – Head of laboratory), Lourenço Mapaco (Veterinarian and researcher – Involved in training, fieldwork and testing of samples), Iolanda Vieira Anahory Monjane (Veterinarian, researcher and country coordinator for Mozambique study, involved in training, fieldwork and testing of samples).

**Central Veterinary laboratories (CVL), Agrarian Research Institute of Zimbabwe, Ministry of Agriculture and Food Security Department of Veterinary Services and Wildlife services, Zimbabwe**, Identify relevant trainees in animal health, attend training and workshops, coordinate field studies in Zimbabwe, collect and test samples collected in Zimbabwe in South Africa, assistance with obtaining local regulatory documents, co-analyze data, report and publish, assess risk mitigation strategies and development of threat reduction policies. **Staff:** Pious Makaya (Veterinarian – Laboratory Head), Babra Bhebhe (Veterinarian and coordinator for Zimbabwe study, involved in training, fieldwork and testing of samples)

**National Ministries of Health, Mozambique**, Identify relevant trainees in human health, attend training and workshops, coordinate human behavior studies in Mozambique, assistance with obtaining local regulatory documents, co-analyze data, report and publish, assess risk mitigation strategies and develop threat reduction policies. **Staff:** Inocência Salvador Chongo (focal point of One Health group at the Ministry of Health - Involve in all of the above)

**National Ministries of Health, Zimbabwe**, Identify relevant trainees in human health, attend training and workshops, coordinate human behavior studies in Zimbabwe, assistance with obtaining local regulatory documents, co-analyze data, report and publish, assess risk mitigation strategies and develop of threat reduction policies. **Staff:** To be identified

**AfricanBats NPC, RSA**, Coordinate and present training and workshops focused on bat biology and taxonomy, develop SOPs focused on these topics, coordinate all field studies focused on *Miniopterus* spp. and assistance with other fieldwork, assistance with RFID tracking and environmental monitoring at bat roosts, echolocation data analyses co-analyze data, report and publish data. Assess risk mitigation strategies and development of threat reduction policies. **Staff:** Ernest Seamark (Chief Executive Officer) and Dr. Mark Keith (Board of Directors) (Involvement of all of the above).

**Ditsong National Museum of Natural History (DNMNH), RSA**, Coordinate and present training and workshops focused on bat biology and taxonomy, developing SOPs focused on these topics, Involved in fieldwork, taxonomic identification of bats collected and administration of museum vouchers, comparison of morphological and genetic identification of bat species, co-analyze data, report and publish data. Co-supervision of students, assess risk mitigation strategies and development of threat reduction policies. **Staff:** Teresa Kearney (Research scientist/taxonomist – Involvement in all of the above).

#### **F. CREDENTIALS (See detailed bio sketches of key staff for additional information):**

**University of Pretoria (UP)** is a leading research-intensive university and is recognized nationally and internationally for the quality of its research and the extent of its research outputs. UP is also ideally situated in the executive capital of South Africa, Pretoria, in close proximity to the International airport (O.R Tambo) ensuring ease of travel to enhance collaborations and student exchange. One Health and zoonotic diseases is an important research theme and the Centre for Viral Zoonoses was established in 2016 to enhance multidisciplinary collaboration between the faculty of

Health Sciences, Natural and Agricultural Sciences and the only Veterinary Science faculty in South Africa. The UP has solid strength in the zoonosis research field and has in the last number of years made a series of significant financial and other contributions to support this research. Recently the Future Africa Institute was established to facilitate interdisciplinary research and this include state of the art training and meeting facilities. UP is also ideally situated close to several important collaborative networks including NICD, Onderstepoort Veterinary Institute (ARC-OVI), NDOH, DALRRD (DAFF) and DEFF. UP has a financial and grant management infrastructure and has successfully managed USA federal funding. Infrastructure include a biosafety level 3 laboratory, ultra-low temperature freezers in a biobank with back-up generator power, molecular and serological laboratories and Sanger DNA sequencing and next generation sequencing facilities on site. It also include information technology and bioinformatics infrastructure. Several established field sites exist as well as basic infrastructure and equipment to sample bats. **PI: Prof. Wanda Markotter** is the Director of the Centre for Viral Zoonoses and since January 2016 she is also occupying a South African Research Chair in “Infectious Diseases of Animals (Zoonoses)” funded by the South African government. She is a virologist who is involved in a multidisciplinary research programme on disease ecology in bat species in South Africa and other African countries leading to several high impact research outputs. Experience include molecular and serological diagnostics and fieldwork to collect samples. Her research group consist of support staff, postdoctoral fellows and several post graduate students that also have extensive experience in this field. She plays a key role in national governmental committees including the National Rabies Advisory Group and National One Health forum steering committee.

**EcoHealth Alliance (EHA)** is a scientific organization, working with local partners in over 30 countries at the nexus of health, biodiversity conservation and international development. EHA has a staff of 35 in New York, including scientists (e.g. social scientists, veterinarians, ecologists, analysts, IT experts, and economists), administration, and communications staff. EHA has an extensive record of publishing high quality, peer-reviewed papers, journals, briefing documents and reports, including seminal work on emerging infectious diseases and bat borne viral zoonoses with particular expertise in modelling of host-virus dynamics and human behavioural analyses. EHA’s ability to produce highly utilized and understandable science-based outputs will contribute significantly to achieving project goals and provide objective methods for tracking project utilization of project findings. In 2014, EHA became the first foreign NGO to sign a Memorandum of Agreement (MOA) with the Government of Malaysia. The MOA is to study zoonotic disease in populations exposed to wildlife and includes three sectors of government: Ministry of Health, The Department of Wildlife and National Parks, and The Department of Veterinary Services. **Co-PI: Dr. Jonathan Epstein** is a veterinary epidemiologist and the Associate Vice President at EHA. He is a technical lead for surveillance and outbreak response under the USAID Emerging Pandemic Threats: PREDICT program, a \$100 million effort focused on predicting and preventing pandemic diseases. Dr. Epstein is recognized internationally for his expertise on the ecology of emerging zoonotic viruses and currently directs research and surveillance programs in West Africa, South and Southeast Asia, and China. He has led investigations of NiV, EBOV, SARS CoV and MERS CoV in Asia, the Middle East, and Africa. He has also served as a consultant for WHO, FAO, OIE, and the Institute of Medicine.

**Uniformed Services University (USU)** is a US federal government health science university that trains military physicians through medical school, military masters of public health and military & civilian doctoral candidates in varying disciplines including emerging infectious diseases, and microbiology. USU hosts the Center for Global Health Engagement chapter, which has a mission to support the Department of Defense Global Health Engagement. USU has a world renowned health science faculty who have close ties with the proximally located Walter Reed Army Institute of Research and Naval Medical Research Centers. The Department of Microbiology and Immunology includes 12 full-time Faculty members, and has an overall focus on mechanisms of infectious diseases

and the host response/immunology. Faculty interests and active research programs at USU are diverse, with many nationally- and internationally-known investigators researching areas of viral immunology, vaccine and antiviral therapeutics, and animal model development. USU is also physically located directly across from the main NIH campus in Bethesda, Maryland. The overall broad scientific environment at both USU and the NIH is highly conducive to productive collaborations.

**National Institute for Communicable Diseases (NICD), Centre for Emerging Zoonotic and Parasitic Diseases (CEZPD)** The NICD is a national public health institute of South Africa, providing reference microbiology, virology, epidemiology, surveillance and public health research to support the government's response to communicable disease threats. The NICD serves as a resource of knowledge and expertise of communicable diseases to the South African Government, Southern African Development Community countries and the African continent. The institution assists in the planning of policies and programmes to support and respond to communicable diseases. CEZPD was established by the amalgamation of six former NICD sections: Special Bacterial Pathogens Reference Laboratory, Special Viral Pathogens Reference Laboratory, Arbovirus Reference Laboratory, Electron Microscopy, Parasitology Reference Laboratory and Vector Control Reference Laboratory. The CEZPD operates the only suit biosafety level 4 (BSL4) facility on the African continent, which places it both strategically and critically in a position to assist in the response of highly dangerous emerging and re-emerging zoonotic pathogens.

**Department of Agriculture, Land Reform and Rural Development (DALRRD previously DAFF), RSA together with KwaZulu Natal, Limpopo and Western Cape Department of Agriculture and Rural Development** and specifically the Animal Health section aim to manage risk associated with animal health by promoting, preventing and controlling animal diseases including zoonoses. This includes formulating policies and rendering epidemiological services for early warning and monitoring of animal diseases. Provincial departments and specifically the state veterinarians are involved in sampling animals.

**National Department of Health (NDoH), RSA** aim to improve the health status through the prevention of illnesses and the promotion of healthy lifestyles and to consistently improve the healthcare delivery system by focusing on access, equity, efficiency, quality and sustainability. The Directorate of Communicable Diseases include zoonoses and include multisector committees to report surveillance data and mobilize outbreak responses. This also include a National One Health forum including all stakeholders.

**National Department of Environment, Forestry and Fisheries (DEFF), RSA** aim to ensure an environment that is not harmful to people's health or wellbeing, and to have the environment protected for the benefit of present and future generations. To this end, the department provides leadership in environmental management, conservation and protection towards sustainability for the benefit of South Africans and the global community.

**Central Veterinary laboratories (CVL), Mozambique,** CVL is a technical department of the Directorate of Animal Science (DCA), of the Agrarian Research of Institute of Mozambique (IAM) and is the national reference laboratory. The role is to perform animal diseases diagnostics and epidemiological studies; to identify and propose research area on animal diseases; to develop research methodologies and standardized techniques for animal diseases and zoonotic diseases; to guarantee the specialized training and follow-up of laboratory technicians and to provide technical assistance to the regional and provincial laboratories. There is a One Health Technical Working Group (TWG) established which includes different stakeholders: Ministries of Health, Agriculture and Food Security, Fisheries, Environmental and Wildlife.

**Central Veterinary laboratories (CVL), Department of Veterinary Services and Wildlife services Zimbabwe,** CVL is a branch under the Directorate of the Division of Veterinary Technical Services of the Department of Veterinary Services. Veterinary Services falls under the Ministry of Lands, Agriculture, Water, Climate, and Rural Resettlement. The role is to provide diagnostic support

for zoonotic diseases and diseases of economic interest in animals, epidemiological disease investigations and surveillance of diseases as well as Food safety monitoring and Port Health Services.

**AfricanBats NPC**, is registered within South Africa as a Not for Profit Company. The vision is to have a functioning, integrated program for education, capacity building, research and management for the conservation of bat populations in Africa. Activities include the publication of African Bat Conservation News and the African Chiroptera Report. AfricanBats NPC has been doing capacity building through workshops and training courses, attended by post-graduate students and emerging scientists undertaking research on bats. Research projects have focused on bat monitoring, bat cave conservation, bat systematics, taxonomy and life histories, bat in protected areas and anthropocene bats.

**Ditsong National Museum of Natural History (DNMNH)**, formerly known as the Transvaal Museum was founded in 1892 and it has, since acted as custodian and documentation centre of South Africa's natural heritage. The Museum's collections and exhibits include fossils, skeletons, skins and mounted specimens of amphibians, fish, invertebrates, reptiles and mammals. It is one of the largest in South Africa and the largest collection of bat specimens in South Africa and extensive taxonomic expertise.

### **III. WORK TO BE PERFORMED**

The project will focus on capacity building in the Southern African region (Table 2) and biosurveillance (Table 3) as summarized and 3 and explained below.

*Capacity building* will focus on South Africa and neighboring countries. Pathogens do not respect borders and a regional approach is needed for South Africa to effectively detect, predict and respond to infectious disease threats. The main activities will be: 1) training representatives from Southern African countries in development of effective surveillance strategies, standard operating protocols, biosafety, data analysis, disease modelling, field and laboratory investigations, effective reporting and communication following a One Health approach; 2) establish diagnostic technologies to detect filo-, henipa- and coronaviruses for the region at a central facilities in South Africa; and 3) build capacity between stakeholders including governmental representatives through joined meetings including development of mitigation and threat reduction strategies to inform policy. Although the biosurveillance part of the project will be focused on South Africa, capacity building will include training of colleagues from Mozambique and Zimbabwe. Trainees, representing animal, human, environmental health and academia, will be selected from each country in line with a One Health focus by the different stakeholders. Theoretical and practical training will take place in South Africa through workshops, at field sites and diagnostic laboratories. In addition to developing emerging researchers and postdoctoral fellows, projects will be developed for at least 4 PhD, 4 MSc and 4 honors students, including students from neighboring countries, with co-supervision between partners. Fellows and students will spend time with different team members to learn laboratory and analytical techniques. By including colleagues from neighboring countries, we will develop a workforce that can then initiate long-term surveillance programs in the respective countries. These projects will be supported in the long-term by the regional diagnostic capacity developed in South Africa in two institutions and access to these facilities for testing to the region. Both these institutions invest in staff and infrastructure independent of this project and funding. The South African Research Chair of Prof. Markotter is also a long-term commitment from the South African government [Department of Science and Innovation (DSI)] and the academic institution (UP). To also ensure sustainability there is close collaboration with all ministries and capacity building is focused on emerging researchers to ensure long-term continuity

Activity	Location	Month and year	Duration in days	Chairs/ Trainers	Attendees	Proposed activities
Project Stakeholder meeting	UP, Pretoria, RSA	June Y1	3	Markotter and Epstein	<p><b>~ 30 attendees</b>  <b>At least one representative of each stakeholders mentioned below</b></p> <p>South Africa:  <i>UP, NICD, DALRRD, nDOH, DEFF, AfricanBats, DNMNH</i></p> <p>Mozambique  <i>CVL Moz, Ministry of Health, Academia, Ministry of Enviromental and Wildlife</i></p> <p>Zimbabwe  <i>CVL Zim, Ministry of Health</i></p> <p>USA  <i>EHA, USU, DTRA representatives</i></p>	<p><b>Y 1</b>                      Introduction to the project, roles and responsibilities, timelines                      Planning of surveillance strategies, standardized SOPs , standardize reporting policy                      Reporting of results and engagements with government (including between countries)                      Planning and design of human behavioral studies, communication strategy and awareness                      Biosafety training including packaging and shipping of samples                      Establishment of SABRENET</p>
	UP, Pretoria, RSA Set up a video conference, Moz and Zim representatives will meet with South African colleagues in South Africa and USU and EHA will dial in from the USA	June Y2	1			<p><b>Y 2, 3 and 4</b>                      Share and discuss results and progress, reporting, publications                      Agree on activities for the next year                      Identify trainees and student involvement                      Develop mitigation and prevention policies, threat reductions based on preliminary results                      Draft a plan for sustainability of biosurveillance for the region and decide on implementation timelines</p>
	New York, USA	June Y3	3			<p><b>Y 5</b>                      Analyze and discuss all results, finalize mitigation strategies and policies for threat reduction                      Finalize the plan for sustainable biosurveillance in the region.                      Prepare final report and publications</p>
	UP, Pretoria, RSA Set up a video conference, Moz and Zim representatives will meet with South African colleagues in South Africa and USU and EHA will dial in from the USA	June Y4	1			
	UP, Pretoria, RSA	June Y5	3			
Modelling and data analysis workshop	UP, Pretoria, RSA	June Y1	2	Olival, Ross, (EHA)	<p><b>~ 30 attendees</b>  <b>At least one representative of each stakeholders mentioned above</b></p>	<p>Epidemiology                      Risk analysis                      GIS                      Hotspot mapping                      Niche modelling                      Introduction to disease modelling</p>
Introduction to bat biology and taxonomy training	UP, Pretoria, RSA	June Y1	4	Kearney (DNMNH), Seamark (African Bats), Phelps (EHA), Markotter (UP)	<p><b>~ 15 attendees</b>  <b>At least one representative of each stakeholders mentioned above</b></p>	<p>Introduction to bat biology, physiology, ecology, taxonomy, echolocation and environmental monitoring. The focus will be on Southern African bat species. Will include practical taxonomic exercises and sampling at both insectivorous and frugivorous bat roosts.</p>
Bat field sampling training	Field sites in South Africa, Mozambique and Zimbabwe	Y1-Y4 various months	14	Markotter (UP), Postdocs (UP), Kearney (DNMNH) Seamark (African Bats), Phelps (EHA)	<p><b>At least one representative of each stakeholders mentioned above</b>                      A strong focus on training students and staff that will be involved in fieldwork</p>	<p>There will be continuous field training. This will consist of each trainee (Identified by the stakeholders) joining at least 2 field visits a year (part of the biosurveillance activity).</p>
Laboratory diagnostic training	UP and NICD laboratories, RSA	Y1-Y5 various months	21	Markotter (UP), Weyer (NICD), Moolla (NICD) Laing (USU) Postdocs (UP and NICD)	<p><b>At least one representative of each stakeholders mentioned above</b>                      Focus will be on training students and staff involved in diagnostic testing</p>	<p>There will be continuous laboratory diagnostic training. This will consist of trainees visiting the diagnostic laboratories (NICD and UP), receive training and perform sample processing, testing and analyses of results.</p>

**Biosurveillance for Viral Zoonoses around Bat-Livestock-Human interfaces in Southern Africa / Markotter & Epstein CBEP-Thrust Area 6, CC WMD**

Activity	Location	Month and year	Days	Chairs/ Trainers	Attendees	Proposed activities
Data interpretation workshop *	EHA, New York UP, RSA EHA, New York UP, RSA EHA, New York	Feb Y1 Feb Y2 Feb Y3 Feb Y4 Feb Y5	5	Markotter (UP), Epstein (EHA)	Markotter (UP), Epstein (EHA) E. Laing (USU) Postdocs UP, NICD, EHA	A smaller team that will do in depth data analysis that can then be discussed and analyzed by the broader group (Stakeholder meeting)

\*Depending on data collected, additional people will attend the data analysis workshops.

**Biosurveillance** activities will be focused in South Africa with limited fieldwork collections in Mozambique and Zimbabwe (Y4). Activities will already start at the beginning of Y1 since ethical approvals and Department of Agriculture and Rural Development (Previously DAFF) Section 20 to perform biosurveillance in Southern Africa is already approved. Minor amendments will be applied for. Due to the proposed project start date (June 2020) no retrospective sample testing will be performed but previous results generated will be part of data analysis.

**Sampling strategy:** Targeted longitudinal surveillance in bats, as well as sampling in potential spillover hosts (cattle, goats, donkeys, and pigs), will be implemented in South Africa and once-off biosurveillance of bats in neighboring countries. The surveillance strategy has been designed based on species previously associated with high consequence pathogens in the literature as well as host and other ecological factors that may play a role in spillover (See background for detail). Cross sectional studies will focus on *Rousettus*, *Rhinolophus*, *Miniopterus* and molossid bat species at several sites in South Africa (Figure 1) to determine the nucleic acid and seroprevalence of filo, henipa- and potentially zoonotic coronaviruses (Table 3). Prevalence depends on many factors, including sample type, seasonality, specific species targeted, target virus and sensitivity of the assay with studies reporting prevalence ranging from 0-100% and the prevalence of nucleic acids is usually much lower than the presence of antibodies. We assumed a nucleic acid and seroprevalence of 10% and sample sizes of individual bats were selected to detect positives with a 95% confidence interval based on estimated population sizes (Markotter, personal communication) and seasonality. Sampling in bats will be non-destructive where blood, swabs (oral and rectal) and urine samples will be collected and this sample strategy has proven to be successful in previous studies (Anthony et al., 2017a). Limited voucher specimens will be collected to confirm species identification where necessary. In addition, will we implement longitudinal surveillance in both *Rousettus* and *Miniopterus* spp. (implicated as filo- and henipavirus hosts), including during birthing periods to investigate seasonality of virus shedding. *Miniopterus* spp. move between Highveld roosts in urban areas during winter months and maternity summer roosts, and therefore several roosts are included to sample representative individuals over the study period. *Rousettus* roosts occur in different biomes in South Africa, and representative roosts are included specifically Black Rock and Table Mountain. Roost type differs and therefore caves, tree roosts, crevices and man-made structures are included in the selected sites and chosen because of a potential bat-animal human interphase. Matlapitsi is in a rural savanna area with free roaming livestock, vegetable and fruit farming. People visit the cave for cultural reasons, and there are fruit trees in-between human dwellings where fruit bats feed. Movement of *R. aegyptiacus* between Matlapitsi and Black Rock has been reported (>500 km) (Jacobsen and Du Plessis, 1976); Black Rock is in a tropical rainfall area, located inside a protected conservation area (Isimangaliso Wetland park), with human settlements and livestock within the foraging distance of the bats; The Table Mountain roost is located in the Table Mountain National Park, representing the fynbos biome and a winter rainfall with tourists visiting the area; Madimatle cave, Limpopo, South Africa is a maternity roost for *Miniopterus* spp., co-roosting with *Rhinolophus* spp. It is an important cultural site frequently visited by people travelling back and forth between this cave and major metropolitan cities in the most populated province in South Africa, Gauteng. It is also surrounded by wildlife farming areas. One-off sampling in Mozambique and Zimbabwe will focus on the cave dwelling *R. aegyptiacus* (implicated as a filo- and henipavirus host) and insectivorous bats co-roosting including know roosts such as Chinoyi caves.

**Biosurveillance for Viral Zoonoses around Bat-Livestock-Human interfaces in Southern Africa / Markotter & Epstein CBEP-Thrust Area 6, CC WMD**

**Table 3: Summary of sampling sites, bat species targeted, sample numbers and sample frequencies.**

Site name (Fig 1)	<i>Rousettus aegyptiacus</i> <sup>#</sup>			<i>Miniopterus</i> spp <sup>#</sup>			<i>Mollosids and Rhinolophus</i> spp <sup>#</sup>		
	Year of sampling and frequency	Sample numbers	Estimated population sizes	Year of sampling and frequency	Sample numbers	Estimated population sizes	Year of sampling frequency	Sample numbers	Estimated population sizes
Matlapitsi Limpopo, RSA*	Y1, Y2, Y3 Monthly	120/mo 1440/year Total=4320	Varies between 6000-20000 with lower numbers during the winter months	Y1, Y2, Y3 Seasonally (4 x/year)	120/visit 480/year Total=1440	Varies between 1000-2500 individuals	Y1, Y2, Y3 Seasonally (4 x/year)	120/visit 480/year Total=1440	Populations sizes are unknown but can be between 1000-2500 individuals
Black Rock KZN, RSA*	Y2 and Y3 Seasonally (4 x/year)	120/visit 480/year Total =960	Varies between 6000-10000 with lower numbers during the winter months	Y2 and Y3 Seasonally (4 x/year)	120/visit 480/year Total=960	Varies between 1000-2500 individuals	Y2 and Y3 Seasonally (4 x/year)	120/visit 480/year Total=960	
Table Mountain Western Cape, RSA	Y2 and Y3 Seasonally (4x/year)	120/visit 480/year Total=960	A small population of about 1000-3000 individuals	Y2 and Y3 Seasonally (4 x/year)	120/visit 480/year Total=960	Varies between 1000-2500 individuals	Y2 and Y3 Seasonally (4 x/year)	120/visit 480/year Total=960	
Madimatle Limpopo RSA*	<i>R. aegyptiacus</i> not present	N/A	N/A	Y1, Y2, Y3 Monthly for Oct – Feb	120/mo for 5 months 600/year Total=1800	Varies between 1000 in the winter months and 500 000 during birthing periods	Y1, Y2, Y3 Seasonally Only 5 month, 2 seasons	120/visit 240/year Total=720	
Other Miniopterus sites (Highveld) X 2 (Mamelodi and Gladysvale)	<i>R. aegyptiacus</i> not present	N/A	N/A	Y1, Y2, Y3 Monthly for March – Sept	120/mo for 7 months 840/year Total=2520	Varies between 1000-2500 individuals	Y1, Y2, Y3 Seasonally Only 7 month, 2 seasons	120/visit 240/year Total=720	
Mozambique*	Y4 Twice/year	200/visit 400/year Total=400	Unknown but <i>R. aegyptiacus</i> population estimated to be 2000-5000	Y4 Twice/year	200/trip 400/year Total=400	Unknown Varies between 1000-2500 individuals	Twice/year (Y4)	200/trip 400/year	
Zimbabwe*	Y4 Twice/year	200/visit 400/year Total=400	Unknown but <i>R. aegyptiacus</i> population estimated to be 2000-5000	Y4 Twice/year	200/trip 400/yea Total=400	Unknown Varies between 1000-2500 individuals	Twice/year (Y4)	200/trip 400/year Total=400	
<b>Total bats sampled</b>	<b>7040</b>			<b>8480</b>			<b>5600</b>		
	<b>21 120</b>								

# Population densities of the bat species differ significantly and is different for the same species between sites and seasons. Estimations are indicated in the table.

\*Sites that will be targeted for once of human behavior studies and collection of human and livestock serum for sero-surveillance. Only human questionnaire-based studies will be performed in Mozambique and Zimbabwe.

Human behavior (KAP analysis) and collection of human serum samples (n=150/site) will be implemented at three sites in South Africa in Y3 (Table 3) where potential human and livestock contact is a possibility. Sampling more than 100 per site will allow us to detect seropositivity with a 95% confidence at a seroprevalence of 3% assuming populations of 500. Livestock samples, including cattle, goats, pigs and donkeys (n=150/species/site), will also be collected in Y3 at South African sites. Only questionnaire-based human studies will be performed in Mozambique and Zimbabwe in Y4.

**Collection of samples and testing:** Sample collection will be performed in full personal protective equipment including disposable tyveks, double latex gloves, leather gloves, respiratory protection

(PAPRs) and gumboots. Oral and rectal swabs, urine and blood will be collected in duplicate. One sample set will be pooled for testing. All samples will be collected in inactivation buffer, DNA/RNA shield (ZymoResearch), at the site of collection, therefore avoiding any transport or storage of potential infectious samples (since viruses, bacteria, fungi and parasites are inactivated) and requirement of high biocontainment laboratories for processing of samples. This also protects the quality of nucleic acids by neutralizing nucleases and eliminates the need for cold-chain, if necessary. DNA/RNA shield abides by Center for Disease Control's (CDC) guidelines for pathogen inactivation and has been validated by various research groups to inactivate both enveloped and non-enveloped viruses such as parvoviruses, Chikungunya Virus, and West Nile Virus, Dengue Virus, Ebolavirus, Herpes Simplex Virus-1, Herpes Simplex Virus-2, Influenza A, Rhinoviruses, and MERS-coronavirus (Nowotny and Kolodziejek, 2014). Serum will be inactivated using 60°C for 15 min. This has been shown to be effective in inactivating viral pathogens (Van Vuren and Paweska, 2010).

**Ecological and environmental data:** Environmental (weather, rainfall and humidity) and ecological data of the bats (age, reproductive status, sex and measurements) will be collected, as well as population size estimates. We will employ marking and tracking technologies such as tattooing, pit tags (RFID), and telemetry systems to monitor virological status in individuals recaptured over time but also to determine foraging patterns (home ranges, distances traveled and habitat selection) and estimate population sizes. There is limited information about the habitat use and foraging patterns of *R. aegypticus*, and tracking this to estimate spillover risk will be a key component of this project. Movement data has been useful in understanding host and virus ranges and where bats may interact with people and livestock (Epstein et al., 2009; de Jong et al., 2013). EHA (Epstein) and the Movement Ecology laboratory (Hebrew University of Jerusalem) have extensive experience in using telemetry in fruit bats and will collaborate with UP on this specific part of the project.

**Diagnostic testing of samples:** Testing for viral antibodies and nucleic acids from all bats samples collected will be performed at UP and NICD, RSA. This will include follow up DNA Sanger sequencing of all positive amplicons. Molecular detection technologies are already established with some improvements needed (Table 4) and synthetic RNA controls will be used as positive controls and to determine sensitivity of the assays. In addition, these assays are conventional nested RT-PCRs, and the assay times are extensive. Given the scope of the proposed project and the high number of samples that will be tested, we aim to adapt these assays to use randomly primed cDNA, which can be used as template for all virus specific assays. This will save cost and processing time. Assays will be optimized on a SYBR Green real-time PCR platform, which will drastically improving throughput by reducing the processing times for sample testing, limits contamination risk and save on costs. Additional characterization of gene regions using Sanger (UP) and high throughput genome sequencing (UP) will be performed on all novel sequences identified. Luminex technology will be established in partnership with USU and will be transferred to both NICD and UP. This will include coupled antigens and controls for henipa- and filoviruses (Marburg and Ebola) and proteins are available for Hendra, Nipah, Cedar, Mojiang, Ghana henipavirus, Ebola virus, Sudan, Reston, Bundibugyo, Tai forest, Cueva, Lloviu, Marburg, Ravn, Mengla and Bombali virus. Currently, there are no antigens available for coronaviruses and cross reactivity complicates the value of such an assay and will therefore be excluded. Negative *R. aegyptiacus* sera available from previous experimental infections are available (NICD) to be used as additional controls to establish and verify cut-off values. NICD is the reference laboratory for human sample testing as well as for filovirus diagnostic testing and therefore the technologies will be established at both NICD and UP.

**Data analyses, reporting and communication strategy:** Data analyses will include statistics, bioinformatics, epidemiology and disease modelling. This will be done annually, including all stakeholders (Table 3). It will also include retrospective results generated before this project started. Standard operating procedures will be established for reporting and will include developing risk mitigation and prevention strategies. A communication strategy will be developed at the start of the project that will include education and awareness materials, also targeting communities.

**Biobank and database:** A secure and up to date database that will be shared by all partners will be established. UP has developed an in-house database that can function on a web-based system and can be adapted for this project. The PACS system is also available to manage sample information. For storage of samples the current biobank infrastructure at UP will be expanded.

**Table 4: Detail of nucleic acid detection methods that will be used in this study**

<b>Paramyxoviruses</b>						
<i>Respiro-, Morbilli-, and Henipavirus</i>	Hemi-nested RT-PCR (RMH assay)	Tong et al., 2008	10-100 copies of RNA (Tong et al., 2008); [Two-step protocol 10 copies of RNA (Bruck, 2019)]	Partial polymerase (L) gene	611 bp (first round); 494 bp (nested round)	The sensitivity and specificity of the assays were evaluated against a range of paramyxoviruses including several human viruses such as measles ( <i>Morbillivirus</i> ) and mumps virus ( <i>Orthorubulavirus</i> ), as well as the zoonotic bat-borne Hendra and Nipah viruses ( <i>Henipavirus</i> genus) amongst others. These assays have been widely applied for biosurveillance in bats which led to the detection of viruses such as Ghanaian bat henipavirus (Drexler et al., 2012), bat mumps orthorubulavirus (Drexler et al., 2012) and viruses related to other human pathogens such as human parainfluenza virus 2 (Mortlock et al., 2019). Additionally, the family wide PAR assay has been successfully used in the USAID PREDICT program for paramyxovirus biosurveillance.
<i>Avula- and Rubulavirus</i>	Hemi-nested RT-PCR (AR assay)	Tong et al., 2008	10-100 copies of RNA (Tong et al., 2008); [Two-step protocol 300 copies of RNA (Mortlock et al., 2019)]	Partial polymerase (L) gene	272 bp (first round); 224 bp (nested round)	
<b>Assay comment:</b> Both the selected assays (RMH and AR) are very sensitive and capable of detecting a diversity of paramyxoviruses. The family wide assay (PAR) was is much less sensitive (500-1000 copies of RNA), hence the selection of the two more specific and sensitive assays for biosurveillance. All three assays were developed and published in 2008 and included the then known diversity of bat-borne paramyxoviruses (Hendra, Nipah, Menangle and Tioman viruses). However, these assays have not yet been updated or evaluated against more recently described bat- and wildlife-borne viruses such as Sosuga, Cedar, Mojiang and Ghanaian bat henipavirus. We aim to evaluate the sensitivity of these established assays against more recently described bat-borne viruses such as Sosuga, Cedar, Ghanaian bat henipavirus and the presumed rodent-borne Mojiang virus and update the primers if necessary.						
<b>Filoviruses</b>						
Diversity targeted	Assay type	Reference	Sensitivity	Targeted gene region	Size of amplicon	Potential to detect zoonotic viruses
Ebola- and Marburg virus and new diversity (Bombali and Mengla)	Qualitative real-time RT-PCR (probe based)	Panning et al., 2007; Rieger et al., 2016 (RealStar® Filovirus Screen RT-PCR Kit)	Panning et al., 2007: Virus dependent (500-500 RNA copies); RealStar kit: ~ 10 RNA copies	Partial polymerase (L) gene	293 bp	Capable of detection of all Ebola- and Marburvirus strains, limited for detection of other viruses/strains (Rieger et al., 2016; Emperador et al., 2019)
	Hemi-nested RT-PCR	Yang et al. 2019, 2017; He et al. 2015	Not determined	Partial polymerase (L) gene	214-478 bp	Capable of detection of Ebola virus strains and Mengla virus (not evaluated for detection of other filoviruses)
	Qualitative real-time RT-PCR (probe based)	Kemenesi et al. 2018	Not determined	Partial polymerase (L) gene	73 bp	Capable of detection of Lloviu virus (not evaluated for detection of other filoviruses)
	RT-PCR	Goldstein et al. 2018	Not determined	Partial polymerase (L) gene	680 bp	Capable of detection of Bombali virus (not evaluated for detection of other filoviruses)
	Quantitative real-time PCR (probe based)	Forbes et al. 2019; Jääskeläinen et al. 2015	6 RNA copies for <i>Zaire ebolavirus</i>	Partial polymerase (L) gene	108 bp	Capable of detection of <i>Zaire ebolavirus</i> and Bombali virus (not evaluated for detection of other filoviruses)
<b>Assay comment:</b> Most diagnostic assays target the <i>Ebola-</i> and <i>Marburgvirus</i> genera and to allow for detection and differentiation, most of these assays target the more variable genes i.e. glycoprotein (GP) and the RNA-dependent RNA polymerase (L) (reviewed in Emperador et al., 2019). Genomic sequences of filoviruses of different genera differ from each other by more than 55% complicating assay selection for use in family-wide targeted surveillance and a combination of several assays (as listed) will be required to allow detection of the complete diversity. Although established assays have been reported to be successful for detection of novel filoviruses (for example Forbes et al. 2019), the majority has not been fully validated or evaluated for detection of all members of the <i>Filoviridae</i> family with important information regarding specificity and sensitivity lacking. Therefore, several assays will be required for surveillance; the Panning/kit assay will be used for detection of Ebola- and Marburgvirus strains in combination with the other assays listed to cover the entire diversity (i.e. Bombali-, Lloviu- and Menglaviruses).						

**Biosurveillance for Viral Zoonoses around Bat-Livestock-Human interfaces in Southern Africa / Markotter & Epstein CBEP-Thrust Area 6, CC WMD**

Coronaviruses						
Diversity targeted	Assay type	Reference	Sensitivity	Targeted gene region	Size of amplicon	Potential to detect zoonotic viruses
Coronaviruses - focused on the mammalian infecting <i>Alpha</i> - and <i>Betacoronavirus</i> (includes SARS coronavirus) genera	Hemi-nested RT-PCR	Geldenhuis et al., 2018	The nested assay is capable of detecting 50 copies of synthetic control RNA (Nkambule, 2019)	Partial region of the RNA dependent RNA polymerase (RdRp) gene	443 bp (first round); 268 bp (nested round)	Capable of detecting the range of human coronaviruses (synthetic controls); detected a MERS-related coronavirus from an insectivorous bat species (Geldenhuis et al., 2018); SARS-related coronaviruses from Horseshoe bats in Rwanda (Markotter et al., 2019)
<p><b>Assay comment:</b> Members of the <i>Coronaviridae</i> family are highly diverse, which complicates sequence detection of all species with one nucleic acid detection assay. The RNA dependent RNA polymerase (RdRp) gene region (or nsp 12) is situated within ORF 1b of the genome, and is highly conserved and a number of nucleic acid detection assays (Stephensen et al., 1999; Poon et al., 2005; Woo et al., 2005; Watanabe et al., 2010; de Souza Luna et al., 2007; Tong et al., 2009; Gouilh et al., 2011; Geldenhuis et al., 2013; Geldenhuis et al., 2018) use a region located between approximately 14,800 and 15,600 nt depending on the genome (in reference to SARS coronavirus AY714217) for coronavirus RNA detection. Since the majority of assays use the same region, it allows overlapping sequence regions to be compared when investigating partial genes. Assays reported in Watanabe et al., 2010 and Quan et al., 2010 are used in the PREDICT project (Anthony et al., 2017a; Anthony et al., 2017b; Wacharapluesadee et al., 2015; Lacroix et al., 2017), though the sensitivity of these assays have not been reported in literature. The Geldenhuis et al., 2018 assay is a hemi-nested RT-PCR assay that is a multiplexed assay focused on diversity of alpha- and betacoronaviruses and correspond to the same regions targeted in these assays. The primers of the Geldenhuis et al., 2018 assay was updated in 2017, and included the latest diversity of coronaviruses (including human and major bat coronavirus lineages).</p>						

**IV. SUMMARY OF TASKS AND PERFORMANCE SCHEDULE**

Table 5: Summary of the tasks that will be performed for the duration of the project. Detailed tasks are indicated in the attached Statement of work (SOW).

TASK	Y1	Y2	Y3	OY4	OY5	TASK	Y1	Y2	Y3	OY4	OY5
<b>1. Build and enhance capacity in Southern Africa to conduct biosurveillance for filo-, henipa- and coronaviruses</b>						<b>3. Conduct targeted observational and human behavior studies</b>					
1.1. Project stakeholder workshop						3.1. Design the study and questionnaires					
1.2. Establishment and sustaining a Southern African Bat Research network (SABRENET)						3.2. Apply for necessary ethical approvals and obtain community permissions					
1.3. Modelling and data analysis workshop						3.3. Collect and analyze data					
1.4. Introduction to bat biology and taxonomy						<b>4. Conduct targeted serological surveys in people and livestock</b>					
1.5. Bat field sampling training						4.1. Scoping visits to potential study sites					
1.6. Establishment of luminex serology technology at UP and NICD						4.2. Apply for necessary permits and ethical approvals					
1.7. Laboratory diagnostic training						4.3. Collection of samples					
1.8. Data interpretation workshop						4.4. Test and analyze data					
<b>2. Implement biosurveillance in bats in Southern Africa and testing of samples</b>						<b>5. Reporting and Communication</b>					
2.1. Cross sectional and longitudinal surveillance in bat species in South Africa						5.1. Discuss results, finalize and compile an annual report including all stakeholders					
2.2. Nucleic acid testing of samples and DNA sequencing of positives.						5.2. Develop a communication plan and implement it					
2.3. Serological testing of serum samples collected from bats and data analysis						5.3. Present at scientific conferences and prepare manuscripts for publication					
2.4. Characterization of additional genes or genome regions of positive samples, verify serological positive results						5.4. Annual report to all governmental partners and stakeholders					
2.5. Enter all data and results into a database and analyze						5.5. Annual report to DTRA					
2.6. Once off surveillance of bats in Mozambique and Zimbabwe						5.6. Attend DTRA technical review

---

Dear colleagues

Hope you are well. As you may recall, we submitted a proposal to DTRA in 2019 for funding and you were listed as partners (See attached). The good news is that the funding was finally awarded. We would like to schedule an orientation project meeting on 19 October from 3-5 pm (Virtual). This will focus on an introduction to the project and activities proposed. We will have a discussion on the work plan proposed, responsibilities and any deviations that we need to make, keeping the current restrictions of the COVID-19 pandemic in mind.

I will also send a separate meeting invite. The meeting will also be recorded and if you cannot join, we will also make this recording available.

Almost a year has passed since the submission of this proposal, please let me know who needs to be included/excluded in this invite since there may have been staff changes since.

This is really an exciting project and we are looking forward to starting the conversations, activities and building capacity in Southern Africa.

Kind regards

Wanda and Jon

Edited by Anthony S. Fauci, National Institute of Allergy and Infectious Diseases, Bethesda, MD, and approved September 14, 2020 (received for review January 8, 2020)

**Nipah virus (NiV) is an emerging bat-borne zoonotic virus that causes near-annual outbreaks of fatal encephalitis in South Asia—one of the most populous regions on Earth. In Bangladesh, infection occurs when people drink date-palm sap contaminated with bat excreta. Outbreaks are sporadic, and the influence of viral dynamics in bats on their temporal and spatial distribution is poorly understood. We analyzed data on host ecology, molecular epidemiology, serological dynamics, and viral genetics to characterize spatiotemporal patterns of NiV dynamics in its wildlife reservoir, *Pteropus medius* bats, in Bangladesh. We found that NiV transmission occurred throughout the country and throughout the year. Model results indicated that local transmission dynamics were modulated by density-dependent transmission, acquired immunity that is lost over time, and recrudescence. Increased transmission followed multiyear periods of declining seroprevalence due to bat-population turnover and individual loss of humoral immunity. Individual bats had smaller host ranges than other *Pteropus* species (spp.), although movement data and the discovery of a Malaysia-clade NiV strain in eastern Bangladesh suggest connectivity with bats east of Bangladesh. These data suggest that discrete multi-annual local epizootics in bat populations contribute to the sporadic nature of NiV outbreaks in South Asia. At the same time, the broad spatial and temporal extent of NiV transmission, including the recent outbreak in Kerala, India, highlights the continued risk of spillover to humans wherever they may interact with pteropid bats and the importance of limiting opportunities for spillover throughout *Pteropus*'s range.**

bats | henipavirus | Nipah virus | *Pteropus* | disease modeling

Outbreaks of zoonotic diseases are often sporadic, rare events that are difficult to predict, but can have devastating consequences (1). Emerging viral zoonoses of wildlife that have become pandemic include HIV/AIDS, 1918 H1N1 influenza virus, severe acute respiratory syndrome (SARS) coronavirus, and the current COVID-19 pandemic caused by SARS-CoV-2 (2–5). Bats are important hosts for many zoonotic viruses, including Ebola virus, SARS-CoV, SARS-CoV-2, and Nipah virus (NiV); the ecological drivers and transmission dynamics of these viruses in their reservoir hosts are poorly understood (6–12). A better understanding of the transmission dynamics of zoonotic pathogens in their natural reservoirs may help anticipate and prevent outbreaks (10, 13).

NiV is an emerging zoonotic paramyxovirus (genus *Henipavirus*) that has repeatedly spilled over from bats to cause outbreaks in people and livestock with high case-fatality rates across a

broad geographic range. To date, human NiV infections have been identified in India, Bangladesh, Malaysia, Singapore, and the Philippines (14–18). It has caused repeated outbreaks in Bangladesh and India, with a mean case-fatality rate greater than 70% (14, 19, 20). A single genus of frugivorous bats (*Pteropus*) appears to be the main reservoir for henipaviruses throughout Asia and Australia (21–25). This includes *Pteropus medius* [formerly *Pteropus giganteus* (26)], the only pteropid bat present in Bangladesh and India (16, 27–30). NiV has several characteristics that make it a significant threat to human and animal health: 1) Its bat reservoir hosts are widely distributed throughout Asia and occur within dense human and livestock populations, leading to widespread frequent spillover events and outbreaks; 2) it can be transmitted directly to humans by bats or via domestic animals; 3) it can be transmitted from person to person; 4) spillover has repeatedly occurred in highly populous and internationally

## Significance

**Nipah virus (NiV) is a zoonotic virus and WHO priority pathogen that causes near-annual outbreaks in Bangladesh and India with >75% mortality. This work advances our understanding of transmission of NiV in its natural bat reservoir by analyzing data from a 6-y multidisciplinary study of serology, viral phylogenetics, bat ecology, and immunology. We show that outbreaks in *Pteropus* bats are driven by increased population density, loss of immunity over time, and viral recrudescence, resulting in multiyear interepizootic periods. Incidence is low, but bats carry NiV across Bangladesh and can shed virus at any time of year, highlighting the importance of routes of transmission to the timing and location of human NiV outbreaks.**

connected regions; 5) it is associated with high mortality rates in people; and 6) there are currently no commercially available vaccines to prevent infection or drugs to mitigate disease (31–33). As a result, the World Health Organization has listed NiV in its R&D Blueprint as one of the 10 highest-priority pathogens for the development of medical countermeasures due to its potential to cause significant outbreaks (34). In May 2018, an outbreak of NiV encephalitis with a 91% mortality rate occurred in a new location—Kerala, India—more than 1,200 km southwest of previous Indian and Bangladeshi outbreaks (35). A single case was subsequently reported in Kerala in 2019, and while local *P. medius* populations have been implicated as the local source of infection, the route of spillover in both instances remains unknown (35, 36).

In Malaysia and Bangladesh, consumption of cultivated food resources contaminated with bat excreta, such as mangoes in Malaysia and date palm sap in Bangladesh and northeastern India, have been identified as the predominant cause of spillover to pigs and people, respectively (37). Human outbreaks occur almost annually in Bangladesh, and the seasonal timing (November to April) and spatial distribution of outbreaks coincide with patterns of raw date-palm-sap consumption in a region termed the “Nipah belt” (38). However, there is variability in the geographic locations and number of spillover events, as well as the number and magnitude of human outbreaks that occur each year (39, 40). Spillover has also occurred outside the predominant season and region of date-palm-sap consumption (41). Whereas no human outbreaks have been reported in eastern Bangladesh, despite date-palm-sap harvesting and consumption, human outbreaks have been reported in Kerala, India, where date-palm sap is not cultivated (38). These observations suggest an alternate route of spillover in certain locations and a critical need to understand the mechanisms of underlying viral infection dynamics in bats and the extent of genetic diversity within the virus—each of which may influence the timing, location, and epidemiology of human outbreaks (38).

Previous research on the transmission dynamics of NiV and Hendra virus in *Pteropus* species (spp.) bats has produced mixed, and sometimes contradictory, findings. NiV, like Ebola, Marburg, Hendra, and some bat coronaviruses, is associated with seasonal spikes in infection that coincide with annual or semi-annual synchronous birth pulses (21, 42–48). Seasonal periods of NiV shedding were observed in *Pteropus hylei* in Thailand, and seasonal spikes in NiV (or a related henipavirus) seroprevalence coinciding with pregnancy periods were observed in *Eidolon dupreanum* in Madagascar (49, 50), but not in *Pteropus vampyrus* or *Pteropus hypomelanus* in Peninsular Malaysia (25). Hendra virus prevalence in Australian pteropid bats has shown multiyear interepizootic periods, during which little virus can be detected, followed by periods of markedly increased viral shedding (51–53). It has been hypothesized that multiyear periodicity in the incidence of henipavirus infections could arise from a buildup and waning of herd immunity in the reservoir host, with reintroduction of virus via immigration, recrudescence, or viral persistence (11, 54–56).

There is a paucity of data related to henipavirus-associated immune dynamics in free-ranging pteropid bats, including the duration of immunity in adults and juveniles, which limits our understanding of population-level viral dynamics. Experimental infections of *Pteropus* bats with Hendra virus and NiV show that bats mount an antibody response following infection with Hendra virus and NiV (57–59). Waning of anti-NiV antibodies was observed in recaptured wild *Eidolon helvum*, a bat related to *Pteropus* spp., in Madagascar (60). Passive transfer and waning of maternal antibodies also occurred in captive *Pteropus* species, and, along with loss of immunity in adults, could contribute to the loss of herd immunity in wild populations (61). Some pteropid bat species are migratory, and interconnected colonies form

a metapopulation, which could allow for viral reintroductions into susceptible colonies (10, 25, 62, 63). In addition, NiV recrudescence has been observed in wild-caught *P. vampyrus* and possibly also in *E. helvum* (64–66). Either of these phenomena could allow NiV to persist regionally during periods of high local immunity. However, no study has yet shown evidence in open, free-ranging bat populations that examines the influence of these factors on NiV transmission dynamics.

Here, we examine the distribution, dynamics, genetic diversity, and underlying drivers of NiV infection in *P. medius* in Bangladesh to improve our understanding of human outbreak patterns. Specifically, we analyze the spatial, temporal, and demographic variation in serological dynamics and viral shedding in bats over a 6-y period to determine the spatiotemporal drivers and dynamics of virus transmission. We also analyze the movement patterns of individual bats and analyze NiV phylogenetics to understand patterns of spatial mixing and virus strain diversity.

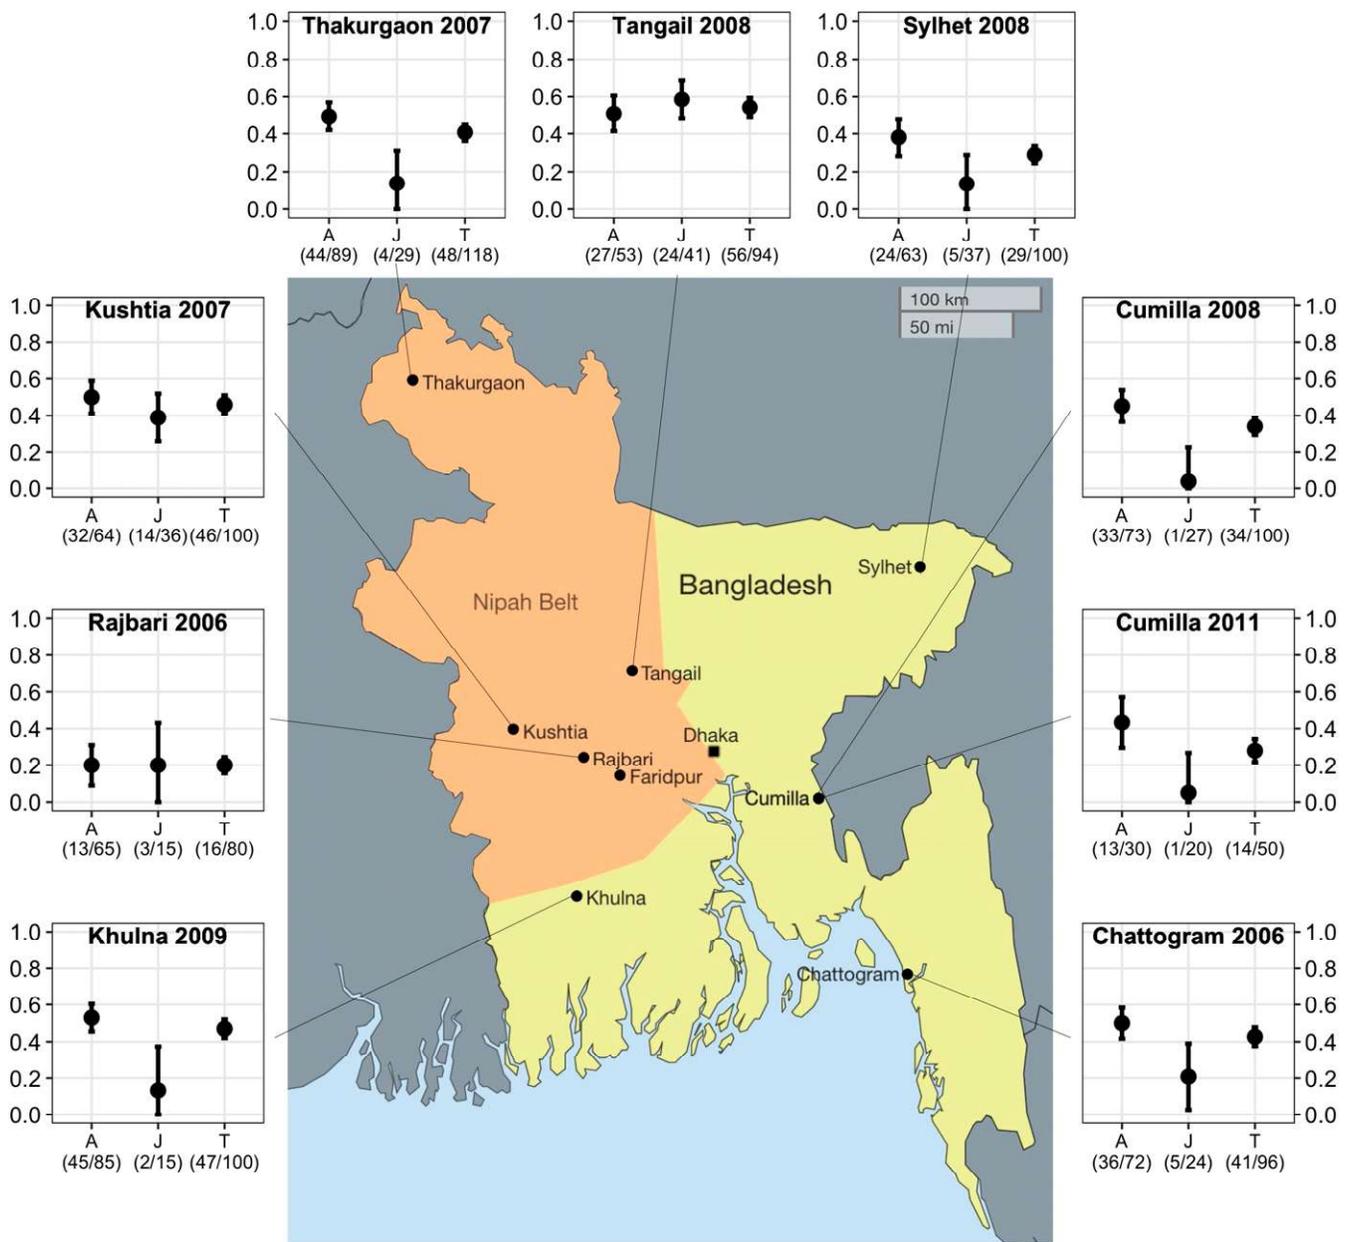

## Results

### Comparative Nipah Seroprevalence and Virus Infection Study in Bats Inside and Outside the Nipah Belt and Concurrent Longitudinal Bat Study Inside the Nipah Belt.

In a cross-sectional spatial study conducted between January 2006 and July 2012, we caught and tested 883 *P. medius* (~100 per district) from eight colonies in different districts across Bangladesh. We detected anti-Nipah immunoglobulin G (IgG) antibodies in all colonies (Fig. 1). Seroprevalence varied by location ( $\chi^2 = 55.61$ ,  $P < 0.001$ ). In most locations, adult seroprevalence exceeded juvenile seroprevalence; in Tangail and Rajbari, seroprevalence was similar across ages. Viral detection in individuals was rare; overall, we detected NiV RNA in 11 of 2,088 individuals and in three pooled oropharyngeal samples (representing five bats, but which could not be resolved to an individual) (Table 1). We detected viral RNA in individual bats in Faridpur and Rajbari and from pooled samples from Thakurgaon and roost urine samples from Cumilla. Of the 11 PCR-positive individuals, three had IgG antibodies (SI Appendix, Table S1). We also detected virus in pooled urine collected from tarps placed below bats at roosts associated with human outbreaks in Bhanga and Joypurhat. The viral prevalence in Rajbari in January 2006 was 3.8% (95% CI: 0 to 11%;  $n = 78$ ). In Faridpur, which is adjacent to Rajbari and where we conducted an intensive longitudinal study (see below), viral prevalence estimates ranged from 0 to 3% (95% CI: 0 to 10%;  $n = 100$  at each of 18 sampling times) (Table 1). NiV RNA was detected in bats from inside (Rajbari, Thakurgaon, and Faridpur) and outside (Cumilla) the Nipah Belt. There was no significant difference between NiV detection rates from individual bats by the two main sample types: urine/urogenital swabs, 0.37% ( $n = 2,126$ ) and oropharyngeal swabs, 0.15% ( $n = 1973$ ) ( $\chi^2 = 1.92$ ,  $P = 0.17$ ). The estimated detection rate from pooled urine samples, collected from tarps placed underneath roosts) across the entire study was 2.5% ( $n = 829$ ), which was significantly higher than either sample type collected from individual bats ( $\chi^2 = 55.6$ ,  $P < 0.001$ ).

**Factors Associated with NiV IgG Serostatus in *P. medius*.** There was no statistical difference between seroprevalence in bats inside the Nipah Belt and outside (95% odds ratio [OR] 1.2, highest posterior density interval [HDPI] 0.47 to 3.1). Adults had higher seropositivity than juveniles (OR 2.4, 1.7 to 3.6 HDPI), and males greater than females (OR 1.6, 1.0 to 2.4 HDPI) (Fig. 2). There was weak evidence that seroprevalence was higher in pup-carrying (OR 4.0, HDPI 0.6 to 34) and pregnant (1.5 times, HDPI 0.85 to 2.8) individuals than other females. Neither mass, forearm length, nor the mass:forearm ratio (a proxy for age) consistently correlated with seropositivity. However, bats with poor body condition (an assessment of pectoral muscle mass by palpation) were less likely to be seropositive (poor/fair body

**Fig. 1.** Map showing age-stratified seroprevalence in *P. medius* colonies, Bangladesh. Bats from eight colonies were sampled and tested for anti-NiV IgG antibodies: four within the “Nipah belt” (orange shaded) and four outside. Seroprevalence of adults (A), juveniles (J), and total seroprevalence (T) are shown with 95% CI error bars. The shaded region represents the “Nipah belt,” where previous human NiV outbreaks have been reported.

condition OR = 0.69, HDPI 0.49 to 0.96). Finally, serostatus was strongly correlated in mother–pup pairs; 39 of 41 pups with seropositive mothers were seropositive, and 32 of 39 pups with seronegative mothers were seronegative.

**Longitudinal NiV Serodynamics in *P. medius*, Faridpur District (2006 to 2012).** We sampled bats quarterly from a single population in the Faridpur district. We also microchipped a total of 2,345 bats between 2007 and 2012. We used generalized additive models (GAMs) to characterize changes in NiV seroprevalence over time. There were significant fluctuations in adult (>24 mo) and juvenile (6 to 24 mo) seroprevalence over the 6-y study period (Fig. 3A). Juvenile seroprevalence ranged from 0 to 44% (95% CI: 37 to 51%), and decreased over the first year of life for bats born in each year (“yearlings”), consistent with loss of maternal

antibodies in juveniles. A more pronounced decrease occurred from mid-October to mid-December than other parts of the year. However, the GAM indicating this had only slightly better fit ( $\Delta AIC$  [ $\Delta$ Akaike information criterion] < 1) than one with a  $q:17$  linear decrease over the whole year (Fig. 3B).

Adult seroprevalence ranged from 31% (95% CI: 20 to 46%) to 82% (95% CI: 77 to 87%) with three cycles of clear variability over the course of the study (Fig. 3A). We found no evidence of regular seasonal fluctuations; a GAM with annual cyclic terms fit worse than one without ( $\Delta AIC > 10$ ). Viral RNA was detected during periods of increasing, decreasing, and stable seroprevalence.

We fitted a series of age-stratified compartmental susceptible–infected–recovered models to examine different biological processes influencing serodynamics, including density-

411 Unk., unknown.

412 \*NiV RNA was detected in three pooled oropharyngeal samples, confirmed by sequencing, although confirmation from individual samples could not be made. These data are not used in prevalence estimates.

413 <sup>†</sup>Detection by qPCR, Ct ranges 20 to 38.

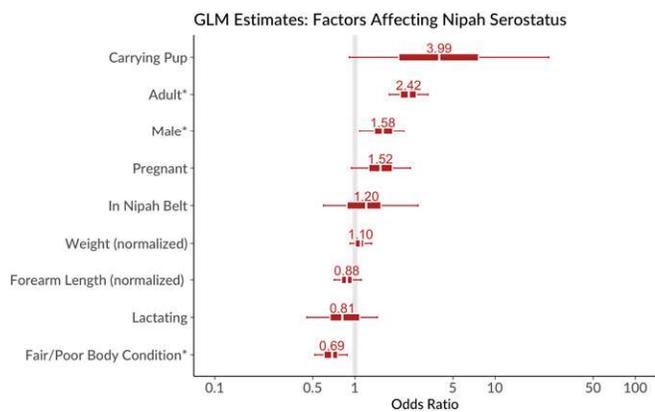

414 vs. frequency-dependent transmission, recrudescence vs. immi-  
 415 gration of infected individuals, and seroreversion (loss of anti-  
 416 bodies) in both juveniles and adults (*Methods* and Fig. 4).  
 417 Density-dependent models were a far better fit to the data than  
 418 frequency-dependent models (difference in log-likelihood 10.0;  
 419  $\Delta AIC = 20.0$ ), suggesting that movements of bats and fluctua-  
 420 tions in colony size alter spatiotemporal variation in the risk of  
 421 NiV infection in bats. In Faridpur (“Domrakhandi/Khaderdi” in  
 422 *SI Appendix, Fig. S1*) during the period of sampling, the roost  
 423 population declined from ~300 bats to 185, which decreased  
 424 transmission potential in the fitted model:  $R_0$  in adult bats was  
 425 estimated to decrease from 3.5 to 2.1 as the number of bats in the  
 426 colony decreased. As a result, over the 6-y study period, the  
 427 fitted model predicted that the threshold for herd immunity  
 428 (i.e., the seroprevalence below which the reproductive ratio  $R_t >$   
 429 1) for adults fell from 72% (when bat counts were highest—in  
 430 2006) to 52% (when bat counts were lowest).

431 The fitted model suggests that serodynamics in juveniles were  
 432 strongly driven by inheritance and loss of maternal antibodies.  
 433 The estimated duration of maternal antibodies was 17.6 wk (95%

434 CI: 13.7 to 25.0), which was much quicker than the loss of anti-  
 435 bodies in adults (290.8 wk, 95% CI: 245.0 to 476.4) (*SI Ap-  
 436 pendix, Table S2*). Finally, models with recrudescence fit the data  
 437 better than models without recrudescence (*SI Appendix, Table  
 438 S2*; difference in log-likelihood 32.6;  $\Delta AIC = 65.1$ ), and models  
 439 with recrudescence fit the data better than models with immi-  
 440 gration ( $\Delta AIC = 3.76$ ).

441 **Mark-Recapture and Seroconversion/Seroreversion.** There were 56  
 442 recapture events over the study period (*SI Appendix, Table S3*).  
 443 Thirty-one bats were recaptured at a nearby roost other than the  
 444 original capture location. This network of roosts, or “roost  
 445 complex,” formed a polygon covering ~80 km<sup>2</sup> and included 15  
 446 roosts sampled during the longitudinal study (*SI Appendix, Fig.  
 447 S2 A and B*). Ten instances of seroconversion (change from IgG-  
 448 negative to IgG-positive) and nine instances of seroreversion  
 449 (positive to negative) were observed (*SI Appendix, Table S3*).  
 450 The mean time between positive and negative tests in adults  
 451 (excluding juveniles with maternal antibodies) was 588 d ( $n = 6$ )  
 452 (range: 124 to 1,082 d).

Q:39 **Fig. 2.** Results of Bayesian generalized linear model of factors affecting Nipah serostatus in bats in cross-sectional study. Bars indicate ORs and 50% (inner) and 95% (outer) credible intervals for model parameters. Factors with asterisks (\*) have 95% CIs that do not overlap one. Model intercept (predicted probability of seropositivity for a juvenile, female bat outside the Nipah belt of mean size and good body condition) was 0.26 (95% CI 0.12 to 0.56).

**Home Range and Intercolony Connectivity Analysis.** Home-range analysis of satellite telemetry data from 14 bats (mean duration of collar data transmission = 6.25 mo; range = 1 to 25 mo; *SI Appendix, Table S4*) showed that the majority of bats roosted within 10 km of where the bats were originally collared, in the Faridpur (Nipah belt) colony, and within 7 km from where the bats in the Cox's Bazaar colony were originally collared (315 km east of Faridpur). The average foraging radius was 18.7 km (SD 21.5 km) for the Faridpur bats and 10.8 km (SD 11.9 km) for the Cox's Bazaar bats (*SI Appendix, Fig. S2*). Home range analysis suggests that bats in Faridpur and Cox's Bazaar (separated by approx. 310 km) would have a <5% probability of intermingling (Fig. 5). Home-range size was larger during the wet season than the dry season (2,746 km<sup>2</sup> vs. 618 km<sup>2</sup>) (*SI Appendix, Figs. S3 and S4*).

**NiV Phylogenetic Analysis.** Phylogenetic analysis of NiV sequences from a 224-nt section of the N gene (nt position 12,90 to 1,509 [position ref gb|FJ513078.1| India]) suggests that strains from both India and Malaysia clades are present in bats in Bangladesh (Fig. 6). This finding was supported by an additional analysis of near-whole N gene sequences (~1,720 nt) from bats, pigs, and humans, including those from a subset of *P. medius* from this and a more recent study by our group (*SI Appendix, Fig. S5*) (67). Eleven 224-nt N gene sequences obtained from bats between 2006 and 2012 (all from the Faridpur population) were identical. Overall, the N gene sequences identified from the Faridpur, Rajbari and Bhanga colonies between 2006 and 2011 had 98.21 to 100% shared nucleotide identity. Sequences from Rajbari district obtained 5 y apart (January 2006 and January 2011) had only a single nucleotide difference, resulting in a synonymous substitution (G to A) at position 1,304, which was found in four other bat NiV sequences from this study, as well as in the NiV isolate from *P. vampyrus* in Malaysia. Five human NiV N gene sequences from various locations within the Nipah belt over the same time period as our bat study show more nucleotide diversity than those from the Faridpur *P. medius* population. Human sequences throughout Bangladesh and from Kerala, India, all nested within the diversity found in *P. medius* (Fig. 6). By contrast, the sequences found in *P. medius* from Cumilla, a location 150 km to the east of Faridpur, showed 80.8 to 82.59% shared nucleotide identity with sequences from *P. medius* in Faridpur and clustered within the Malaysia group of NiV sequences. The two Cumilla sequences were identical to each other and had up

to 87.95% shared nucleotide identity to sequences from *P. lylei* in Thailand.

## Discussion

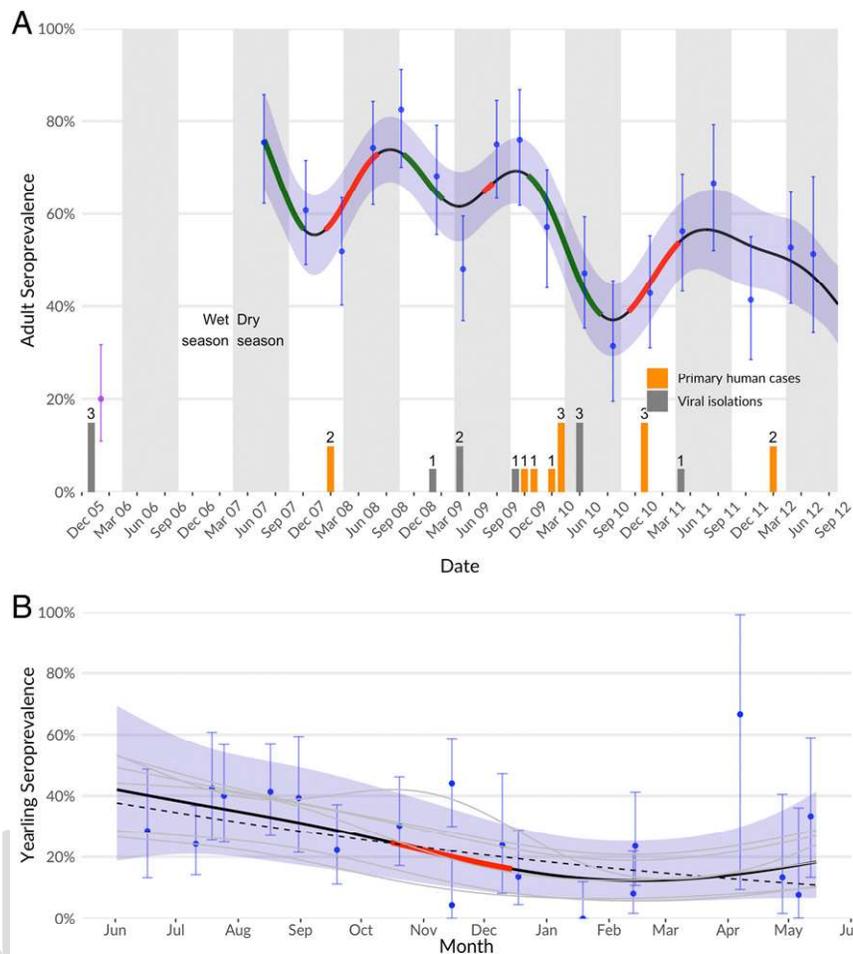

Our findings suggest that NiV circulation occurs in bat populations throughout the country. We observed that virus can be shed by bats at any time of year and that viral dynamics are cyclical, but not annual or seasonal. Our models fit to serological data suggest that these cycles may be driven by demographic and immunological factors; the waning of herd immunity through turnover or individual waning in bat populations allows heightened viral transmission when seroprevalence passes below a critical threshold. Previous studies from Bangladesh suggested that human NiV outbreaks occur primarily within a defined region in western Bangladesh, termed the “Nipah belt,” during a defined season (November through April) (41, 68). These ob-

servations raised the question of whether the timing and location of human infections are due solely to differences in the frequency and intensity of date-palm-sap consumption, or whether ecological factors such as the distribution and timing of bat viral infection also play a role (19, 38, 69). Our extensive survey of *P. medius*, which is common across Bangladesh and throughout the Indian subcontinent, demonstrates that viral circulation within their populations is not limited to the Nipah belt (16, 27, 30). A number of mechanisms have been proposed for the maintenance of acute viral infections in bat populations, which are often formed of interconnected colonies, including synchronous birthing and subsequent loss of maternal antibodies (11, 43, 45); lowered immunity within pregnant females due to stress; nutritional stress and other factors (47); immigration of infected individuals from other colonies (62, 70, 71); and recrudescence within previously infected individuals (11, 64, 72). However, little is known about how henipaviruses are transmitted among wild bats. *Pteropus* species are typically gregarious and their roosts, often comprising multiple hardwood trees, and are highly socially structured, with individuals segregated by age, sex, and social dominance (69, 73, 74). Interactions among individuals are often dependent on their grouping, and the intensity of social interactions varies with specific behaviors such as mother-pup interactions, play (juveniles), territorial fighting (adult males), and mating (adults) (74). Our data and previous experiments show that henipaviruses can be shed orally, urogenitally, in feces, and in birthing fluids (59, 75). This suggests that multiple mechanisms for transmission are possible, including mutual grooming, fighting, mating, exposure to excreta or birthing fluids, and ingestion of food contaminated by saliva. Roost size also increases seasonally during mating and birthing periods, which the fitted models suggest would increase transmission, if seroprevalence is below the herd-immunity threshold (30, 73). While *P. medius* does not roost with other bat species, it does feed with other frugivorous bats, and it's possible that interspecies viral transmission occurs during feeding (76, 77). In Madagascar, henipavirus antibodies have been detected in multiple species of frugivorous bats, though it is unknown whether the same virus or antigenically related viruses was shared among them (60). While serological evidence suggests that it is possible henipaviruses circulate in other frugivorous bat species, our findings, as well as those of others (16, 59), suggest that in Bangladesh, *P. medius* is the main natural reservoir for NiV. Henipaviruses other than Nipah may be circulating in *P. medius* (28). We assumed that the anti-IgG antibodies detected by the serological assays used in this study were specific to NiV, but it is possible that the enzyme-linked immunosorbent assay (ELISA) used in the cross-sectional study may have detected antibodies against unknown henipaviruses, which could elevate NiV seroprevalence estimates. An advantage of the Luminex assay used in the longitudinal study is that we could compare median fluorescent intensity (MFI) values to multiple specific henipaviruses (Nipah, Hendra, and

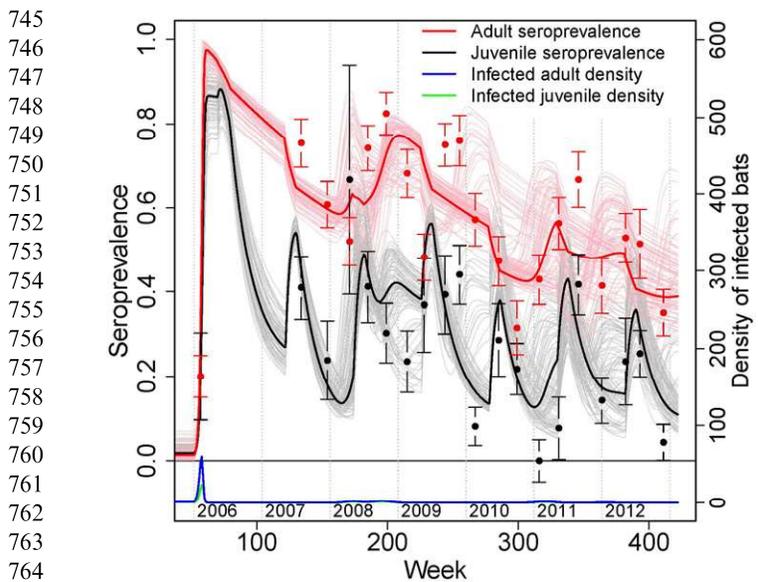

**Fig. 3.** Serodynamics of the Faridpur bat population, measured and fit to a GAM. (A) Adult seroprevalence over time, with measured values and 95% CI in blue and mean GAM prediction and 95% shown with line and surrounding shaded areas. Point from February 2006 (purple) is shown separately due to ELISA vs. Luminex measure. Periods of significant change (where GAM derivative 95% does not overlap zero) are shown in red (increasing) and green (decreasing). Periods of increase indicate viral-circulation events in the adult population; these do not occur with consistent periodicity or seasonality. Counts of primary human cases from local district (dark gray) and bat viral detections (orange; Table 1) are shown on bottom for comparison. (B) Juvenile seroprevalence during the first year of life (“yearlings”). All years’ measurements are collapsed onto the scale of a single year overlain to show yearling dynamics. Measured values and 95% CIs are shown in blue, and mean and 95% CIs for the GAM model pooled across cohorts are shown with line and surrounded shaded areas. GAM realizations for individual years are in gray and overall effect in black. The period of significant decline in the GAM is shown in red. Juvenile seroprevalence decreases over the course of the year and is not distinguishable from a simple linear decrease ( $\Delta AIC < 1$ , dotted line).

Cedar) and differentiate between specific reactions to NiV and reactions to the other viruses, which could indicate antibodies against an unknown henipavirus. Hendra and Cedar viruses are enzootic in Australian *Pteropus* spp. and are not known to occur in Bangladesh, so we considered reactions to these viruses NiV-negative results.

Our modeling indicates that NiV is primarily driven by immunity and density-dependent transmission dynamics among bats, with cycles of higher seroprevalence dampening intracolony transmission followed by waning of antibody titers within individuals and death of seropositive individuals. Waning humoral immunity against NiV has been consistently shown in henipavirus studies of African pteropodid bats (56, 60). Our recapture data provided reported evidence of the loss of detectable NiV IgG antibodies in individual free-ranging bats, which supports the fitted model suggesting limited duration individual immunity and the importance of population-level waning immunity. The consistently decreasing seroprevalence that we observed in juveniles suggests that they lose maternal antibodies over their first year (the fitted model estimates after 3 to 5 mo), consistent with other studies of maternal antibodies against henipaviruses

in pteropodid bats (47, 56, 61, 65). Our analysis do not support the hypothesis (45) that seasonal pulses of these new seronegative individuals are sufficient to drive new outbreaks because high seroprevalence in adults limited transmission in several years (Fig. 4).

NiV reintroduction into a colony may occur from a persistently infected individual (e.g., via recrudescence) or immigration of an infected individual. Our analyses suggested that recrudescence was a more important driver of transmission dynamics than immigration. Recrudescence of henipavirus infection has been observed for NiV in captive *P. vampyrus* (64), for henipavirus in captive *E. helvum* (56, 66), and humans infected by NiV (78) and Hendra virus (79). It is difficult to know from serology alone whether wild-caught seronegative bats had been previously infected. Experimental infections comparing naive to previously infected *P. medius* that have sero-reverted would provide a better understanding of how humoral immunity influences individual susceptibility to infection and inform dynamics models attempting to explain viral maintenance within bat populations (60).

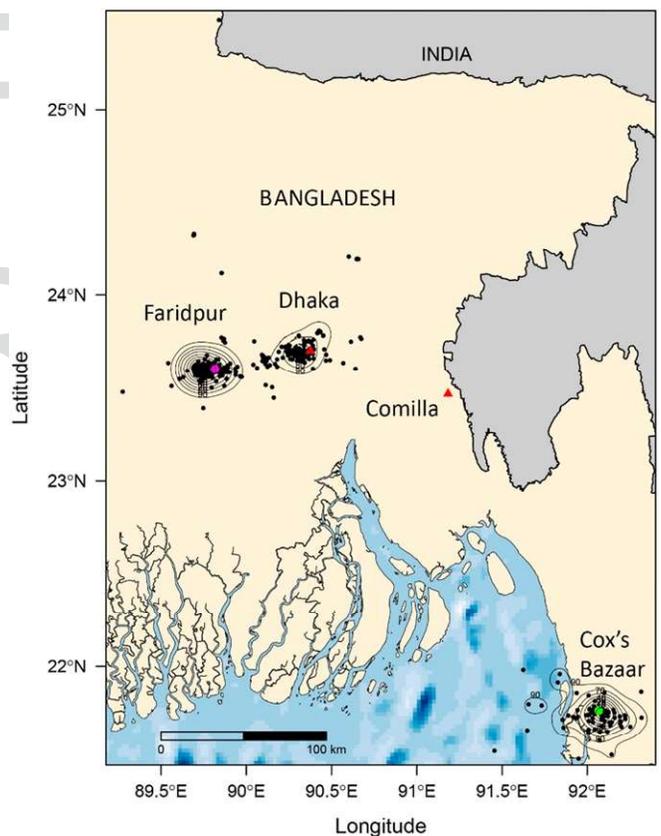

**Fig. 4.** Longitudinal data and fitted model for NiV serological dynamics in adult and juvenile bats. Red and black points show observed data ( $\pm 1$  SE), and solid lines show the fitted model (thick lines show the trajectory for the model with maximum-likelihood parameter estimates; thin lines show realizations for parameter estimates drawn from the estimated distributions) for the fraction of adults and juveniles seropositive for NiV (left axis), and the model-estimated number of infected adult and juvenile bats (bottom and right axes). See *Methods* for details of model structure.

Our longitudinal study was limited to a single population of interacting subcolonies and bat populations across Bangladesh likely represent a dynamic metapopulation. Our roost count data and recapture data from microchipped bats showed how roost sizes can fluctuate and that bats shift among local roosts. The fitted model strongly suggested that decreases in local roost counts substantially reduced local transmission potential of NiV. However, a larger study across multiple regional populations would be needed to understand how local shifts in bat colonies impact broader fluctuations in regional populations and spatial patterns of NiV transmission.

Understanding how bat populations connect across landscapes is important for understanding viral maintenance, and studying local and migratory bat movements can provide important ecological information related to viral transmission, including how bats move between different colonies (62, 80). Our satellite telemetry data suggest that *P. medius* exists as a metapopulation, like other pteropid species (11, 71). The numbers of individuals we collared represents a small sample size; however, they are comparable to other bat satellite telemetry studies of related species, and our data suggest that bat dispersal in Bangladesh may currently be more localized than other species elsewhere. *P. medius* appear to travel shorter distances and remain within a smaller home range (321.46 and 2,865.27 km<sup>2</sup> for two groups) than *P. vampyrus* in Malaysia (64,000 and 128,000 km<sup>2</sup>) and *Acerodon jubatus* in the Philippines, both of which are similarly sized fruit bats (62, 81). Pteropid bat migration is primarily driven by seasonal food-resource availability (63, 82–84). In Bangladesh, *P. medius* prefer to roost in human-dominated environments in highly fragmented forests, as opposed to less-populated, intact forested areas, such as in national parks (85). The conversion of land to villages and farmland over recent human history has likely led to increased food availability for *P. medius* and may have reduced the impetus for long-distance migration (37). This may reflect a similar adaptation to anthropogenic food resources, as observed over the last few decades in

Australian *Pteropus* species (71). Home ranges were significantly smaller during the dry season, which corresponds to winter months and the time when most female bats are pregnant, likely resulting in them flying shorter distances to conserve energy. Genetic analysis of *P. medius* across Bangladesh has shown that, historically, there has been extensive gene flow and intermixing among populations, and we did observe a few instances of longer-distance flights; however, the movement data indicated that, overall, these bats had much smaller home ranges (80). Less connectivity among bat populations across Bangladesh may influence NiV transmission by creating longer interepizootic periods and larger amplitude fluctuations in population-level immunity in *P. medius* compared to more migratory species (71). Bat movement and population connectivity may also influence the genetic diversity of NiV found in different locations.

The potential existence of a more transmissible or pathogenic strain of NiV already circulating in bats further underscores the need to strengthen efforts to prevent spillover. While the overall strain diversity among NiV has not been well characterized due to a dearth of isolates, two distinct NiV clades have been described: a Bangladesh clade, that includes sequences identified in India and Bangladesh; and a Malaysian clade, that comprises sequences from Malaysia, Cambodia, The Philippines, and Thailand (18, 67, 86). Our findings of substantially different NiV sequences in Faridpur and Cumilla suggest that viruses from both clades are circulating in Bangladesh. Strains of NiV from these two clades are associated with differences in pathogenesis, epidemiological and clinical profiles in humans and animal

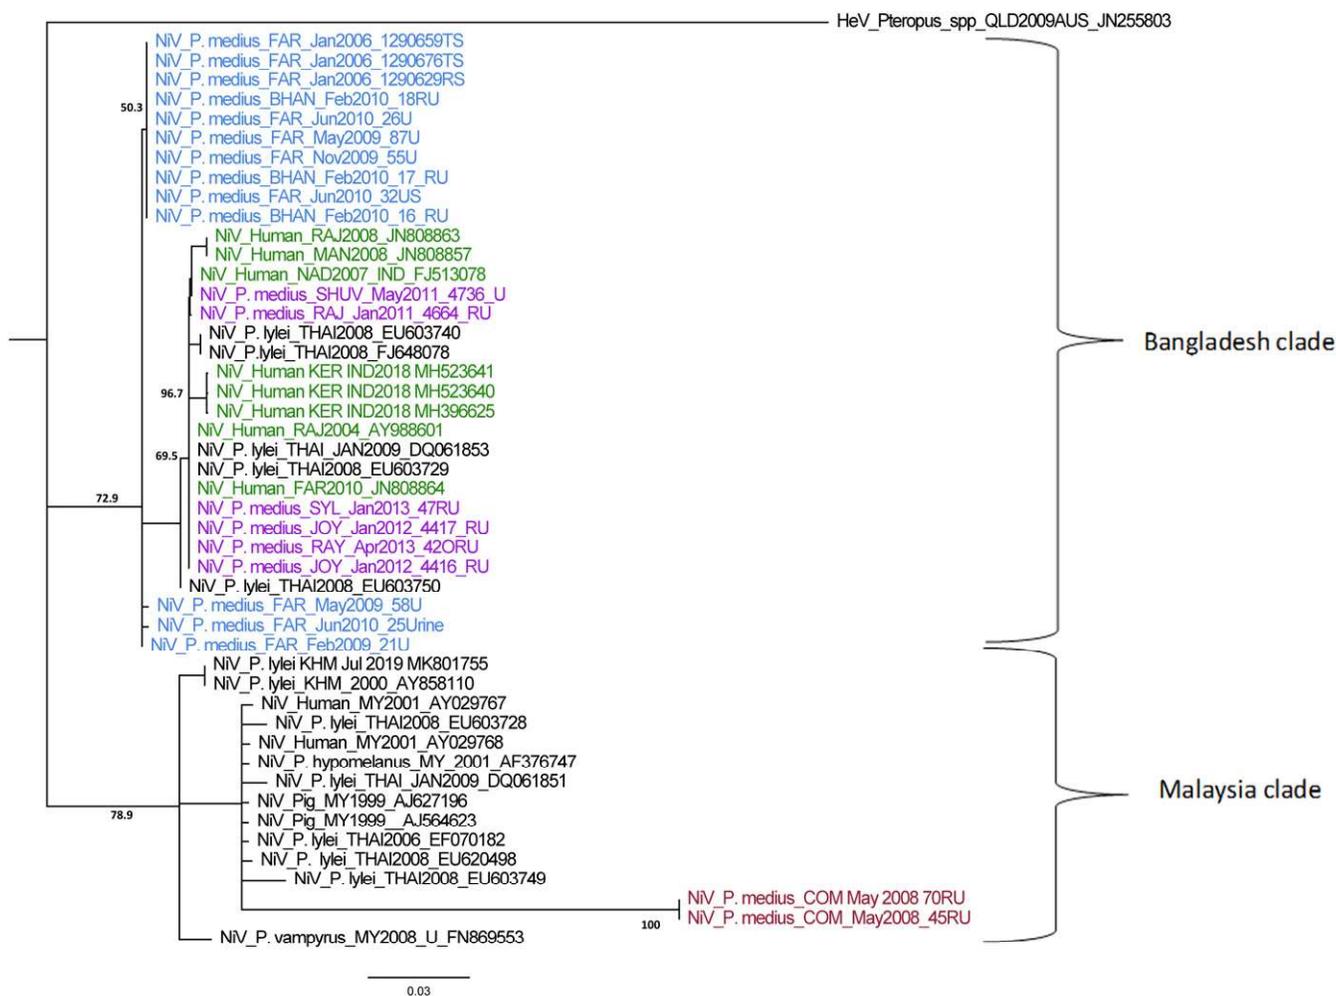

**Fig. 5.** Satellite telemetry and home-range analysis. Location data from satellite collars ( $n = 14$ ) placed on 11 bats from Faridpur and 3 bats from Cox's Bazaar, Chattogram, collected between 2009 and 2011 were used to calculate local and long-range movement patterns and home range for these two groups.

**Fig. 6.** NiV partial N-gene phylogeny (224 nt). Phylogenetic neighbor-joining tree created in Geneious Prime 2019 using a Tamura-Nei model with 1,000 bootstrap replicates and Hendra virus as an outgroup (117) is shown. Branch lengths are shown as the number of substitutions per site. Sample collection date, location, and GenBank accession numbers are included in the label for each sequence, except *P. medius* sequences we collected (GenBank accession nos. MK995284–MK995302). Blue labels indicate bat sequences from Faridpur and Bhanga (an outbreak response in Faridpur). Purple sequences are from *P. medius* from other roosts sampled during the longitudinal study. Red sequences are from *P. medius* in Cumilla. Green sequences are human NiV sequences from Bangladesh and India.

models, and observed shedding patterns in bats (49, 87–91). Phenotypic variation in NiV could influence human outbreak patterns by altering transmission to, or pathogenesis in, humans and the likelihood of smaller outbreaks being identified or reported (92). Human-to-human NiV transmission via contact with respiratory and other secretions has been regularly observed in Bangladesh and India, including the recent 2018 outbreak in Kerala (14, 68, 93), whereas transmission among people was not a common feature of the Malaysia outbreak, despite close contact between cases and health care providers (94, 95). NiV cases in Bangladesh have shown more strain diversity than in the Malaysia outbreak, which could be due to greater virus diversity in *P. medius* (96).

Until now, there have been very few Nipah sequences obtained from *P. medius*. We found that Nipah N-gene sequences from bats from the Faridpur population were nearly identical over time, compared to variation in N-gene sequences from bats and humans from other locations observed over the same time period (2006 to 2010). This suggests that there may be locally prevalent and stable NiV genotypes that persist within bat colonies. Human NiV genotype diversity is likely a reflection of the diversity of the NiV strains in the local bats that seed

outbreaks (10). This is also supported by viral sequences obtained from humans and bats associated with the 2018 NiV outbreak in Kerala, India, where human NiV sequences were most closely related to local *P. medius* sequences (97).

Connectivity of pteropid bats in Bangladesh with those in Southeast Asia could explain the observed strain diversity in our study. Historical interbreeding of *P. medius* with pteropid species found in Myanmar, Thailand, and Malaysia and our telemetry findings showing bats are capable of flying hundreds of kilometers could explain the presence of a Malaysia clade NiV sequence in bats from Cumilla (80). NiV Bangladesh strains have also been found in *P. lylei* in Thailand (98). The N gene of the Cumilla NiV strain differs from those reported from bats in the Nipah belt by 20%, whereas NiV Malaysia and NiV Bangladesh differ by only 6 to 9% and are associated with different clinical profiles. Whole-genome sequence would have allowed for better characterization of the Cumilla strain; however, this was not obtained. Despite the short sequences used in our analysis, the N gene is generally conserved relative to other genes and is representative of the diversity across henipavirus genomes (86). We would expect the rest of the Cumilla viral genome to also be highly divergent, potentially even qualifying it as a different

henipavirus species. It is, therefore, plausible that the clinical profile of a 20% divergent Nipah-related virus differs significantly from known strains. Sequence information from an isolated human NiV case in Cumilla has not been reported, so comparison to the sequence we found in bats was not possible (41). Studies linking viral genotype to clinical outcomes in people would provide additional insight into the effect of strain diversity in bats on the potential for larger-scale human outbreaks.

Our study sheds light on the sporadic nature of human NiV outbreaks, with multiyear interepizootic periods in South Asia. PCR results show that overall NiV incidence in *P. medius* is low, consistent with previous studies of Hendra virus and NiV (25, 47, 52). The fitted model suggests that transmission increases when bat populations have become susceptible through waning immunity (11). In the current study, observed seroprevalence patterns and the fitted model suggest that three periods of transmission occurred over the 6 y of sampling, each of which followed periods of low adult and juvenile seroprevalence. Viral detection in bats has coincided with some human outbreaks, supporting the hypothesis that spillover is a sporadic event (67, 97). In our study periods, low seroprevalence in bats was not always followed by outbreaks in humans. We detected NiV RNA during periods of both increasing and high seroprevalence, consistent with recrudescence, which was strongly supported by the fitted model and has been demonstrated in captive animals (64–66). This likely contributes to the sporadic variation in human outbreaks (e.g., spillover events) from year to year in Bangladesh.

Overall, our results suggest that NiV outbreaks in humans stem from an interaction of four factors: 1) multiyear fluctuations in transmission intensity among bats driven by immunity and colony size/density-dependent transmission; 2) relatively localized bat movements creating spatially variable transmission dynamics; 3) occasional shedding by previously infected bats due to recrudescence; and 4) highly seasonal contact between bats and humans via consumption of raw date-palm sap. The timing of multiple factors involved in driving transmission dynamics needs to align for intracolony NiV transmission events and further align with human behavior and availability of a route of spillover for human outbreaks to occur, as previously hypothesized (99). We further conclude that NiV dynamics in bats combined with the seasonality and specific geography of date-palm-sap consumption in Bangladesh likely explains the sporadic nature of human outbreaks in the region (38).

These findings suggest that human NiV outbreaks in other regions of Bangladesh (and Asia) where *Pteropus* bats occur are also likely to be sporadic and rare, leading to underreporting or a lack of reporting. This is probably exacerbated by the fact that the clinical syndrome is similar to that of other common infections, such as Japanese encephalitis, malaria, and measles (100). Understanding whether some NiV strains are capable of causing mild or asymptomatic cases will provide important insights about why outbreaks have not been detected in areas such as eastern Bangladesh or other parts of Asia, where host, virus, and potential routes of spillover exist. One reason is that mild or asymptomatic cases would be unlikely to be detected by current surveillance systems. About half of all Nipah outbreaks in Bangladesh between 2007 and 2014 were unreported, suggesting that many cryptic spillover events have occurred (101). The 2018 and 2019 spillover events in Kerala, India, which were linked to local *P. medius* colonies and which occurred in an area that does not cultivate date-palm sap, further emphasize the point, but raise questions about the mechanism of spillover.

In the last two decades, the world has experienced large epidemics of bat-associated viruses, including Ebola in West Africa and Democratic Republic of the Congo, SARS coronavirus, and SARS-CoV-2. The World Health Organization has listed NiV and other henipaviruses as priority pathogens for vaccine and

therapeutic research and development, along with Ebola viruses and coronaviruses. Surveillance for henipaviruses and antibodies in bats and people where they are in close contact will help determine spillover risk; characterize henipavirus genetic diversity; and understand the genetic determinants of NiV transmissibility and pathogenicity among humans. These measures may help target interventions that reduce spillover, substantially improving our ability to reduce the risk of a more transmissible strain of NiV emerging and causing a large-scale epidemic with significant human and animal mortality.

**Methods**

The study period was between January 2006 and November 2012. The study was conducted under Tufts University Institutional Animal Care and Use Committee protocol G929-07 and International Centre for Diarrheal Diseases Research, Bangladesh (ICDDR,B) Animal Experimentation Ethical Committee Protocol 2006-012 with permission from the Forest Department, Government of Bangladesh. Locations were selected based on whether the district had any previously recorded human NiV encephalitis clusters at the time of this study and was therefore inside the Nipah Belt (e.g., Rajbari, Tangail, Thakurgaon, and Kushtia) or whether they had not and were outside the Nipah Belt (e.g., Cumilla, Khulna, Sylhet, and Chattogram). The Thakurgaon study was conducted as part of an NiV outbreak investigation and coincided with ongoing human transmission (102). Between 2006 and 2012, three different studies of *P. medius* with similar bat-sampling protocols were performed: 1) a cross-sectional spatial study with a single sampling event in each of the eight locations listed above; 2) a longitudinal study of a Faripur bat colony with repeated sampling approximately every 3 mo from July 2007 to November 2012; and 3) a longitudinal study of the Rajbari colony with repeated sampling at a monthly interval between 12 mo period between April 2010 and May 2011. Opportunistic sampling of *P. medius* was also performed during this time period during NiV outbreak investigations (Bangha, Faridpur [February 2010], Joypurhat [January 2012], Rajbari [December 2009], and West Algi, Faridpur [January 2010]). Bats were captured using mist nets at locations within eight different districts across Bangladesh between January 2006 and December 2012 (Fig. 1).

**Capture and Sample Collection.** For the country-wide cross-sectional and Faridpur longitudinal study, ~100 bats were sampled at each sampling event, which lasted 7 to 10 d. This sample size allowed us to detect at least one exposed bat (IgG antibody-positive) given a seroprevalence of 10% with 95% confidence. Bats were captured using a custom-made mist net of ~10 m × 15 m suspended between bamboo poles, which were mounted atop trees close to the target bat roost. Catching occurred between 11 PM and 5 AM as bats returned from foraging. To minimize bat stress and chance of injury, nets were continuously monitored, and each bat was extracted from the net immediately after entanglement. Personal protective equipment was worn during capture and sampling, which included dedicated long-sleeve outerwear or Tyvek suits, P100 respirators (3M), safety glasses, nitrile gloves, and leather welding gloves for bat restraint. Bats were placed into cotton pillowcases and held for a maximum of 6 h before being released at the site of capture. Bats were sampled at the site of capture using a field laboratory setup. Bats were anesthetized by using isoflurane gas (103), and blood, urine, oropharyngeal swabs, and wing-membrane biopsies (for genetic studies) were collected. For some sampling periods, rectal swabs were collected, but due to resource constraints, these samples were deemed to likely be lower-yield than saliva and urine for NiV and were discontinued during the study. For each bat sampled, we recorded age, weight, sex, physiologic and reproductive status, and morphometric measurements, as described (27). Bats were classified as either juveniles (approximately 4 to 6 mo—the age by which most pups are weaned) to 2 y old (the age when most *Pteropus* species reach sexual maturity) or adults (sexually mature) based on body size and the presence of secondary sexual characteristics, pregnancy, or lactation—indicating reproductive maturity (27, 104).

Up to 3.0 mL of blood was collected from the brachial vein and placed into serum tubes with serum clot activator (Vacutainer). Blood tubes were stored vertically on ice packs in a cold box, and serum was allowed to separate overnight. Serum was drawn from the tube after 24 h, placed in a screw-top cryovial (Corning), and stored in a liquid nitrogen dewar (Princeton Cryogenics). Sterile pediatric swabs with polyester tips and aluminum shafts were used to collect urogenital and rectal samples, and larger polyester swabs with plastic shafts (Fisher) were used to collect oropharyngeal samples. All swabs were collected in duplicate, with one set being placed individually in cryotubes containing lysis buffer (either trireagent or NucliSENS Lysis buffer;

1177 Q:27 BIOMERIEUX) and the second set in viral transport medium (VTM). All tubes  
1178 were stored in liquid nitrogen in the field and then transferred to  
1179 a  $-80^{\circ}\text{C}$  freezer.

1180 During each sampling event, pooled urine samples were collected beneath  
1181 bat roosts using polyethylene sheets ( $2' \times 3'$ ) distributed evenly under the  
1182 colony between 3 AM and 6 AM. Urine was collected from each sheet either  
1183 by using a sterile swab to soak up droplets or a sterile disposable pipette.  
1184 Swabs or syringed urine from a single sheet were combined to represent a  
1185 pooled sample. Each urine sample was divided in half and aliquoted into  
1186 lysis buffer or VTM at an approximate ratio of one part sample to two parts  
1187 preservative.

1188 **Serological and Molecular Assays.** Sera from the cross-sectional survey were  
1189 heat-inactivated at  $56^{\circ}\text{C}$  for 30 min, as described (105), prior to shipment to  
1190 the Center for Infection and Immunity at Columbia University for analysis.  
1191 Samples were screened for anti-NiV IgG antibodies using an ELISA, as de-  
1192 scribed in ref. 27. Sera from the longitudinal studies were sent to the Aus-  
1193 tralian Animal Health Laboratory and were gamma-irradiated upon receipt.  
1194 Because of the large sample size and development of a high-throughput  
1195 multiplex assay of comparable specificity and sensitivity, for these samples,  
1196 we used a Luminex-based microsphere binding assay to detect anti-Nipah G  
1197 IgG antibodies reactive to a purified NiV-soluble G-protein reagent, as de-  
1198 scribed (106, 107). Samples resulting in an MFI value of 250 and below are  
1199 considered negative for other bat species, and previous studies have  
1200 reported using a threshold of at least three times the mean MFI of negative  
1201 sera to determine the cutoff (47, 108–110). For this study, MFI values of over  
1202 1,000 were considered positive for NiV antibodies, an approach considered  
1203 appropriate for research purposes for bats.

1204 **Total nucleic acids from swabs and urine samples were extracted and**  
1205 **complementary DNA was synthesized by using SuperScript III (Invitrogen)**  
1206 **according to manufacturer's instructions. A nested RT-PCR and a real-time**  
1207 **assay targeting the N gene were used to detect NiV RNA in samples (111). An**  
1208 **RT-qPCR designed to detect the nucleocapsid gene of all known NiV isolates**  
1209 **was also utilized (112). Oligonucleotide primers and probe were as described**  
1210 **(112). Assays were performed by using AgPath-ID One-StepRT-PCR Reagents**  
1211 **(ThermoFisher) with 250 nM probe, 50 nM forward, and 900 nM reverse**  
1212 **primers. Thermal cycling was  $45^{\circ}\text{C}$  for 10 min, followed by 45 cycles of  $95^{\circ}\text{C}$**   
1213 **for 15 s and  $60^{\circ}\text{C}$  for 45 s. Cutoff values were cycle threshold ( $C_T$ )  $\leq 40$  for**  
1214 **positive and  $C_T \geq 45$  for negative. Results with  $C_T$  values between 40 and 45**  
1215 **were deemed indeterminate, i.e., not conclusively positive or negative.**  
1216 **Samples with NiV RNA detected by real-time PCR were confirmed by gel**  
1217 **electrophoresis and product sequencing.**

1218 A subset of NiV-positive samples was processed by high-throughput se-  
1219 quencing (HTS) on the Ion Torrent PGM platform in order to obtain addi-  
1220 tional NiV genomic sequence. Libraries were prepared according to the  
1221 manufacturer's instructions, and 1 million reads were allocated per sample.  
1222 HTS reads were aligned against host reference databases to remove host  
1223 background by using the bowtie2 mapper, and host-subtracted reads were  
1224 primer-trimmed and filtered based on quality, GC content, and sequence  
1225 complexity. The remaining reads were de novo assembled by using Newbler  
1226 (Version 2.6) and mapped to the full-length NiV genome. Contigs and  
1227 unique singletons were also subjected to homology search by using Mega-  
1228 Blast against the GenBank nucleotide database, in case variance in parts of  
1229 the genome precluded efficient mapping. From these data, N-gene con-  
1230 sensus sequences were constructed by using Geneious (Version 7.1) and were  
1231 used for phylogenetic analyses.

1232 **Phylogenetic Analysis.** All *P. medius* NiV sequences have been submitted to  
1233 GenBank, and accession numbers are included in Fig. 6. Sequence align-  
1234 ments were constructed by using ClustalW in Geneious Prime software (113).  
1235 Phylogenetic trees of NiV N-gene sequences were constructed by using  
1236 neighbor-joining algorithms, and figures were constructed in FigTree  
1237 (Version 1.4.2).

1238 **Satellite Telemetry and Home-Range Analysis.** We developed a collar system to  
1239 attach 12g solar-powered Platform Terminal Transmitters (PTTs) (Microwave  
1240 Telemetry) to adult bats using commercial nylon feline collars with the  
1241 buckle removed and 0-gauge nylon suture to attach the PTT to the collar  
1242 and to fasten the collar around the bat's neck. Collars were fitted to the bat  
1243 such that there was enough space to allow for normal neck movement and  
1244 swallowing, but so that the collar would not slip over the head of the animal  
1245 (SI Appendix, Fig. S6). PTTs were programmed with a duty cycle of 10 h on  
1246 and 48 h off. Data were accessed via the Argos online data service (argos-  
1247 system.org). A total of 14 collars were deployed as follows: February 2009:  
1248 three males and three females from a colony in Shuvarampur, Faridpur

1179 district; February 2011: three males and two females from the same colony;  
1180 and April 2011 Cox's Bazaar, three bats from a colony in Cox's Bazaar,  
1181 Chattogram district. Bats were selected based on size, such that the total  
1182 weight of the collar ( $\sim 21$  g) was less than 3% of the bat's body mass (SI  
1183 Appendix, Table S3).

1184 The individual telemetry dataset was combined for each region, and its  
1185 aggregate utilization distributions (UDs) were computed in R by using  
1186 package "adehabitatHR" (114). Population-specific home range is repre-  
1187 sented by the \*95% area enclosure of its UD's volume. The volume of in-  
1188 tersection between the colonies quantifies the extent of home-range  
1189 overlap. To evaluate the potential for contact with the Cox's Bazaar colony,  
1190 we calculated the most likely distance moved ("mldm") for each sampled bat  
1191 at Faridpur, where the population was more intensively monitored. Move-  
1192 ment distance was measured in kilometers with respect to a center location  
1193 ( $w$ ) shared by the whole colony. This information was used to predict how  
1194 likely an animal was to use the landscape.

1195 **Statistical Approach—Cross-Sectional Study.** We fit a Bayesian generalized  
1196 linear model with a logit link and a Bernoulli outcome to identify potential  
1197 predictors which influenced a bat's serostatus. We included age, sex, age-  
1198 and sex-normalized mass and forearm length, mass:forearm ratio, body  
1199 condition, and whether the bat was pregnant, lactating, or carrying a pup,  
1200 using weak zero-centered normal priors for all coefficients. We included  
1201 location of sampling as a group effect (similar to a random effect in a fre-  
1202 quentist context) nested within Nipah Belt or non-Nipah Belt regions. We fit  
1203 the models and performed posterior predictive checks in R 3.4.3, using the  
1204 **rstanarm** and **rstan** packages.

1205 **Statistical Approach—Longitudinal Study.** We fit binomial GAMs (115) to the  
1206 time series of adult and juvenile seroprevalence in the longitudinal study.  
1207 We included annual, synchronous birthing that occurred between March  
1208 and April. We assumed that pups weaned from their dams at 3 mo and  
1209 became independent flyers, and that maternal antibodies waned after 6 mo,  
1210 at which point pups transitioned into the "juvenile" class (30, 61). We as-  
1211 summed that juveniles became sexually mature at 24 mo and entered the  
1212 "adult" class based on other pteropid species (30, 47, 116). For juveniles, we  
1213 modeled the birth cohort of bats as separate random effects in a pooled  
1214 model of juvenile seroprevalence starting from June of their birth year, June  
1215 being the earliest month we sampled free-flying juveniles in any cohort. We  
1216 determined the cohort year of juveniles by using cluster analysis to group  
1217 individuals by weight, assuming that those in the smallest group were born  
1218 in the current year and those in the larger group were born the previous  
1219 year. Of juveniles captured, 92% were yearlings. For adults, we analyzed Q:31  
1220 seroprevalence of adults as a single pool over the entire course of the study.  
1221 We tested models with and without annual cyclic effects.

1222 Where time series had significant temporal autocorrelation (adults only),  
1223 we aggregated data by week. We determined periods of significant increase  
1224 or decrease as those where the 95% CI of the GAM prediction's derivative did  
1225 not overlap zero. We fit the models and performed checks in R (Version  
1226 3.4.3), using the **mgcv** package.

1227 To examine the importance of different biological mechanisms in trans-  
1228 mission, we fit an age-structured (adult and juvenile) maternally immune  
1229 ( $M$ )–susceptible ( $S$ )–infected ( $I$ )–recovered ( $R$ ) model with recrudescence ( $R$   
1230 to  $I$ ) and loss of immunity ( $R$  to  $S$ ) to the seroprevalence data on a weekly  
1231 timescale:

$$1232 \frac{dS_J}{dt} = -S_J(\beta_{JJ}I_J + \beta_{AJ}I_A) - \mu_J S_J + bN_A(t-5) \frac{S_A}{N_A} - bN_A(t-52) \frac{S_J}{N_J}(1-\mu_J)^{52} + \lambda M_J$$

$$1233 \frac{dI_J}{dt} = S_J(\beta_{JJ}I_J + \beta_{AJ}I_A) - \gamma I_J - bN_A(t-52) \frac{I_J}{N_J}(1-\mu_J)^{52}$$

$$1234 \frac{dR_J}{dt} = \gamma I_J - \mu_J S_J - \mu_J R_J - bN_A(t-52) \frac{R_J}{N_J}(1-\mu_J)^{52}$$

$$1235 \frac{dM_J}{dt} = bA(t-5) \frac{R_A}{N_A} - \lambda M_J - \mu_J M_J - bN_A(t-52) \frac{R_A}{N_A}(1-\mu_J)^{52} \lambda^{52}$$

$$1236 \frac{dS_A}{dt} = -S_A(\beta_{AA}I_A + \beta_{JA}I_J) - \mu_A S_A + \tau R_A + bN_A(t-52) \frac{S_J}{N_J}(1-\mu_J)^{52}$$

$$1237 \frac{dI_A}{dt} = S_A(\beta_{AA}I_A + \beta_{JA}I_J) - \gamma I_A - \mu_A I_A + bN_A(t-52) \frac{I_J}{N_J}(1-\mu_J)^{52} + \Delta R_A$$

$$1238 \frac{dR_A}{dt} = \gamma I_A - \mu_A R_A + bN_A(t-52) \frac{R_J}{N_J}(1-\mu_J)^{52} - \tau R_A - \Delta R_A$$

We included a class  $M$  for the density of juvenile bats with maternal antibodies to allow for the biological possibility that maternal antibodies are lost at a much higher rate than antibodies acquired following infection. The subscripts  $J$  refer to juveniles and  $A$  to adults;  $\beta$  is the transmission rate;  $\gamma$  is the recovery rate;  $\mu$  is the mortality rate;  $\tau$  is the rate of loss of adult immunity;  $\lambda$  is the rate of loss of maternal antibodies (61);  $\Delta$  is the adult recrudescence rate ( $R$  to  $I$ ); and  $b$  is the birth rate (pups join the juvenile population after 5 wk). Juveniles transition to adults after 52 wk. We included terms for loss of antibody in adults ( $\tau$ ,  $S$  to  $R$ ) and viral recrudescence ( $\Delta$ ,  $R$  to  $I$ ) based on previous studies on captive bats that demonstrated the existence of these processes without providing enough data to characterize them precisely (64, 65). We fit this deterministic model to the seroprevalence data by maximum likelihood, which assumes that deviations from the model are due to observation error. We estimated the CIs around maximum-likelihood parameter estimates using likelihood profiles using the *profile* function in package *bbmle* in R (Version 3.2.2).

We used model fitting and model comparison to examine the need for several of the biological processes in the model above that could influence NiV dynamics. First, we examined both density- and frequency-dependent transmission by comparing the fit of the model above to one with transmission terms that have population size ( $N_A$  or  $N_J$ ) in the denominator. Second, we examined the CIs of the parameters describing viral recrudescence, loss of antibodies in adult bats, and loss of antibodies in juvenile bats. If the confidence bounds for these parameters included zero, then these biological processes are not needed to explain the serological dynamics. Finally, we examined the confidence bounds for parameters describing the loss of maternal and nonmaternal antibodies ( $\tau$  and  $\lambda$ ) to determine if the rate of loss of these two types of immunity were different. We note that this model structure has similarities to a susceptible–infected–latently infected

( $L$ )–infected (SIL) model (if latently infected individuals are seropositive), but the model above differs in allowing for the possibility of individuals to transition from the  $R$  class back to the  $S$  class.

**Code Availability.** SIR model code written in R is available upon request.

**Data Availability.** All molecular sequences are available via GenBank (GenBank accession nos. MK995284–MK995302). The datasets generated during and/or analyzed during the current study are available from the corresponding author on reasonable request.

**ACKNOWLEDGMENTS.** We thank Pitu Biswas, Md. Sheikh Gofur, Abdul Hai, and Craig Smith for assistance in the field; Toph Allen, Parvies Hosseini, and Emma Mendelsohn for technical input; Eliza Choi, Yan-Ru Feng, and Lianying Yan for preparing recombinant viral glycoproteins; Jennifer Barr, Vishal Kapoor, Neil Renwick, and Mohammad Ziadur for laboratory diagnostic and technical support; anonymous reviewers for their useful comments; and the Government of Bangladesh for permits and logistical support that made this work possible. This study was funded by an NIH National Institute of Allergy and Infectious Diseases (NIAID) Awards AI067549 (to J.H.E.) and AI054715 (to C.C.B.); NIH Fogarty International Center Ecology and Evolution of Infectious Diseases (EEID) Award R01 TW005869 (to P.D.); NSF-NIH EEID Award EF-0914866 (to A.M.K.); NIH NIAID Award U19 AI109761 (to W.I.L.); US Agency for International Development PEER Award 226 (to M.S.U.K.); and the US Agency for International Development Emerging Pandemic Threats: PREDICT Program (P.D., J.H.E., A.I., S.J.A., N.R., C.Z.-T., and K.J.O.). The ICDDR,B is also grateful to the Governments of Bangladesh, Canada, Sweden, and the United Kingdom for providing core/unrestricted support.

# AUTHOR QUERIES

## AUTHOR PLEASE ANSWER ALL QUERIES

1

- Q: 1\_Please review 1) the author affiliation and footnote symbols, 2) the order of the author names, and 3) the spelling of all author names, initials, and affiliations and confirm that they are correct as set.
- Q: 2\_Please review the author contribution footnote carefully. Ensure that the information is correct and that the correct author initials are listed. Note that the order of author initials matches the order of the author line per journal style. You may add contributions to the list in the footnote; however, funding may not be an author's only contribution to the work.
- Q: 3\_Please review your open access and license selection and confirm that it is correct.
- Q: 4\_Certain compound terms are hyphenated when used as adjectives and unhyphenated when used as nouns. This style has been applied consistently throughout where (and if) applicable.
- Q: 5\_For affiliations a, c, d, f, g, and m, please provide a division and/or department.
- Q: 6\_Please confirm the postal codes added to affiliations a, b, c, e, g, i, k, and m. Please provide postal codes for affiliations d, f, h, j, and l. Please also confirm Commonwealth Scientific and Industrial Research Organisation as added to affiliation e.
- Q: 7\_If you have any changes to your Supporting Information (SI) file(s), please provide revised, ready-to-publish replacement files without annotations.
- Q: 8\_On the cover sheet, M.S.-L. is listed as being affiliated with the Food and Drug Administration, but it is not included in the affiliations. If the author was at Food and Drug Administration at the time of the study and/or writing of the paper, please add an affiliation, including division and/or department, city, state, and zip code. If it is a present address, please provide the same information in a footnote.
- Q: 9\_Please spell out WHO in the Significance Statement.
- Q: 10\_Claims of priority or primacy are not allowed, per PNAS policy (<https://www.pnas.org/page/authors/format>); therefore, the term “for the first time” has been deleted (in sentence beginning “We show...”).
- Q: 11\_Please confirm that spp. was spelled out correctly.
- Q: 12\_Please confirm that SARS was spelled out correctly.
- Q: 13\_Please confirm that spp. was spelled out correctly.
- Q: 14\_Please confirm Pteropus lylei, Pteropus vampyrus, and Pteropus hypomelanus.
- Q: 15\_Please confirm that IgG was spelled out correctly.
- Q: 16\_Please confirm that M:FA was spelled out correctly.
- Q: 17\_Please confirm that AIC was spelled out correctly.
- Q: 18\_Please confirm that Nov and Apr were spelled out correctly.

# AUTHOR QUERIES

## AUTHOR PLEASE ANSWER ALL QUERIES

2

- Q: 19\_Please note that references have been renumbered due to several duplicate references.
- Q: 20\_Claims of priority or primacy are not allowed, per PNAS policy (<https://www.pnas.org/page/authors/format>); therefore, the term “first” has been deleted (in sentence beginning “Our recapture...”).
- Q: 21\_Please confirm edits: “The fitted model suggests that transmission increases when bat populations have become susceptible through waning immunity (11).”
- Q: 22\_Please confirm edits: “In our study periods, low seroprevalence in bats was not always followed by outbreaks in humans.”
- Q: 23\_Please confirm that DRC was spelled out correctly.
- Q: 24\_Please confirm that IACUC was spelled out correctly.
- Q: 25\_Please confirm that ICDDR,B was spelled out correctly.
- Q: 26\_Please confirm that AEEC was spelled out correctly.
- Q: 27\_Please confirm VTM as the abbreviation for viral transport medium.
- Q: 28\_Please confirm that cDNA was spelled out correctly.
- Q: 29\_All data related to this paper that are not within the main text or SI should be cited in the data availability statement, per PNAS policy (<https://www.pnas.org/page/authors/journal-policies#xi>). In addition, all data cited in the text, including newly created data, should be cited in the reference list. For each new reference, please provide the following information: 1) author names, 2) data/page title, 3) database name, 4) a direct URL to the data, 5) the date on which the data were accessed or deposited (not the release date), and 6) where the new reference citation should be added in the main text and/or data availability statement.
- Q: 30\_Please indicate whether the data have been deposited in a publicly accessible database before your page proofs are returned. The data must be deposited BEFORE the paper can be published. Please also confirm that the data will be accessible upon publication.
- Q: 31\_Please confirm edits (to avoid starting a sentence with a numeral): “Of juveniles captured, 92% were yearlings.”
- Q: 32\_Please confirm GenBank accession nos.
- Q: 33\_Please indicate whether the data have been deposited in a publicly accessible database before your page proofs are returned. The data must be deposited BEFORE the paper can be published. Please also confirm that the data will be accessible upon publication.
- Q: 34\_All data related to this paper that are not within the main text or SI should be cited in the data availability statement, per PNAS policy (<https://www.pnas.org/page/authors/journal-policies#xi>).

---

All,

Attached are the author proofs for our PNAS paper. Please check that your name and affiliation, including department and postal code, are correctly written.

I'll address the other questions listed.

Please send me any necessary corrections by Friday morning, 10 AM EDT.

Cheers,  
Jon

*EcoHealth Alliance develops science-based solutions to prevent pandemics and promote conservation*

**Year 5: Task 4. Conduct targeted serological surveys in people and livestock** *Description and execution:* As for Y4. *Subtasks:* 5.4.1 Test samples and analyze results *Resources:* As for Y4 *Metrics of success:* Successfully test human serum and livestock samples from South Africa and analyze results *Deliverables:* Obtain serological results from human and livestock serum at bat-human-livestock interphases in South Africa to determine potential spillover.

**Year 5: Task 5. Reporting and communication strategy** *Description and execution:* As for Y1-5. *Subtasks:* 5.5.1. Discuss results and compile an annual report, including all stakeholders 5.5.2. Develop a communication plan and implement it 5.5.3. Present at scientific conferences and prepare manuscripts for publications 5.5.4. Annual report to governmental partners 5.5.5. Annual report to DTRA. 5.5.6. Attend DTRA technical review. *Resources:* As for Y1-4 *Metrics of success:* All stakeholders partake in analyses and reporting of results and development of a communication strategy *Deliverables:* Final reporting to stakeholders and DTRA, scientific publications and conference contributions, communication to the general public, risk and threat mitigation.

### SUMMARY OF PERFORMANCE SCHEDULE

Table: Summary of the tasks that will be performed for the duration of the project (Also in project narrative).

TASK	Y1	Y2	Y3	OY4	OY5	TASK	Y1	Y2	Y3	OY4	OY5
<b>1. Build and enhance capacity in Southern Africa to conduct biosurveillance for filo-, henipa- and coronaviruses</b>						<b>3. Conduct targeted observational and human behavior studies</b>					
1.1.Project stakeholder workshop						3.1.Design the study and questionnaires					
1.2.Establishment and sustaining a Southern African Bat Research network (SABRENET)						3.2.Apply for necessary ethical approvals and obtain community permissions					
1.3.Modeling and data analysis workshop						3.3.Collect and analyze data					
1.4.Introduction to bat biology and taxonomy						<b>4. Conduct targeted serological surveys in people and livestock</b>					
1.5.Bat field sampling training						4.1.Scoping visits to potential study sites					
1.6.Establishment of Luminex serology technology at UP and NICD						4.2.Apply for necessary permits and ethical approvals					
1.7.Laboratory diagnostic training						4.3.Collection of samples					
1.8.Data interpretation workshop						4.4.Test and analyze data					
<b>2. Implement biosurveillance in bats in Southern Africa and testing of samples</b>						<b>5. Reporting and Communication</b>					
2.1.Cross-sectional and longitudinal surveillance in bat species in South Africa						5.1.Discuss results, finalize and compile an annual report including all stakeholders					
2.2 Nucleic acid testing of samples and DNA sequencing of positives.						5.2. Develop a communication plan and implement it					
2.3. Serological testing of serum samples collected from bats and data analysis						5.3. Present at scientific conferences and prepare manuscripts for publication					
2.4. Characterization of additional genes or genome regions of positive samples, verify positive serological results						5.4. Annual report to all governmental partners and stakeholders					
2.5. Enter all data and results in a database and analyze						5.5. Annual report to DTRA					
2.6.Once off surveillance of bats in Mozambique and Zimbabwe						5.6. Attend DTRA technical review					

and analyses of results. Human serum samples will be tested by NICD and livestock at UP. *Subtasks:* 4.4.1 Test samples and analyze results *Resources:* UP: one research scientists, one postdoc, one postgraduate student, and research assistants (testing of samples and analyses of results). NICD: two research scientists, one postgraduate student, and a postdoc (testing of samples and analyzes of results). EHA: two research scientists (analyzes of results). nDOH, RSA (analyzes of results). Department of Agriculture and Rural development Limpopo and KwaZulu Natal, DLRRD (analyzes of results). *Metrics of success:* Successfully testing of human and livestock serum samples from South Africa and analyses of results *Deliverables:* Obtain serological results from human and livestock serum at bat-human-livestock interphases in South Africa to determine potential spillover.

**Year 4: Task 5. Reporting and communication strategy** *Description and execution:* As for Y1-Y3. *Subtasks:* 4.5.1. Discuss results and compile an annual report, including all stakeholders 4.5.2. Develop a communication plan and implement it 4.5.3. Present at scientific conferences and prepare manuscripts for publications 4.5.4. Annual report to governmental partners 4.5.5. Annual report to DTRA. 4.5.6. Attend DTRA technical review. *Resources:* As for Y1-3 with four additional postgraduate students from Moz and Zim included. *Metrics of success:* As for Y1-Y3 with reporting of results for Y4 included. *Deliverables:* Annual reporting to stakeholders and DTRA, scientific publications and conference contributions, communication to the public, risk, and threat mitigation.

**Year 5 (Optional): Task 1. Continued: Build and enhance capacity in Southern Africa to conduct biosurveillance for filo-, henipa- and coronaviruses** *Description and execution:* As in Y4 but with no new enrollments of students and no field training since all fieldwork activities end in Y4. Diagnostic training will continue. All students will complete degrees in Y5. The stakeholder workshop will be in South Africa (3 days) and will involve finalizing results and reporting, mitigation strategies and policies for threat reduction, finalize a sustainable biosurveillance plan for the region, and preparation of a final report and publications. It will also include a final data interpretation workshop (5 days) in New York, USA. *Subtasks:* 5.1.1. Project stakeholder workshop 5.1.2. Sustain the Southern African Bat Research Network (SABRENET) 5.1.3. Continuous use of the Luminex serology technology at UP and NICD 5.1.4. Laboratory diagnostic training 5.1.5. Data interpretation workshop. 5.1.6. Attend DTRA technical review. *Resources:* As for Y4. *Metrics of success:* As for Y4 with all students completing degrees (additional six students in Y5), final report, and finalization of threat reduction and mitigation strategies. *Deliverables:* Surveillance and communication capacity enhanced with specific results reported, development of risk mitigation strategies and finalization of a biosurveillance plan for the region, completion of training of all partners, completion of student degrees.

**Year 5: Task 2. Implement biosurveillance in bats in Southern Africa and testing samples** *Description and execution:* No more sampling will be done, sample testing will be completed, including characterization and follow up of serological positives and analyses of results *Subtasks:* 5.2.1 Nucleic acid testing of samples and DNA sequencing of positives 5.2.2. Serological testing of serum samples collected from bats and data analysis 5.2.3 Characterization of additional genes or genome regions of positive samples and verify serological positives 5.2.4. Enter all data and results in a database and analyze. *Resources:* As for Y 4. *Metrics of success:* Complete testing of all samples and analyses of results. *Deliverables:* Completion of all sample testing and analyses of results, data of nucleic acid, and seroprevalence for several bat species in Southern Africa, longitudinal data analyzed together with environmental and ecological factors to determine factors that increase spillover risk.

**Year 5: Task 3. Conduct targeted observational and human behavior studies** *Description and execution:* As for Y3 and Y4 with only data analyzes to be performed and no additional data collection. *Subtasks:* 5.3.1. Analyses of data collected in South Africa in Y3 and in Moz and Zim in Y4. *Resources:* As for Y 4. *Metrics of success:* Analyzes of all results *Deliverables:* Completed analyses of results and obtain data on risk activities for spillover

publications and conference contributions, communication to the public, risk and mitigation strategies.

**Year 4 (Optional): Task 1. Continued: Build and enhance capacity in Southern Africa to conduct biosurveillance for filo-, henipa- and coronaviruses** *Description and execution:* As for Y1, Y2, and Y3 with a stakeholder workshop (1 day) using video calling and African partners meeting in South Africa and USA partners dialing in. The data interpretation workshop will be in South Africa (5 days). No more field sampling will take place in South Africa in Y4, but sampling will commence in Zim, and Moz and field training will, therefore, be done at these sites. Diagnostic training visits in South Africa will continue as in previous years. Four additional postgraduate students will be identified from Moz and Zim (biosurveillance and human behavior studies in Moz and Zim). *Subtasks:* 4.1.1. Project stakeholder workshop 4.1.2. Sustain the Southern African Bat Research Network (SABRENET) 4.1.3. Bat field sampling training 4.1.4. Continuous use of the Luminex serology technology at UP and NICD 4.1.5. Laboratory diagnostic training 4.1.6. Data interpretation workshop. *Resources:* As for Y1-Y3 with additional postgraduate students from Moz and Zim enrolling. *Metrics of success:* As for Y1-Y3 with five additional postgraduate students graduating (enrolled in Y2). *Deliverables:* As for Y1-Y3 with additional students graduating, biosurveillance data from Moz and Zim will be included in analysis.

**Year 4: Task 2. Implement biosurveillance in bats in Southern Africa and testing samples** *Description and execution:* In Y4, sampling will only be done at selected sites in Moz and Zim (twice/year n=2400) and all diagnostic testing will still be done in South Africa. The testing of samples collected in South Africa in Y1-Y3 will be completed. *Subtasks:* 4.2.1. Cross-sectional and longitudinal surveillance in bat species in South Africa (only testing) 4.2.2. Nucleic acid testing of samples and DNA sequencing of positives 4.2.3. Serological testing of serum samples collected from bats and data analysis 4.2.4. Characterization of additional genes or genome regions of positive samples and verify serological positives 4.2.5. Enter all data and results in a database and analyze 4.2.6. Once of surveillance of bats in Mozambique and Zimbabwe. *Resources:* As for Y3 with an additional four post graduate students from Moz and Zim being involved in fieldwork, testing of samples in South Africa, and analyzes of results. *Metrics of success:* Participation in fieldwork and diagnostic training of at least one representative from each partner, supervision of students and two students completing degrees (enrolled in Y3), testing of samples collected in Y1-Y4, DNA sequencing of all positive molecular results and identify samples for further genomic characterization and serological follow up, environmental, ecological and movement data collected, all data entered into the database, analyzed and communicated to the relevant stakeholders. *Deliverables:* Perform all fieldwork collections as specified in the grant schedule, entering all data into the database, testing of samples and analyzing results for Y1-Y4, ecological and movement data on bats, longitudinal data for Y1-Y3.

**Year 4: Task 3. Conduct targeted observational and human behavior studies** *Description and execution:* In Y4, no additional data will be collected in South Africa, but we will collect data at two sites in Moz and Zim (n=150/site), and data analysis for South Africa will continue. These studies will be coordinated by UP (Markotter and postdoc), EHA (Epstein and Hagan), NICD (Weyer and postdoc) and Ministry of Health of Zim and Moz. *Subtasks:* 4.3.1. Collection and analysis of data at Zim and Moz sites 4.3.2. Analysis of data collected at South African sites. *Resources:* UP: one research scientist and one postdoc (data collection and analysis). NICD: 1 research scientist and a postdoc (data collection and analysis). EHA: two research scientists (data collection and analysis). Ministry of Health Moz and Zim and postgraduate student (data collection and analyses). *Metrics of success:* Obtain 150 completed questionnaires per site and analyze results. *Deliverables:* Completed questionnaires and analyses of results for South Africa, Zim and Moz. Identify high-risk behavior.

**Year 4: Task 4. Conduct targeted serological surveys in people and livestock** *Description and execution:* No additional samples will be collected, and the focus will be on testing of samples

samples and DNA sequencing of positives 3.2.3. Serological testing of serum samples collected from bats and data analysis 3.2.4. Characterization of additional genes or genome regions of positive samples and verify serological positives 3.2.5. Enter all data and results in a database and analyze 3.2.6. Obtain ethical clearance and permits for sampling in Moz and Zim in Y4. *Resources:* As for Y2 with two additional postgraduate students (UP) enrolling and CVL Moz and Zim coordinating and obtaining permits and ethical clearances for sampling. *Metrics of success:* Participation in fieldwork and diagnostic training of at least one representative from each partner, supervision of students and four students completing degrees, testing of samples collected in Y1, Y2 and Y3, DNA sequencing of all positive molecular results and identify samples for further genomic characterization and serological follow up, environmental, ecological and movement data collected, all data entered into the database, analyzed and communicated to the relevant stakeholders. *Deliverables:* Perform all fieldwork collections as specified in the grant schedule, entering all data into the database, testing of samples and analyzing results for Y1, Y2 and Y3, ecological and movement data on bats, preliminary longitudinal data for sites where sampling started in Y1.

**Year 3: Task 3. Conduct targeted observational and human behavior studies** *Description and execution:* In Y3, data will be collected at three sites in South Africa (n=150/site) where potential human and livestock contact is a possibility as described in the narrative. These studies will be coordinated by UP (Markotter and postdoc), EHA (Epstein and Hagan), NICD (Weyer and postdoc), nDOH, RSA. We will also obtain ethical clearance for studies to be conducted in Moz and Zim in Y4. *Subtasks:* 3.3.1. Collection and analysis of data at South African sites. 3.3.2. Obtain ethical clearances for studies in Moz and Zim *Resources:* UP: one research scientist and one postdoc (data collection and analysis), NICD: one research scientist, and a postdoc (data collection and analysis). EHA: two research scientists (data collection and analysis). nDOH, RSA (data collection and analysis), Ministry of Health Moz and Zim (ethical clearance for studies in Y4). *Metrics of success:* Obtain 150 completed questionnaires per site, obtain ethical clearances for studies in Y4 in Moz and Zim. *Deliverables:* Completed questionnaires and analyses of results for South Africa and ethical clearances for studies in Moz and Zim. Identify high-risk behavior.

**Year 3: Task 4. Conduct targeted serological surveys in people and livestock** *Description and execution:* Collect serum samples from humans and livestock at three sites in South Africa [human serum samples (n=150/site) and livestock are 150/samples per site/species for cattle, donkeys, goats, and pigs]. The collection of human serum samples will be done in collaboration with nDOH and livestock in collaboration with the Department of Agriculture and Rural Development of the different provinces. Human serum samples will be tested at NICD and livestock at UP. *Subtasks:* 3.4.1 Collection of samples 3.4.2. Test and analyze samples *Resources:* UP: one research scientist, one postdoc, one postgraduate student (collection and testing of livestock samples). NICD: two research scientists, postdoc, one postgraduate student (sample collection and testing of human serum samples). EHA: two research scientists (analyzes of results). nDOH, RSA (facilitating collection of human serum samples and analyzes of results). Department of Agriculture and Rural Development Limpopo and KwaZulu Natal, state veterinarians (collection of livestock samples and analyzes of results). *Metrics of success:* Successfully collect human serum and livestock samples from all three sites, test and analyze results *Deliverables:* Obtain serological results from human and livestock serum at bat-human-livestock interphases in South Africa to determine potential spillover.

**Year 3: Task 5. Reporting and communication strategy** *Description and execution:* As for Y1 and Y2. *Subtasks:* 3.5.1. Discuss results and compile an annual report, including all stakeholders 3.5.2. Develop a communication plan and implement it 3.5.3. Present at scientific conferences and prepare manuscripts for publications 3.5.4. Annual report to governmental partners 3.5.5. Annual report to DTRA. 3.5.6. Attend DTRA technical review. *Resources:* As for Y1 and Y2 with two additional postgraduate students (UP) enrolling. *Metrics of success:* As for Y1 and Y2, with reporting of results for Y3 included. *Deliverables:* Annual reporting to stakeholders and DTRA, scientific

Obtain ethical clearance and community permission, design of questionnaires. *Deliverables:* Ethical clearance, design a questionnaire.

**Year 2: Task 4. Conduct targeted serological surveys in people and livestock** *Description and execution:* Obtain ethical clearance and permits to conduct sampling in Y3 at three sites in South Africa. The collection of human serum samples will be done in collaboration with nDOH and livestock in collaboration with the Department of Agriculture and Rural Development of the different provinces. *Subtasks:* 2.4.1 Scoping visits to potential study sites 2.4.2. Apply for necessary permits and ethical approval. *Resources:* UP: one research scientist and one postdoc (involved in study design and obtaining ethical clearances), NICD: two research scientists and a postdoc (involved in design of the study and obtaining ethical clearances). EHA: two research scientists (assist with planning and development of the study). nDOH, RSA (Involve in planning of the study). Department of Agriculture and Rural Development Limpopo and KwaZulu Natal, state veterinarians (planning of the study and obtaining permits). *Metrics of success:* Obtain ethical clearance and permits *Deliverables:* Ethical clearance and permits.

**Year 2: Task 5. Reporting and communication strategy** *Description and execution:* As for Y1. *Subtasks:* 2.5.1. Discuss results and compile an annual report, including all stakeholders, 2.5.2. Develop a communication plan and implement it 2.5.3. Present at scientific conferences and prepare manuscripts for publications 2.5.4. Annual report to governmental partners 2.5.5. Annual report to DTRA. 2.5.6. Attend DTRA technical review. *Resources:* UP: one research scientist, three postdocs, eight postgraduate students and four research assistants (data analysis, reporting, and communication of results). NICD: three research scientists, one postdoc (data analysis, reporting, and communication of results). EHA: five research scientists, one postdoc, and one PhD (data analysis, reporting, and communication of results). USU: Two research scientists and three research assistants (data analysis, reporting, and communication of results). AfricanBats: One consultant and one research scientist (data analysis, reporting, and communication of results). DNMNH: One research scientist (data analysis, reporting, and communication of results). nDOH, DEFF, DLRRD, Ministries and CVL, Moz and Zim (data analysis, reporting, and communication of results). *Metrics of success:* All stakeholders partake in analyses and reporting of results (Y1 and Y2), development of a communication strategy and implementation, risk and mitigation strategies. *Deliverables:* Annual reporting to stakeholders and DTRA, scientific publications and conference contributions, communication to the public, risk and mitigation strategies.

**Year 3: Task 1. Continued: Build and enhance capacity in Southern Africa to conduct biosurveillance for filo-, henipa- and coronaviruses** *Description and execution:* As in Y2 except for the stakeholder workshop (3 days) and data interpretation workshop that will be in New York, USA (5 days). Enrollment of two additional students (MSc/PhD) focusing on human behavioral studies and human and livestock serology. *Subtasks:* 3.1.1. Project stakeholder workshop 3.1.2. Sustain the Southern African Bat Research Network (SABRENET) 3.1.3. Bat field sampling training, 3.1.4. Continuous use of the Luminex serology technology at UP and NICD 3.1.5. Laboratory diagnostic training 3.1.6. Data interpretation workshop. *Resources:* As for Y2 with two additional postgraduate students (UP). *Metrics of success:* As for Y2 with four postgraduate students completing degrees (enrolled in Y1) and two new students enrolled. *Deliverables:* Surveillance and communication capacity enhanced with specific results reported, development of risk mitigation strategies and improvement on a draft biosurveillance plan for the region, training individuals of all partners, continuous diagnostic capacity at two South African laboratories, student training and completion of student degrees, sustain the regional network.

**Year 3: Task 2. Implement biosurveillance in bats in Southern Africa and testing of samples** Biosurveillance activities for South Africa as for Y2 (n=7200). Planning, obtaining ethical clearance, and permits for sampling in MOZ and Zim in Y4 will commence. *Subtasks:* 3.2.1. Cross-sectional and longitudinal surveillance in bat species in South Africa 3.2.2. Nucleic acid testing of

capacity in two South African laboratories, perform training, generation of Luminex reagents, attend data interpretation workshop). AfricanBats: one consultant (attend workshops, present fieldwork training). DNMNH: one research scientist (attend workshops, present fieldwork training). DALLRD, nDOH, DEFF, CVL and Ministries of Health, Moz and Zim: (Attend all workshops and training, analyzes of results). Metrics of success: Present all training and workshops as indicated in the grant schedule, training of students, fellows, researchers, and technologists representative of all partners, enrollment, and supervision of postgraduate students, sustain SABRENET, support Luminex technology and continuous supply of reagents to UP and NICD. Deliverables: Surveillance, reporting, and communication capacity enhanced by attendance of workshop and training by all partners and reporting of results, sustain a regional research network, serological diagnostic capacity continued in two South African laboratories and continuous support, enrollment, and supervision of students.

**Year 2: Task 2. Implement biosurveillance in bats in Southern Africa and testing of samples** As for Y1 with the addition of two sites (Black Rock and Table Mountain) for South Africa (n=7200). Sample testing will also commence in the NICD laboratory in Y2. DNA sequencing, NGS characterization of positive samples (UP and NICD) as well as follow up serological testing (NICD) will be performed. Subtasks: 2.2.1. Cross-sectional and longitudinal surveillance in bat species in South Africa, 2.2.2. Nucleic acid testing of samples and DNA sequencing of positives 2.2.3. Serological testing of serum samples collected from bats and data analysis 2.2.4. Characterization of additional genes or genome regions of positive samples and verify serological positives 2.2.5. Enter all data and results into a database. Resources: UP: one research scientist, three postdocs, four research assistants, eight postgraduate students (See task 1) (conduct fieldwork, laboratory diagnostic testing, enter all data into a database, analyze results). NICD: two research scientists, one postdoc (conduct fieldwork and build diagnostic capacity). EHA: two research scientists, one postdoc, one PhD student (perform limited fieldwork, movement tracking, disease ecology). USU: one research scientist (establish diagnostic Luminex capacity and analyze results), three research assistants (assist with training, analyses of results and generation of Luminex reagents for testing). AfricanBats: one consultant and one research scientist (fieldwork, specifically the *Miniopterus* studies and movement tracking). DNMNH: one research scientist (fieldwork). Department of Agriculture and Rural Development Limpopo: state veterinarians (assist in sample collection). nDOH, DLRRD, DEFF, Moz and Zim partners (attend field and diagnostic training (task 1)). Metrics of success: Participation in fieldwork and diagnostic training of at least one representative from each partner, supervision of students, testing of samples collected in Y1 and Y2, DNA sequencing of all positive molecular results and identify samples for further genomic characterization and serological follow up, environmental, ecological and movement data collected, all data entered into the database, analyzed and communicated to the relevant stakeholders. Deliverables: Perform all fieldwork collections as specified in the grant schedule, entering all data into the database, testing of samples and analyzing results for Y1 and Y2, ecological and movement data on bats.

**Year 2: Task 3. Conduct targeted observational and human behavior studies** Description and execution: In Y1, only training on conducting human behavior was conducted. In Y2 planning, design of questionnaires and obtaining ethical clearance and community permissions will commence for three sites in South Africa where potential human and livestock contact is a possibility as described in the narrative. These studies will be coordinated by UP (Markotter and postdoc), EHA (Epstein and Hagan), NICD (Weyer and postdoc), nDOH, RSA. Subtasks: 2.3.1. Design the study and questionnaires 2.3.2. Apply for necessary ethical approvals and obtain community permissions. Resources: UP: one research scientist and one postdoc (study design and developing of questionnaires). NICD: two research scientists and a postdoc (design of the study and questionnaires, obtaining ethical clearances). EHA: two research scientists (assist with planning and development of questionnaires). nDOH, RSA (Involve in planning and design of questionnaires). Metrics of success:

of samples in collaboration with nDOH and the Department of Agriculture and Rural Development of the different provinces. Testing of human serum samples with the Luminex will be done at NICD and livestock samples at UP. Subtasks: This activity will only start in Y2.

**Year 1: Task 5. Reporting and communication** Description and execution: The grantee will synthesize all data collected and analyses of results, including outputs on capacity building activities. This

will be discussed at the annual stakeholder workshop and finalized (task 1). A final report will be prepared for all partners and an annual report to DTRA. Results will also be communicated to all relevant governmental agencies, the public and relevant communities using different forums. Scientific results will be published and presented at conferences and scientific meetings. Subtasks: 1.5.1. Discuss results and compile an annual report including all stakeholders 1.5.2. Develop a communication plan and implement it 1.5.3. Present at scientific conferences and prepare manuscripts for publications 1.5.4. Annual report to governmental partners 1.5.5. Annual report to DTRA. 1.5.6. Attend DTRA technical review. Resources: UP: one research scientists, three postdocs, four post graduate students and four research assistants to be involved in data analysis, reporting and communication of results. NICD: three research scientists to be involved in data analysis, reporting, and communication of results. EHA: five research scientists to be involved in data analysis, reporting, and communication of results. USU: Two research scientists and three research assistants to be involved in data analysis, reporting, and communication of results. AfricanBats: One consultant and one research scientist to be involved in data analysis, reporting, and communication of results. DNMNH: one research scientists to be involved in data analysis, reporting, and communication of results. nDOH, DEFF, DLRRD, Ministries and CVL laboratories in Moz and Zim (to be involved in data analysis, reporting, and communication of results). Metrics of success: All stakeholders partake in analyses and reporting of results (Y1), development and implementation of a communication strategy, risk and mitigations strategies. Deliverables: Annual reporting to stakeholders and DTRA, scientific publications and conference contributions, communication to the public, risk and mitigation strategies.

**Year 2: Task 1. Continued: Build and enhance capacity in Southern Africa to conduct biosurveillance for filo-, henipa- and coronaviruses** Description and execution: No additional training workshops are scheduled for Y2, except a stakeholder and data interpretation workshop. The stakeholder workshop will be held using video conferencing with all the African partners meeting in South Africa and interacting with USU and EHA in New York and Washington, respectively (1 day). It will focus on sharing results and progress, planning of activities for the year, reporting, identifying trainees and students, develop mitigation and threat reduction strategies, and development of a draft plan for sustainability of biosurveillance in the region. A data interpretation workshop is planned in South Africa (5 days), and training at field sites and diagnostic laboratories will continue as in Y1. An additional PhD student (disease modeling, EHA), two MSc/PhD and two honors students [corona and paramyxovirus surveillance (UP)] will be identified. USU will continue to be involved in training, troubleshooting and data analysis of the Luminex technology and will continue to supply reagents. Subtasks: 2.1.1. Project stakeholder workshop 2.1.2. Sustain the Southern African Bat Research Network (SABRENET) 2.1.3. Bat field sampling training 2.1.4. Continuous use of the Luminex serology technology at UP and NICD 2.1.5. Laboratory diagnostic training 2.1.6. Data interpretation workshop. Resources: UP: one research scientists and three postdocs (attend workshops, conduct field, and laboratory diagnostic training and facilitate diagnostic capacity development and testing, attend data interpretation workshop), eight postgraduate students (attend training activities). NICD: two research scientists, one postdoc (attend workshops, establish diagnostic capacity and facilitate diagnostic training). EHA: five research scientists, one postdoc (attend workshops, facilitate disease modelling, training in fieldwork, sustain regional networks, attend data interpretation workshop), USU: one research scientist and three research assistants (attend workshops, support Luminex

the following; *Rousettus aegyptiacus* (n=7040), *Miniopterus* spp. (n=8480) and molossid and *Rhinolophus* spp. (n=5600) with a total of 21 120 bats sampled over five years and the total per year varies, depending on the sample sites included. Y1 will include Maplapitsi, Madimatle and *Miniopterus* sites (n=4320) in South Africa including RFID and radio tracking technologies to investigate bat movement. Samples will be collected in duplicate with one sample set pulled for testing and another kept for future follow up. Inactivated samples will be transported to UP and tested using molecular and serological methods (postdocs, research assistants). NICD will also assist with sample testing from Y2 onwards when technologies have been established. Amendments to current ethics and DAFF section 20 approvals will be made in Y1, and current permits will be extended (UP, Markotter; DLRRD) Subtasks: 1.2.1. Cross-sectional and longitudinal surveillance in bat species in South Africa 1.2.2. Nucleic acid testing of samples and DNA sequencing of positives 1.2.3. Serological testing of serum samples collected from bats and data analysis 1.2.4. Characterization of additional genes or genome regions of positive samples and verify serological positives 1.2.5. Enter all data and results in a database and analyze. Resources: UP: one research scientist, three postdocs, four research assistants, four postgraduate students (See task 1) (conduct fieldwork, laboratory diagnostic testing, enter all data into a database, analyze results), NICD: two research scientists (conduct fieldwork and build diagnostic capacity). EHA: two research scientists (perform limited fieldwork, movement tracking), USU: one research scientist (establish diagnostic Luminex capacity and analyze results), three research assistants (assist with training, analyses of results and generation of Luminex reagents for testing). AfricanBats: one consultant and one research scientist (fieldwork, specifically the *Miniopterus* studies and movement tracking). DNMNH: one research scientist (fieldwork). Department of Agriculture and Rural Development Limpopo: state veterinarians (assist in sample collection). nDOH, DLRRD, DEFF, Moz and Zim partners (attend field and diagnostic training (task 1). Metrics of success: Participation in fieldwork and diagnostic training of at least one representative from each partner, supervision of students, testing of samples collected in Y1, DNA sequencing of all positive molecular results and identify samples for further genomic characterization and serological follow up, environmental, ecological and movement data collected, all data entered into the database, analyzed and communicated to the relevant stakeholders. Deliverables: Perform all fieldwork collections as specified in the grant schedule, entering all data into the database, testing of samples and analyzing results for Y1, preliminary ecological and movement data on bat species that can inform subsequent movement studies for Y2 and Y3.

**Year 1: Task 3. Conduct targeted observational and human behavior studies** Description and execution: In Y1, only training on how to conduct human behavior studies will be presented as part of the annual stakeholder workshop (See task 1). Y2 will be used for planning and obtaining ethical and community permissions, Y 3 for data collection in RSA and planning and ethical clearance for studies in Zim and Moz, Y4 for Moz, and Zim data collection and Y5 for analysis. Human behavior, KAP analysis, will be implemented at three sites in South Africa in Y3 where potential human and livestock contact is a possibility as described in the narrative. It will include serum collection at South African sites and only questionnaire-based human studies in Moz and Zim. These studies will be coordinated by UP (Markotter), EHA (Epstein and Hagan), NICD (Weyer), nDOH and Ministries of Health in Moz and Zim. Subtasks: 1.3.1 Training to do human behavioral studies. Resources: UP: one research scientist and one postdoc (Attend training). NICD: two research scientists (attend training), EHA: two research scientists (present training). nDOH, Ministries of Health Moz, and Zim (attend training). Metrics of success: Build capacity to perform human behavioral studies Deliverables: Build capacity to perform human behavioral studies.

**Year 1: Task 4. Conduct targeted serological surveys in people and livestock** Description and execution: Human and livestock samples, including cattle, goats, pigs, and donkeys (n=150/species/site), will be collected in Y3 at South African sites only. Sampling more than 100 animals/species/site will allow us to detect seropositivity with a 95% confidence at a seroprevalence of 3% assuming populations of 500. UP (Markotter) and NICD (Weyer) will coordinate the collection

insectivorous bats. Subtasks: 1.1.1. Project stakeholder workshop 1.1.2. Establishment of a Southern African Bat Research Network (SABRENET) 1.1.3. Modeling and data analysis workshop 1.1.4. Introduction to bat biology and taxonomy 1.1.5. Bat field sampling training 1.1.6. Establishment of Luminex serology technology at UP and NICD 1.1.7. Laboratory diagnostic training 1.1.8. Data interpretation workshop. Resources: UP: one research scientist and three postdocs (attend workshops, conduct field and laboratory diagnostic training and facilitate diagnostic capacity development and testing, attend data interpretation workshop), one administrative assistant, (coordinate project including financial and grant management and communication between partners), four postgraduate students (attend training activities). NICD: two research scientists (attend workshops, establish diagnostic capacity and facilitate diagnostic training). EHA: five research scientists (attend workshops, facilitate training in disease modeling, risk modeling, human behavior and communication, fieldwork and development of SOPs, establishment of SABRENET, attend data interpretation workshop), one part-time administrative assistant (facilitate communication and management between the Co-PIs and partners). USU: one research scientist and three research assistants (attend workshops, establish Luminex capacity in two South African laboratories, perform training, generation of Luminex reagents, attend data interpretation workshop). AfricanBats: one consultant (attend workshops, present bat biology and taxonomy, and fieldwork training). DNMNH: one research scientist (attend workshops, present bat biology, taxonomy, and fieldwork training). DALLRD, nDOH, DEFF, CVL and Ministries of Health, Moz and Zim: (Attend all workshops and training). Metrics of success: Present all training and workshops as indicated in the grant schedule, development of standardized SOPs, standardized reporting and communication strategies, training of students, fellows, researchers and technologists representative of all partners, enrollment of postgraduate students, establishment of SABRENET, establishment of Luminex technology and supply of reagents to UP and NICD. Deliverables: Surveillance, reporting and communication capacity enhanced by attendance of workshop and training by all partners, establishment of a regional research network, serological diagnostic capacity established in two South African laboratories, enrollment of students

**Year 1: Task 2. Implement biosurveillance in bats in Southern Africa and testing of samples** Description and execution: Biosurveillance activities will be focused in South Africa (Y1-Y3) with limited fieldwork collections in Moz and Zim (Y4). Cross-sectional studies will focus on *Rousettus*, *Rhinolophus*, *Miniopterus* and Molossid bat species at several sites in South Africa [Matlapitsi (Y1-3), Madimatle (Y1-3), Table mountain (Y2-3), Black Rock (Y2-3), *Miniopterus* roosts (Y1-3)] to determine the nucleic acid and seroprevalence of filo, henipa- and potentially zoonotic coronaviruses. Sampling in bats will be non-destructive where blood, swabs (oral and rectal) and urine samples will be collected. In addition, we will implement longitudinal surveillance in both *Rousettus* and *Miniopterus* spp. (implicated as filo- and henipavirus hosts), including during birthing periods to investigate seasonality of virus shedding. Once-off sampling in Moz and Zim will focus on the cave-dwelling *R. aegyptiacus* and insectivorous bats co-roosting, including know roosts such as Chinoyi caves. Environmental (weather, rainfall and humidity) and ecological data of the bats (age, reproductive status, sex and measurements) will be collected, as well as population size estimates. We will employ marking and tracking technologies such as tattooing, pit tags (RFID), and telemetry systems to monitor virological status in individuals recaptured over time but also to determine foraging patterns (home ranges, distances traveled and habitat selection) and estimate population sizes. Fieldwork activities will be coordinated by UP (Markotter and postdocs) in collaboration with EHA (Epstein and Phelps), NICD (Weyer), AfricanBats (Seamark and Keith), DNMNH (Kearney) and Department of Agriculture and Rural Development of the relevant provinces (State veterinarians). Ecological and environmental data will also be collected. Testing for viral antibodies and nucleic acids from all bats samples collected will be performed at UP and NICD, RSA, including follow up DNA Sanger sequencing of all positive amplicons and bioinformatics analysis and follow up of serological positives. Detailed sample numbers are indicated in the project narrative but include

**Year 5 (optional): Task 1.** Continued: Build and enhance capacity in Southern Africa to conduct biosurveillance for filo-, henipa- and coronaviruses – Stakeholder workshop, data interpretation workshop, and diagnostic training, Sustain SABRENET. **Task 2.** Continued: Implement biosurveillance in bats in Southern Africa and testing of samples – No more sampling, complete testing of samples **Task 3.** Continued: Conduct targeted observational and human behavior studies – No more data collection, only analyze data **Task 4.** Conduct targeted serological surveys in people and livestock –No more sampling, only testing of samples **Task 5.** Continued: Reporting and Communication – All reporting, develop a communication plan and implement, publications

## DETAILED TASKS

**Year 1: Task 1. Build and enhance capacity in Southern Africa to conduct biosurveillance for filo-, henipa- and coronaviruses** *Description and execution:* Capacity building will focus on South Africa, Mozambique, and Zimbabwe and will follow a One Health approach. It will include development of effective surveillance strategies, developing standard operating protocols, training in biosafety, data analysis, basic epidemiological principles, geographic information systems (GIS), disease modeling, design of human behavioral studies, effective reporting and communication, bat biology and taxonomy and continuous field and laboratory diagnostic training. Analysis of results, reporting, and development of mitigation and threat reduction strategies will involve all stakeholders. Training workshops will be in Y1 and coordinated by UP (Markotter) and EcoHealth Alliance (EHA) (Epstein), after which annual practical training in fieldwork (Y1-Y4), diagnostics (Y1-Y5) and data analysis (Y1-Y5) will continue. Trainees representing animal, human, environmental health and academia will be selected from each partner and country and identified at annual stakeholder workshops. In Y1, a stakeholder workshop (3 days) will be held in Pretoria, RSA, chaired by Markotter (UP) and Epstein (EHA). At least one representative of each partner will attend. This workshop will introduce the projects, roles, responsibilities, timelines, finalize and plan surveillance strategies, development and agreement of standard operating protocols and decide on a standardized reporting policy. General training on biosafety, including sample shipment, human behavioral studies and communication strategies (UP (Markotter; EHA, Epstein and Hagan) will be presented to the larger group after which specific workshops on modeling, data analysis (2 days) (EHA, Olival, Ross) and bat biology and taxonomy (4 days) (AfricanBats, Seamark, DNMNH (Kearney) will commence. Bat field sampling (UP, Markotter and postdocs; EHA, Phelps) and diagnostic training (UP, Markotter and postdocs; NICD, Weyer and Moolla) will be scheduled throughout Y1 with trainees joining field visits (See task 2) and training visits to diagnostic laboratories, UP and NICD (21 days/visit). This will include individuals of the Central Veterinary Laboratories (CVL) from Mozambique (Moz) and Zimbabwe (Zim); postgraduate students involved in research projects and well as technical staff of the partners. A data interpretation workshop is scheduled annually (Y1 in New York, USA for five days). The Co-PIs (Markotter, Epstein), Uniformed University Services (USU, Laing) and postdocs (UP, NICD and EHA) will do in-depth data analysis that can be presented and discussed at stakeholder workshops. Diagnostic technologies to detect filo-, henipa- and coronaviruses for the region at central facilities in South Africa (UP and NICD) will be established. Since molecular technologies are already well established, the focus will be on building serological capacity specifically Luminex technology, in collaboration with USU. USU will present on-site training in South Africa (after the stakeholder workshop), provide reagents (Y1-Y5), and data analysis support (Laing, research assistants x 3). Reagents will be expressed proteins to detect the diversity of filo and paramyxoviruses and positive control antibodies. UP has access to a Bioplex system, but an additional instrument will be purchased in Y1 to accommodate the high throughput of samples collected and tested in this project. Four postgraduate students (PhD/MSc) will be identified in Y1 that will be co-supervised by Markotter (UP), Epstein (EHA), Liang (USU) and NICD (Weyer) respectively (Y1-Y3). Student projects will focus on Luminex filovirus serology, filovirus nucleic acid detection, and movement tracking of frugivorous and

sampling, viral detection techniques, developing standardized protocols, ecological and environmental data collection and observational and human behavior studies.

2) Establishment of serological and nucleic acid detection platforms in key partner laboratories in human and animal health in South Africa that will sustainably build and enhance regional diagnostic capacity and will generate comparable data across the region.

3) Targeted serological and molecular surveillance and screening of samples in bats, as well as additional serological surveillance in potential spillover hosts (livestock and humans) at selected bat-human-animal interphases.

4) Assessing human behavioral risk for exposure to these agents at selected bat-human-animal interphases.

5) Multi-stakeholder workshops to develop a sustainable regional biosurveillance strategy, analyze results and develop mitigation strategies and threat reduction policies for the region.

## **DETAILED DESCRIPTION OF TASKS**

### **SUMMARY**

**Year 1: Task 1.** Build and enhance capacity in Southern Africa to conduct biosurveillance for filo-, henipa- and coronaviruses – Stakeholder workshop and training, data interpretation workshops, the establishment of SABRENET, transfer Luminex technology. **Task 2.** Implement biosurveillance in bats in Southern Africa and testing of samples – Cross-sectional and longitudinal at three sites in South Africa. **Task 3.** Conduct targeted observational and human behavior studies – Only theoretical training in Y1. **Task 4.** Conduct targeted serological surveys in people and livestock – Only start in year 2. **Task 5.** Reporting and Communication – All reporting, develop a communication plan and implement, publications

**Year 2: Task 1.** Continued: Build and enhance capacity in Southern Africa to conduct biosurveillance for filo-, henipa- and coronaviruses – Stakeholder workshop, data interpretation workshop, field sampling, and diagnostic training, Sustain SABRENET. **Task 2.** Continued: Implement biosurveillance in bats in Southern Africa and testing of samples - Cross-sectional and longitudinal at five sites in South Africa. **Task 3.** Continued: Conduct targeted observational and human behavior studies – Design and plan South African studies, ethical clearances. **Task 4.** Conduct targeted serological surveys in people and livestock – Site visits, planning, and ethical clearances, Only in South Africa. **Task 5.** Continued: Reporting and Communication – All reporting, develop a communication plan and implement, publications

**Year 3: Task 1.** Continued: Build and enhance capacity in Southern Africa to conduct biosurveillance for filo-, henipa- and coronaviruses – Stakeholder workshop, data interpretation workshop, field sampling, and diagnostic training, Sustain SABRENET. **Task 2.** Continued: Implement biosurveillance in bats in Southern Africa and testing of samples - Cross-sectional and longitudinal at five sites in South Africa. **Task 3.** Continued: Conduct targeted observational and human behavior studies – Collect data in South Africa, plan studies and obtain ethical clearances for Mozambique and Zimbabwe. **Task 4.** Conduct targeted serological surveys in people and livestock in South Africa. **Task 5.** Continued: Reporting and Communication – All reporting, develop a communication plan and implement, publications

**Year 4 (optional): Task 1.** Continued: Build and enhance capacity in Southern Africa to conduct biosurveillance for filo-, henipa- and coronaviruses – Stakeholder workshop, data interpretation workshop, field sampling, and diagnostic training, Sustain SABRENET. **Task 2.** Continued: Implement biosurveillance in bats in Southern Africa and testing of samples - Cross-sectional and longitudinal at two sites in Mozambique and Zimbabwe, testing of all samples. **Task 3.** Continued: Conduct targeted observational and human behavior studies – Analyze data from South African sites and collect data from Mozambique and Zimbabwe **Task 4.** Conduct targeted serological surveys in people and livestock –Test samples and analyze data **Task 5.** Continued: Reporting and Communication – All reporting, develop a communication plan and implement, publications

## **Biosurveillance for Viral Zoonoses around Bat-Livestock-Human interfaces in Southern Africa**

### **STATEMENT OF WORK**

#### **BACKGROUND**

Over the past four decades, approximately 75% of important emerging and re-emerging diseases were of zoonotic origin and most of these originating from Africa (Chan et al., 2010) and from a wildlife origin (Daszak et al., 2000, Olival et al., 2017). This includes paramyxoviruses in the genus *Henipavirus* such as Hendra (HeV) and Nipah virus (NiV), filoviruses that include Ebola (EBOV) and Marburg virus (MARV), as well as coronaviruses like severe acute respiratory syndrome coronavirus (SARS-CoV), all select agents, causing outbreaks with high mortality in humans. Surveillance data for the Southern African region has been limited, with mostly opportunistic, once-off sampling events focused on restricted geographical regions and selected bat species (Geldenhuys et al., 2013; Ithete et al., 2013; Cronje 2017; Bourgarel et al., 2017; Paweska et al., 2018; Mortlock et al., 2019). Most of these studies were conducted by the University of Pretoria (UP) and collaborators with select agents in bats comprising only a small part of these projects. Also, this surveillance only included molecular detection of pathogens and very limited serological investigations in bat species and none in potential spillover hosts. Preliminary studies indicate that seasonal reproduction of *R. aegyptiacus* drives viral infection dynamics, and that gradual loss of passive immunity among juveniles in this bat population increases the number of susceptible individuals, creating favorable conditions for viral spread. It also results in changes in virus shedding and seroconversion patterns, which are driven by sex, age and reproductive condition of female bats. To understand infection dynamics, longitudinal studies are needed. Southern Africa possesses a rich diversity of bat fauna, including both frugivorous and insectivorous bat species (Monadjem et al., 2010) and this includes *Rousettus*, *Rhinolophus* and *Miniopterus* spp. as well as several free-tail bat species (Mollosidae) implicated as potential hosts for high consequence pathogens in other studies. Livestock such as cattle, goats, and pigs, are also present throughout Southern Africa and overlaps with bat diversity hotspots (Robinson et al., 2014; StatsSA2016). People with frequent close contact with bats due to religious, cultural or sociological reasons (Markotter, personal communication) also inhabit the same areas. Understanding contact between bats, humans and other animals, including behavior analysis, is needed to understand risk in areas where these viral pathogens are present. South Africa plays a prominent role in the Southern African region with laboratory capacity that can be expanded and shared to strengthen sustainable biosurveillance in the region. These pathogens can easily affect any country and therefore biosurveillance capacity must include regional networks and engagement with neighboring countries. This project will strengthen South Africa's, and the region's, capacity to develop and implement surveillance strategies with appropriate biosafety and biosecurity principles, detect pathogens (both molecular and serological) in bats before outbreaks occur, recognize and diagnose outbreaks if they do occur and develop appropriate reporting strategies for the region. All this information can be used collectively to assess risk, predict potential outbreaks, and develop risk mitigation strategies that can be used throughout the region.

#### **OBJECTIVES AND SCOPE**

The overall objective is to detect filo-, henipa- and zoonotic coronaviruses in bat populations in Southern Africa and evidence of spillover in humans and livestock.

Specific objectives to achieve this are:

1) Regional training and establishment of networks in Southern Africa [Southern Africa Bat Research Network (SABRENET)] focused on biosafety, bat capturing techniques, bat taxonomy, virological

## **Biosurveillance for Viral Zoonoses around Bat-Livestock-Human interfaces in Southern Africa**

### **TECHNICAL PROPOSAL**

#### **I. ABSTRACT**

Bat species, which are widespread in the Southern African region and beyond, have been identified as hosts of a number of viral agents, including filo- and viruses related to the Middle East respiratory syndrome (MERS) corona- and paramyxo- such as the henipaviruses. These viruses have proven to cause substantial human morbidity and mortality, threaten livestock and wildlife health and have pandemic potential. However, their distribution and potential to infect people and livestock in Southern Africa are unknown. This project will focus on building capacity and enhancing surveillance, including early detection programs for henipa-, filo- and zoonotic coronaviruses in Southern Africa. The project will specifically address the following: 1) regional training, including biosafety, bat capturing techniques, clinical sampling, viral detection and serological techniques, developing standardized protocols, ecological data collection and human behavioral studies; 2) establishment of serological and nucleic acid detection technologies in South Africa to develop sustainable regional diagnostic capacity that can be shared; 3) targeted serological and molecular surveillance in bats as well as serological surveillance in potential spillover hosts (livestock and humans); 4) assessing human behavioral risk for exposure to these agents; and 5) multi-stakeholder workshops to develop a sustainable regional biosurveillance strategy, analyze results and develop mitigation strategies and threat reduction policies for the region. Planning, training, execution and reporting will use an interdisciplinary One Health approach involving local government agencies of the respective countries including the Departments of Health, Agriculture, Environment, Veterinary and Wildlife Services to ensure long-term sustainability and stakeholder preparedness. The proposed project closely aligns with the aims of the Cooperative Biological Engagement Program with regards to support for biosurveillance, capacity building and threat reduction.

#### **II. SCOPE**

##### **A. OBJECTIVE:**

The overall objective is to detect filo-, henipa- and zoonotic coronaviruses in bat populations in Southern Africa and evidence of spillover in humans and livestock.

Specific objectives to achieve this are:

- 1) Regional training and establishment of networks in Southern Africa [Southern Africa Bat Research Network (SABRENET)] focused on biosafety, bat capturing techniques, bat taxonomy, virological sampling, viral detection techniques, developing standardized protocols, ecological and environmental data collection and observational and human behaviour studies.
- 2) Establishment of serological and nucleic acid detection platforms in key partner laboratories in human and animal health in South Africa that will sustainably build and enhance regional diagnostic capacity and will generate comparable data across the region.
- 3) Targeted serological and molecular surveillance and screening of samples in bats, as well as additional serological surveillance in potential spillover hosts (livestock and humans) at selected bat-human-animal interphases.
- 4) Assessing human behavioral risk for exposure to these agents at selected bat-human-animal interphases.
- 5) Multi-stakeholder workshops to develop a sustainable regional biosurveillance strategy, analyze results and develop mitigation strategies and threat reduction policies for the region.

We propose to test the following **hypothesis**: A diversity of potentially zoonotic henipa-, filo- and coronaviruses circulate in bats in South Africa and neighboring Mozambique and Zimbabwe, and may previously have infected livestock and people in areas where interactions between bats and such

hosts occur. Enhancing biosurveillance and building regional capacity will reduce biothreats by improving the ability to detect, diagnose and report emerging and re-emerging pathogens of biosecurity concern.

## **B. BACKGROUND:**

Over the past four decades, approximately 75% of important emerging and re-emerging diseases were of zoonotic origin and most of these originating from Africa (Chan et al., 2010) and from a wildlife origin (Daszak et al., 2000; Olival et al., 2017). This includes paramyxoviruses in the genus *Henipavirus* such as Hendra (HeV) and Nipah virus (NiV), filoviruses that include Ebola (EBOV) and Marburg virus (MARV), as well as coronaviruses like severe acute respiratory syndrome coronavirus (SARS-CoV), all select agents, causing outbreaks with high mortality in humans. Fatal zoonoses have significant financial implications, with the World Bank estimating economic losses between 1997 to 2009 of US\$80 billion, and that US\$6.7 billion per year could be saved globally by preventing emerging disease outbreaks (Mazet et al., 2015). International agencies such as CDC, USDA, WHO and OIE have identified zoonotic diseases as a threat to global health security with pathogens not adhering to international borders and the ability to spread extensively and rapidly.

**Filoviruses:** The family *Filoviridae* are negative-sense, single-stranded RNA viruses represented by six genera of which two, *Ebolavirus* and *Marburgvirus* (Kuhn et al., 2019), cause fatal hemorrhagic fever outbreaks in humans. The diversity of filoviruses have also expanded in recent years with several novel viral detections in bats including Lloviu virus (LLOV) in Schreibers' long-fingered bats (*Miniopterus cf schreibersii*) in Spain and Hungary (Kemenesi et al., 2018), Mengla virus from China in rousette fruit bats (*Rousettus* spp.) and cave nectar bats (*Eonycteris* spp.) (Yang et al., 2019), as well as Bombali virus from Sierra Leone and Kenya associated with molossid bats [Angolan free-tailed bat (*Mops condylurus*) and the little free-tailed bat (*Chaerephon pumilus*)] (Goldstein et al., 2018; Forbes et al., 2019). MARV was first identified in 1967 in green monkeys imported into Europe from Uganda after laboratory workers became infected (Olival and Hayman, 2014) and has since been detected and isolated in several African countries. Substantial evidence now exists that the Egyptian rousette fruit bat (*Rousettus aegyptiacus*) is a reservoir of MARV (Towner et al., 2009; Amman et al., 2012), and this species is widespread throughout Africa and into the Middle East. Historically, detections have been from central and eastern Africa, but recently MARV was also detected in *R. aegyptiacus* in the northern regions of South Africa (Paweska et al., 2018) and Sierra Leone. Detections have been opportunistic and sporadic, and not always corresponding to where human outbreaks have been identified or representative of the geographic range of the reservoir, which highlights a lack of surveillance. Longitudinal studies identified distinct viral pulses in juvenile bats that corresponded to the timing of human outbreaks, implicating birthing pulses as a driver of infection (Amman et al., 2012). Experimental infection studies of MARV virus in captive-bred Egyptian fruit bats reported viral RNA in oral and vaginal secretions, as well as excreta implicating these as potential routes of transmission (Swanepoel et al., 1996; Leroy et al., 2005; Amman et al., 2015). The first *Ebolavirus* spp. was discovered in 1976 and the genus now consists of six species: *Zaire ebolavirus*, Ebola virus (EBOV), *Bundibugyo ebolavirus*, Bundibugyo virus (BDBV), *Sudan ebolavirus*, Sudan virus (SUDV), *Tai Forest ebolavirus*, Tai Forest virus (TAFV), *Bombali ebolavirus*, Bombali virus (BOMV) and *Reston ebolavirus*, Reston virus (RESTV) (Kuhn et al., 2019) with potentially unique ecological niches. More than 25 human outbreaks have occurred with the most significant being the 2013-2016 outbreak in Guinea, Sierra Leone and Liberia where more than 11000 people died (Spengler et al., 2016). Index cases were reported to have had contact with dead wildlife including non-human primates and antelope, however, these species are not considered viral reservoirs since they also succumbed to the disease. Viral RNA for EBOV has only been detected in bat species with distributions restricted to West Africa and not occurring in Southern Africa, including the hammer-headed bat (*Hypsignathus monstrosus*), Franquet's epauletted fruit bat (*Epomops franqueti*) and little collared fruit bat (*Myonycteris torquata*) (Leroy et al., 2005). However, a recent detection of EBOV has been reported in a Greater long-fingered bat (*Miniopterus*

*cf inflatus*) in Liberia (Epstein personal communication) expanding the potential geographic range for EBOV. Ebolavirus reactive antibodies are present in an even wider range of bat species, including *Epomophorus*, *Rousettus* and *Mops* spp. that do occur in Southern Africa (Olival and Hayman, 2014). RESTV had been detected in *Miniopterus cf schreibersii* in the Philippines (Jayme et al., 2015) again implicating the *Miniopterus* genus. Pigs are currently the only species of livestock known to be at risk of infection by an ebolavirus species as demonstrated by studies in the Philippines and China indicating that they are naturally infected with RESTV (Marsh et al., 2011). The reservoir and geographical distribution of EBOV and other Ebola virus species are still not clear with limited surveillance performed in the Southern African region in wildlife species due to the historical absence of human outbreaks.

**Paramyxoviruses:** This is negative-sense single-stranded RNA viruses capable of infecting a diverse host range including mammals, birds, reptiles and fish (Virtue et al., 2009). HeV and NiV were first detected in the 1990s following outbreaks of fatal respiratory and encephalitic illness in Australia and Malaysia, respectively (Murray et al., 1995; Chua et al., 1999). During the initial emergence, both viruses spilled over into the human population from pteropid bats by means of intermediate hosts, i.e. horses and pigs respectively. Multiple NiV outbreaks have subsequently been reported from Bangladesh and India linked to repeated spillover events from flying foxes of the *Pteropus* genus directly to humans followed by a high rate of human-to-human transmission and high mortality (Gurley et al., 2007a; Chadha et al., 2006; Arunkumar et al., 2018). These viruses have been shown to be excreted in bat urine, saliva and feces (Chua et al., 2002; Smith et al., 2011). In Bangladesh, contamination of date palm sap by bats while feeding overnight, is the primary route of spillover, though other mechanisms of spillover may exist elsewhere (Gurley et al., 2007b). In Malaysia, pigs were infected by pteropid bats after eating dropped fruit contaminated with saliva, and subsequently infected farmers and abattoir workers (Chua et al., 1999; Paton et al., 1999). Initially, the distribution of henipaviruses was believed to be restricted to the geographical distribution of *Pteropus* spp. in Australia and South-East Asia, however, detections of henipavirus-related virus antibodies and nucleic acids in African fruit bat species has expanded the geographical range (Hayman et al., 2008; Drexler et al., 2009). Serological evidence of these viruses in bat populations in several African counties including Zambia, Tanzania, Malawi, Madagascar, and Cameroon, as well as several islands in the Gulf of Guinea were reported (Peel et al., 2012; Peel et al., 2013; Brook et al., 2019). In addition, serological evidence in pigs (Hayman et al., 2011) and antibodies in Cameroonian locals were also identified (Pernet et al., 2014), highlighting the potential of spillover. A number of studies also reported the detection of henipa- and rubulavirus-related viral RNA in several bat species on the African continent (Drexler et al., 2012; Baker et al., 2012; Mortlock et al., 2015) including *Rousettus* and the Straw-coloured fruit bat (*Eidolon helvum*) (Peel et al., 2013). Sosuga virus (*Pararubulavirus* genus) has been the only paramyxovirus associated with human disease on the African continent, following the identification of the virus as the causative agent of a non-fatal febrile disease in a single human infection (Albarino et al., 2014), believed to have spilled over from *R. aegyptiacus* in Uganda (Amman et al., 2015). Various research studies, mostly targeted towards HeV and NiV, have reported strong seasonality associated with dry winters, correlations with bat densities, nutritional stress, and various events during the bat reproductive period (Plowright et al., 2008; Dietrich et al., 2015; Paez et al., 2017; Mortlock et al., 2019) as drivers of infection. The diversity and viral dynamics of henipa- and other potentially zoonotic paramyxoviruses in African bat species are poorly understood with only limited sporadic surveillance.

**Coronaviruses:** These are positive-sense RNA viruses divided into four genera, namely, *Alphacoronavirus*, *Betacoronavirus*, *Gammacoronavirus*, and *Deltacoronavirus*. A number of subgenera were recently assigned to each of these genera (Wong et al., 2019) due to an expansion of global diversity. These viruses can undergo recombination, creating new variants that may result in spillover infections and manifest as respiratory pathogens in humans that are transmitted through aerosols. Bat coronaviruses are predominantly excreted in faecal material, though oral swabs, and

urine have also tested positive implicating several routes of transmission. Severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) coronaviruses emerged in 2002 and 2012 respectively, and both pandemics resulted in significant morbidity and mortality (10% and 35%, respectively) in humans, which was exacerbated by global travel (Berry et al., 2015). Global coronavirus surveillance increased significantly after the detection of SARS. In the subsequent search for the reservoir, serological and partial nucleic acid detection in 2005 linked SARS-CoV to horseshoe bats (*Rhinolophus*) in China by identifying a closely related virus. Subsequent studies identified an even larger diversity of SARS-CoV-related viruses in horseshoe bats worldwide (Hu et al., 2017; Lau et al., 2010), however, the virus protein responsible for receptor-binding that mediates cellular entry (spike protein) (Li et al., 2005) was unable to interact with the SARS-CoV virus receptor. Thus, it is unlikely that any of these identified SARS-CoV related viruses were the source of the SARS-CoV human outbreak (Li et al., 2005). Recently a bat SARS-related CoV was found to possess a spike protein that facilitated binding to the same virus receptor as SARS-CoV (Ge et al. 2013; Yang et al., 2016), indicating the potential to cross species barriers and infect humans directly. In 2012, Middle East Respiratory syndrome virus (MERS) was identified in the Arabian Peninsula (Zaki et al., 2012), and a partial nucleic acid sequence was detected in an Egyptian tomb bat (*Taphozous perforates*) from Saudi Arabia (Memish et al., 2013). It has subsequently been shown that detected bat MERS-related CoVs are only distantly related to MERS-CoV and dromedary camels are considered the reservoir species transmitting the virus to people. Diverse coronavirus sequences were found in many different bat species worldwide, leading to the hypothesis that bats host the genetic diversity of the *Alphacoronavirus* and *Betacoronavirus* mammalian infecting genera (Woo et al., 2012), however, the risks and factors important to spillover is unknown (Hu et al., 2017; Anthony et al., 2017a). The diverse SARS-related coronaviruses circulating within the horseshoe bat (*Rhinolophus*) genus throughout their Asian, European or African distribution make this an important host genus to monitor for viral diversity and novel emergences.

**Surveillance data for the Southern African region** has been limited, with mostly opportunistic, once off sampling events focused on restricted geographical regions and selected bat species (Geldenhuys et al., 2013; Ithete et al., 2013; Cronje 2017; Bourgarel et al., 2018; Paweska et al., 2018; Mortlock et al., 2019). Southern Africa possesses a rich diversity of bat fauna including both frugivorous and insectivorous bat species (Monadjem et al., 2010) distributed across several biotic zones, but mostly concentrated in the eastern region of the continent, including areas in South Africa, Mozambique, Zimbabwe, Malawi and Zambia (Cooper-Bohannon et al., 2016). In addition to the taxonomic diversity, these bat species also exemplify a diversity of roosting behavior and site selection including trees, rock crevices and man-made structures. This include *Rousettus*, *Rhinolophus* and *Miniopterus* spp. as well as several free-tail bat species (Molossidae) implicated as potential hosts for high consequence pathogens in other studies. If pathogens are present, several factors play a role in spillover to other species and very few studies investigated this. This include host ecology, movement of bats (both foraging and long term movement), viral shedding and routes of transmission. These factors may be seasonal, emphasizing the need for longitudinal studies. Livestock such as cattle, goats, and pigs, are also present throughout Southern Africa and overlaps with bat diversity hotspots (Robinson et al., 2014; StatsSA2016). People with frequent close contact with bats due to religious, cultural or sociological reasons (Markotter, personal communication) also inhabit the same areas. This bat-human-animal interphase and risk for spillover has not been studied in the region. Habitat loss, primarily through deforestation has been increasing in the Southern African region (Brink and Eva, 2009), and there is evidence of increased bushmeat consumption (Regan et al., 2015; Lindsey et al., 2013). Understanding contact between bats, humans and other animals, including behavior analysis, are needed to understand risk in areas where these viral pathogens are present.

Several factors need to be considered when designing biosurveillance strategies in bats. Individuals do not generally exhibit signs of disease, populations can be large with low viral

prevalence and seasonality affect prevalence and transmission. Detection of viral nucleic acids can therefore be challenging and should be paired with **serological surveys**, which take advantage of long-term antibody persistence. Serology has some limitations including inherent antibody cross reactivity between target and related viruses, statistical interpretation of seropositive cut-offs, limited bat specific assays and control sera, and not being able to directly characterize the infectious agent involved. As a result, greater value can be achieved when combining serological surveys with molecular detection assays and subsequent viral characterization. When investigating potential spillover in non-bat hosts, such as domestic animals and humans, serology can be a more comprehensive strategy given the commercially available reagents that can be used to detect both past/convalescent (immunoglobulin G) and recent/acute (immunoglobulin M) infections. Serological assays for emerging zoonotic pathogens are limited and mostly based on in-house assays using different methodologies including virus neutralization, ELISA, western blots and indirect fluorescent assays (IFAs) and can only detect evidence of exposure to a single virus target. Multiplex serological assays using Luminex xMAP-based technology offer the advantage to simultaneously detect virus specific and cross-reactive antibodies in a single test, saving time, resources and cost. Since the volume of bat sera collected in surveillance is limited, this is a major advantage. The Luminex system is based on the principles of flow cytometry, allows for multiplexing at least 100 analytes in a single microplate well and uses very small sample volumes (2 µl). This assay uses inactivated serum and recombinant reagents, which means the analysis can be performed in a Biosafety Level 2 laboratory. This technology has been successfully used in surveillance studies in bats and spillover hosts including detection of antibodies against paramyxoviruses and filoviruses (Brook et al., 2019; Laing et al. 2018; Hayman et al., 2011; Peel et al., 2012; Chowdhury et al., 2014;) (See preliminary results for more detail). Broadly reactive **molecular RT-PCR assays** based on the conserved regions of viral genomes at family or genus level have been successfully used in surveillance studies for the viral families targeted in this proposal (See work plan for detail). These assays target short genomic regions that can be sufficient for determining phylogenetic relationships, but not formal genus or viral species demarcation that requires longer gene and/or genome sequences. For this, additional sequencing data is needed including targeting regions that may be important in spillover potential such as the receptor-binding and virulence factor encoding regions.

### **C. RELEVANCE; SCIENTIFIC AND THREAT REDUCTION IMPACT:**

South Africa plays a prominent role in the Southern African region with laboratory capacity that can be expanded and shared to strengthen sustainable biosurveillance in the region. These pathogens can easily affect any country and therefore biosurveillance capacity must include regional networks and engagement with neighboring countries. Surveillance data will identify presence but also shedding of high consequence viruses in different seasons, bat species and biomes. Serological investigations will identify if spillover in livestock and humans occurred in the past and behavioral analysis will investigate risk factors for potential spillovers that may happen in the future. This project will strengthen South Africa's, and the region's, capacity to develop and implement surveillance strategies with appropriate biosafety and biosecurity principles, detect pathogens (both molecular and serological) in bats before outbreaks occur, recognize and diagnose outbreaks if they do occur and develop appropriate reporting strategies for the region. All this information can be used collectively to assess risk, predict potential outbreaks, and develop risk mitigation strategies that can be used throughout the region. It follows a One Health approach involving multi-sectoral stakeholders including government engagement and local communities to enhance communication and threat reduction activities. A regional network, Southern African Bat Research Network (SABRENET), will be established to improve communication and collaboration between countries and between disciplines. Sustainability and threat reduction will be specifically addressed by workshops involving all stakeholders from multiple Southern African countries and to align with the Global Health Security Agenda, and comply with the International Health Regulations (IHR) and other reporting guidelines. This project is closely aligned with the goals of the Cooperative Biological Engagement

Program (CBEP) and align with several of the Biological Threat Reduction Programme (BTRP) Lines of effort (LOE) including National Regulatory Frameworks (LOE3), Disease detection (LOE4), Laboratory diagnosis (LOE5), Epidemiological Analysis and investigation (LOE6) and Reporting and Communication (LOE7).

**D. PRELIMINARY WORK AND ESTABLISHED COLLABORATIONS (See table 1 for explanation of abbreviations for institutions):**

The two major partners, UP, South Africa (Markotter) and EHA, USA (Epstein) will combine their expertise in implementing surveillance programs and diagnostic sample testing. The major partners will also establish regional networks, and link with international networks including the Bat One Health Network (BOHRN), EcoHealthNet (an NSF-funded disease ecology research training program led by EHA), and the Western Asia Bat Research Network (WABNet). UP and EHA initiated discussions about possible collaborations five years ago and both UP and EHA currently collaborate with CEZPD-NICD. UP also collaborated with AfricanBats NPC (Seamark) and DNMNH (Kearney) since 2004. This includes training activities, joint fieldwork, co-supervision of students, as well as several joint publications. UP already has DAFF section 20 approval to research zoonotic pathogens in bats in Southern Africa and regularly communicate surveillance data to DAFF and NDoH. UP has been collaborating with USU (Broder) since 2017, and has initiated acquisition of Luminex reagents for filo- and henipavirus testing including a signed Material transfer agreement. EHA also have a successful collaboration with USU. EHA and CEZPD-NICD have a joint DTRA project on Rift Valley fever virus since 2014. UP has previously collaborated with the CVL laboratories in Mozambique and Zimbabwe, with joint publications on rabies as an output. Preliminary surveillance activities in small mammals were also conducted in Mozambique in 2017, and a preliminary visit to the CVL laboratory in Zimbabwe was conducted in 2018 to discuss future collaborations. Previous studies led by the South African team, including UP, CEZPD-NICD, DNMNH and AfricanBats have reported detections of several potential zoonotic pathogens in bats (Figure 1). This work was performed under the South African Research Chair of Prof. Markotter funded by the South African Department of Science and Innovation (ongoing) and the Global Disease Detection Programme of the Centers for Disease Control and Prevention (USA) 2016-2019. Biosurveillance on select agents in bats was only a small part of these projects, and therefore surveillance studies were sporadic and limited in scope to only specific bat species and limited

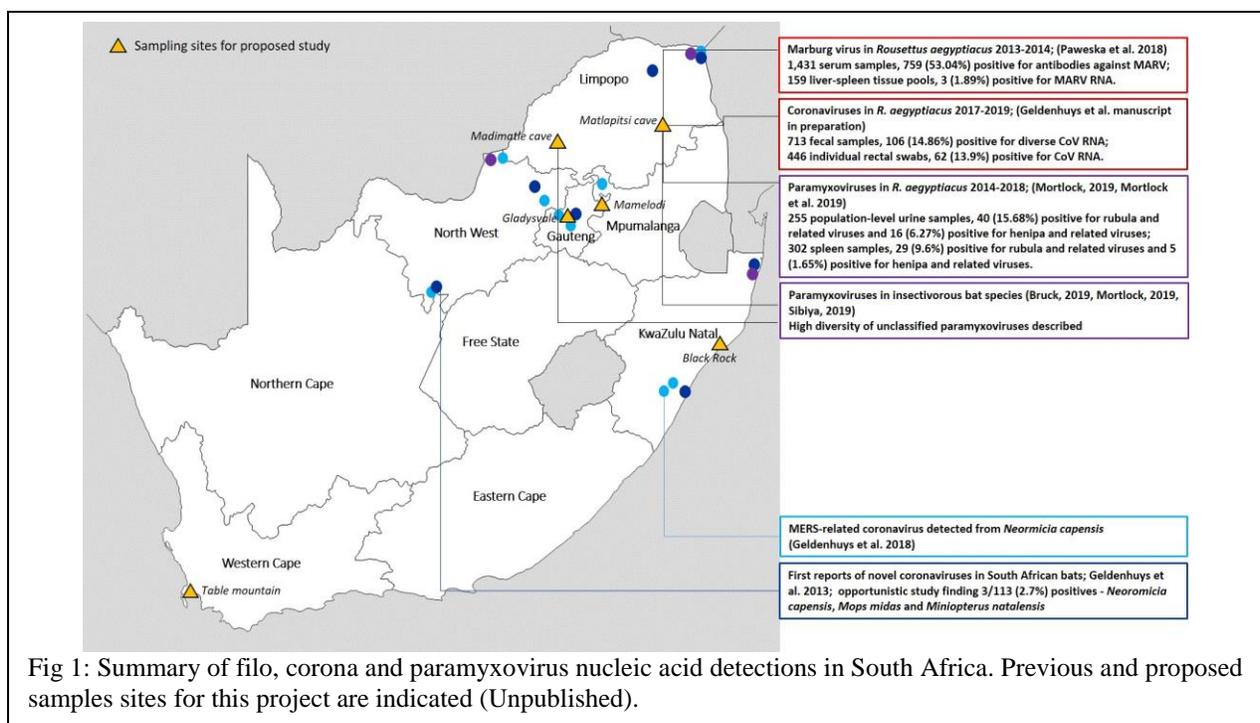

Fig 1: Summary of filo, corona and paramyxovirus nucleic acid detections in South Africa. Previous and proposed samples sites for this project are indicated (Unpublished).

geographical locations in South Africa. In addition, this surveillance only included molecular detection of pathogens and very limited serological investigations in bat species and none in potential spillover hosts. Preliminary studies indicate that seasonal reproduction of *R. aegyptiacus* drives viral infection dynamics, and that gradual loss of passive immunity among juveniles in this bat population increases the number of susceptible individuals, creating favorable conditions for viral spread (Figure

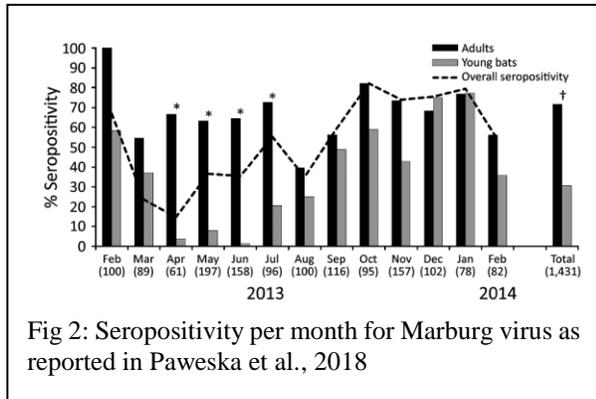

Fig 2: Seropositivity per month for Marburg virus as reported in Paweska et al., 2018

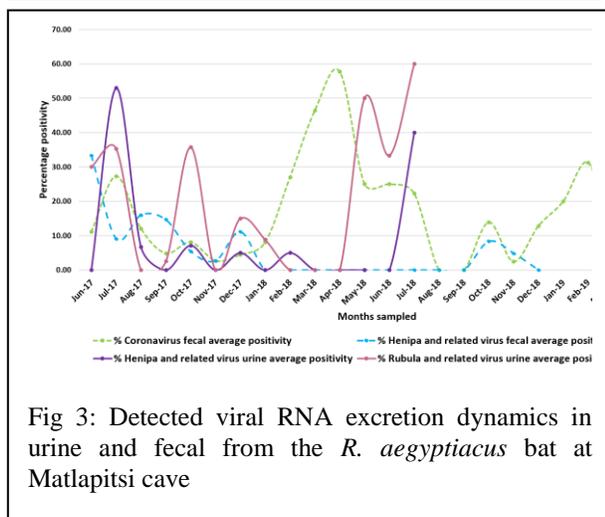

Fig 3: Detected viral RNA excretion dynamics in urine and fecal from the *R. aegyptiacus* bat at Matlapitsi cave

2). It also results in changes in virus shedding and seroconversion patterns, which are driven by sex, age and reproductive condition of female bats (Figure 2 and 3). Molecular assays to detect paramyxo-, corona- and filoviruses are established in the South African laboratories (UP and NICD) with some improvements needed (see detail under Work plan). Serology was not part of previous studies, with the exception of targeted Marburg virus serological studies. At the time, we had no feasible serological option available that could accommodate a multiplex platform suitable for low amounts of sera collected from bats and we initiated discussions to obtain luminex reagents from USU. Purified oligomeric, receptor-binding protein (G) of henipaviruses (e.g. HeV and NiV) have been used by the USU lab and collaborators for several years in antigen-based immunoassays to differentiate antibodies specific to HeV or NiV (Bossart et al., 2007), and in biosurveillance studies to examine exposure to these high priority viruses (Chowdhury et al., 2014; Peel et al., 2012) (Figure 4). With the isolation of new viruses including Cedar virus (CedV), Ghana virus (GhV) and Mojiang virus (MojV), the lab has continued to generate tetrameric henipavirus G for all presently described henipaviruses, and expand the HeV/NiV

immunoassay into a pan- henipavirus multiplex assay capable of simultaneously

detecting and differentiating henipavirus-specific antibodies. Furthermore, USU constructed native-

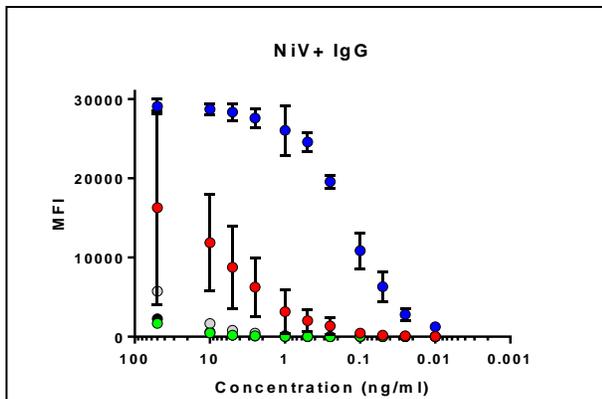

Figure 4: Pan-henipavirus immunoassay can specifically differentiate between antibodies reactive with heterologous viruses. Rabbits were immunized with virus specific G antigens. Antisera were screened with multiplex pan-henipavirus immunoassay in two independent experiments in technical triplicates; bars indicate 95% confidence intervals.

like glycoprotein antigens of all presently described filoviruses to generate a pan-filovirus antigen-based immunoassay that can be simultaneously used with the pan-henipavirus immunoassay to detect antibodies reactive with four of the WHO priority pathogens with pandemic potential. This pan-filovirus immunoassay was used by Laing et al. to detect serologic evidence of Asiatic filoviruses, antigenically-like ebolaviruses, in three fruit bat species collected in Singapore (Laing et al., 2018) (Figure 5).

This assay was also used at the National Centre for Biological Sciences, Bangalore, India in a DTRA BTRP supported project to Duke-NUS researcher Dr. Ian Mendenhall, to detect exposure to Asiatic filoviruses in bats and humans hunting these bats for food, implicating likely cross-species transmission of novel filoviruses at this wildlife-human interface (Figure 6) (Dovich et al., 2019).

This pan-filovirus/henipavirus immunoassay has

been transferred to three laboratories in Peninsular Malaysia where it is being utilized in serology-based biosurveillance of wildlife (e.g. bats), livestock and indigenous human communities, funded by DTRA BTRP to Co-PI J. Epstein and contributed further evidence that a diversity of novel Asiatic

filoviruses, distantly related to Reston virus, but with unknown pathogenesis, circulate in certain species of bats.

In collaboration with DNMNH, a taxonomic database for bat species, including voucher specimens with morphological classification and genetic sequence confirmation, has been generated for most South African bat species, and for some species in Zimbabwe and Mozambique. UP, USU and EHA have developed several standard operation procedures and training material for past studies including

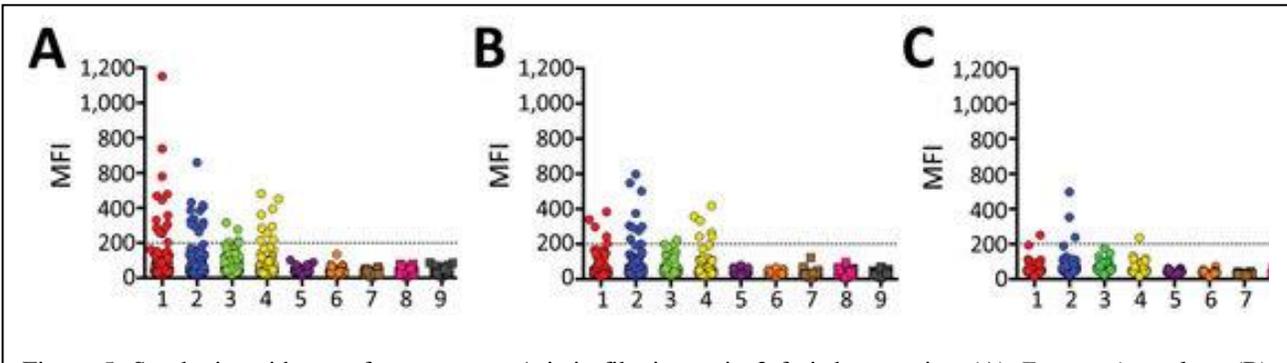

Figure 5. Serologic evidence of exposure to Asiatic filoviruses in 3 fruit bat species. (A) *Eonycteris spelaea* (B) *Cynopterus brachyotis* (C) *Penthetor lucasi*. Mean fluorescence intensity (MFI) values obtained from Bio-Plex assay (Bio-Rad, Hercules, CA, USA) screening of individual serum samples from bats of 3 species with soluble filovirus glycoproteins. Dashed line indicates the cutoff value at 200 MFI. 1, *Zaire ebolavirus*; 2, *Bundibugyo ebolavirus*; 3, *Tai Forest ebolavirus*; 4, *Sudan ebolavirus*; 5, *Reston ebolavirus*–monkey; 6, *Reston ebolavirus*–pig; 7, Marburg virus–Musoke; 8, Marburg virus–Angola; 9, Ravn virus.

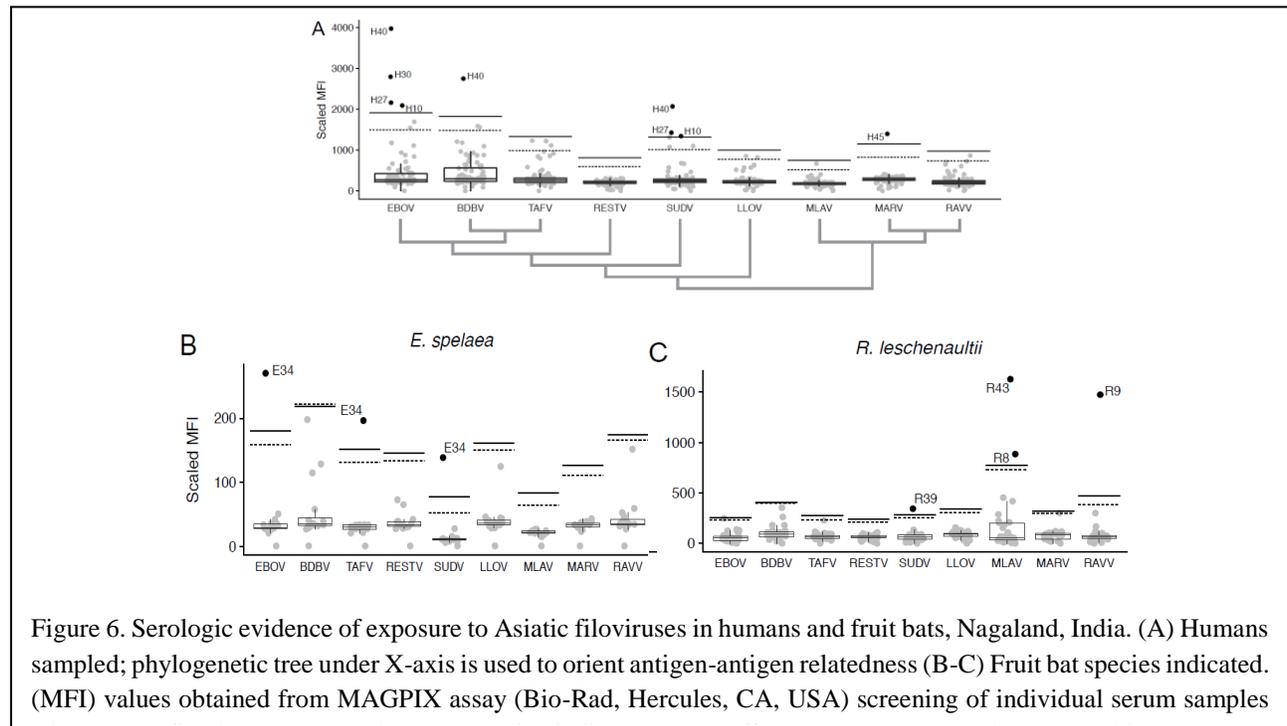

Figure 6. Serologic evidence of exposure to Asiatic filoviruses in humans and fruit bats, Nagaland, India. biosafety, collection of bat samples, RT-PCR testing, DNA sequencing, bioinformatics analysis, luminex serological testing and behavioral risk assessment tools. This will be revised in Y1 and improved where necessary.

**E. INSTITUTIONS AND ROLES (Summarized in table 1):**

**University of Pretoria (UP; prime (PI)), Pretoria RSA,** Will finalize and implement the study design, coordinate overall project, coordinate and present training and workshops, develop and finalize SOPs, supervise Hons, MSc, PhD and post-doctoral students, obtain relevant regulatory and

ethical approvals in coordination with relevant government departments; coordinate and perform all field work, coordinate sample testing and testing of all animal samples, coordinate behavioural studies in coordination with relevant government agencies and partners; build diagnostic capacity in the UP laboratory (focused on animal sample testing) that can be shared including hosting and training of partners from neighbouring countries; data analyses, report and publish data; disease modelling and assessing risk mitigation strategies; and development of threat reduction policies. UP will be responsible for all contractual obligations with DTRA including reporting. **Staff:** Wanda Markotter (PI, Overall coordination – involved in all activities listed above), Jessica Coertse (Postdoctoral fellow, Bat filovirus surveillance), Marike Geldenhuys (Postdoctoral fellow, Bat coronavirus surveillance), Marinda Mortlock (Postdoctoral fellow, Bat paramyxovirus surveillance), Liz Basson (Grant administrator), Research assistants x 4 (fieldwork, processing and testing of samples (molecular and serology), database management) (To be hired), students to be identified (PhD, MSc and Honours),

**EcoHealth Alliance (EHA; sub (Co-PI), NY USA,** Will co-develop and implement the study design, coordinate and present training workshops, develop and finalize SOPs, co-supervise students, develop and implement human behavioural studies in coordination with relevant government agencies; fieldwork training and sampling (limited), data analyses, report and publish data; disease modelling and assess risk mitigation strategies; and development of threat reduction policies, develop awareness material. **Staff:** Jonathan Epstein (Co-PI – Involved in all activities listed above), Noam Ross (Disease modelling), Kendra Phelps (Fieldwork training and finalizing SOPs), Kevin Olival (Risk mapping, Developing SOPs & participating in training workshops, linkage with other bat networks e.g. WABNet), Emily Hagan (Develop and direct behavioural risk tools and analysis, assist in developing and implementing risk reduction strategies, community engagement and outreach material development), 1 postdoc and 1 PhD student who will work on disease modelling in bats and spatial analysis of movement data, respectively (To be identified).

**Uniformed Services University (USU, sub CO-I), Maryland USA,** Will develop and transfer Luminex reagents and SOPs to UP and NICD; train laboratory staff; co-supervise MSc and PhD students involved in serological projects; analysis and interpretation of filo-, henipa-, and coronavirus serological data; standardization of multiplex immunoassay and data interpretation. Assess risk mitigation strategies and development of threat reduction policies. **Staff:** Eric Laing (Co-investigator – Involved in all activities listed above), Christopher Broder (Head of the research group, scientific expertise and guidance), Laboratory technicians x 3 (Preparation of Luminex reagents at USU and assistance with training and data analysis).

**National Institute for Communicable Diseases (NICD) Centre for Emerging Zoonotic and Parasitic Diseases (CEZPD) (CO-I), RSA,** Develop SOPs specifically for laboratory diagnostics, fieldwork and reporting, co-supervise Hons, MSc, PhD and post-doctoral students, obtain relevant regulatory and ethical approvals pertaining to human studies in coordination with relevant government departments; coordinate and perform field work, involved in human behavioural and serological studies in coordination with relevant government agencies; build diagnostic capacity in the NICD laboratory that can be shared including hosting and training of partners, provide serological positive and negative serum panels, verify positive serology results obtained from the luminex, analyse results, report and publish data. Assess risk mitigation strategies; and development of threat reduction policies **Staff:** Jacqueline Weyer (Co-investigator – Involved in all of the above), Janusz Paweska (Head of the research group, scientific expertise and guidance), Naazneen Moolla (Medical scientist – Assistance and verification of luminex serological results), Postdoctoral fellow (Human and livestock serology) to be identified.

**Table 1: Prime and partner institutions and summarized roles**

	Study design and coordination	Contractual obligation with DTRA and in-country lead	Regulatory and ethical requirements	Coordinate and/or attend training	Development of SOPs	Collection of bat samples	Collection of host, environmental and ecological data	Collection of livestock samples	Collection of human samples	Molecular testing of samples	Transfer of Luminex technology and testing of samples	Human behavioral studies	Disease modelling	Co-analyze and reporting of data. Risk mitigation strategies and development of threat reduction policies
University of Pretoria (UP), Centre for Viral Zoonoses, South Africa (PI: Prof. Markotter)														
EcoHealth Alliance (EHA), USA (Co-PI: Dr Epstein)														
Uniformed Services University (USU), USA (CO-I: Dr Laing)														
National Institute for Communicable Diseases (NICD), Centre for Emerging Zoonotic and Parasitic Diseases (CEZPD), South Africa (Co-I: Dr. Weyer)														
Department of Agriculture, Land Reform and Rural development (DALRRD previously DAFF), South Africa together with KwaZulu-Natal, Limpopo and Western Cape Department of Agriculture and Rural Development														
National Department of Health (NDoH), South Africa														
National Department of Environment, Forestry and Fisheries (DEFF), South Africa														
Central Veterinary laboratories (CVL), Agrarian Research Institute of Mozambique, Ministry of Agriculture and Food Security, Department of Veterinary Services and Wildlife services, National Ministries of Health, Mozambique and Zimbabwe														
AfricanBats NPC, South Africa, Mr. Seamark														
Ditsong National Museum of Natural History (DNMNH), South Africa: Dr Kearney														

**Department of Agriculture, Land Reform and Rural Development (DALRRD previously DAFF) together with KwaZulu, Limpopo and Western Cape Departments of Agriculture and Rural development, RSA,** Identify representatives and attend training, meetings and workshops from the animal health sector, assistance with obtaining local regulatory documents and import permits, take part in and assist with field studies for collection of bat and livestock samples in South Africa, co-analyze data, report and publish, assess risk mitigation strategies and development of threat reduction policies. **Staff:** Grietjie de Klerk, DVM (Director - Involve in all of the above), Alicia Cloete (Epidemiologist, Involve in all of the above), State veterinarians for sampling areas; Limpopo, Western Cape and KwaZulu Natal RSA (assist and facilitate collection of bat and livestock samples and reporting).

**National Department of Health (nDoH), RSA,** Identify representatives and attend training, meetings and workshops from the human health sector, assist with collection of human samples and behavioral questionnaires in South Africa, co-analyze data, report and publish. Assess risk mitigation strategies and development of threat reduction policies. **Staff:** Wayne Ramkrishna (Epidemiologist - Involve in all of the above)

**National Department of Environment, Forestry and Fishery (DEFF) RSA**, Identify representatives and attend training, meetings and workshops from the environmental health sector, co-analyze data, report and publish, assess risk mitigation strategies and development of threat reduction policies. **Staff:** Abednego Baker - Involve in all of the above.

**Central Veterinary laboratories (CVL), Agrarian Research Institute of Mozambique, Ministry of Agriculture and Food Security, Mozambique**, Identify relevant trainees in animal health, attend training and workshops, coordinate field studies in Mozambique, collect and test samples collected in Mozambique in South Africa, assistance with obtaining local regulatory documents, co-analyze data, report and publish, assess risk mitigation strategies and development of threat reduction policies. **Staff:** Sara Achá (Veterinarian and researcher – Head of laboratory), Lourenço Mapaco (Veterinarian and researcher – Involved in training, fieldwork and testing of samples), Iolanda Vieira Anahory Monjane (Veterinarian, researcher and country coordinator for Mozambique study, involved in training, fieldwork and testing of samples).

**Central Veterinary laboratories (CVL), Agrarian Research Institute of Zimbabwe, Ministry of Agriculture and Food Security Department of Veterinary Services and Wildlife services, Zimbabwe**, Identify relevant trainees in animal health, attend training and workshops, coordinate field studies in Zimbabwe, collect and test samples collected in Zimbabwe in South Africa, assistance with obtaining local regulatory documents, co-analyze data, report and publish, assess risk mitigation strategies and development of threat reduction policies. **Staff:** Pious Makaya (Veterinarian – Laboratory Head), Babra Bhebhe (Veterinarian and coordinator for Zimbabwe study, involved in training, fieldwork and testing of samples)

**National Ministries of Health, Mozambique**, Identify relevant trainees in human health, attend training and workshops, coordinate human behavior studies in Mozambique, assistance with obtaining local regulatory documents, co-analyze data, report and publish, assess risk mitigation strategies and develop threat reduction policies. **Staff:** Inocência Salvador Chongo (focal point of One Health group at the Ministry of Health - Involve in all of the above)

**National Ministries of Health, Zimbabwe**, Identify relevant trainees in human health, attend training and workshops, coordinate human behavior studies in Zimbabwe, assistance with obtaining local regulatory documents, co-analyze data, report and publish, assess risk mitigation strategies and develop of threat reduction policies. **Staff:** To be identified

**AfricanBats NPC, RSA**, Coordinate and present training and workshops focused on bat biology and taxonomy, develop SOPs focused on these topics, coordinate all field studies focused on *Miniopterus* spp. and assistance with other fieldwork, assistance with RFID tracking and environmental monitoring at bat roosts, echolocation data analyses co-analyze data, report and publish data. Assess risk mitigation strategies and development of threat reduction policies. **Staff:** Ernest Seamark (Chief Executive Officer) and Dr. Mark Keith (Board of Directors) (Involvement of all of the above).

**Ditsong National Museum of Natural History (DNMNH), RSA**, Coordinate and present training and workshops focused on bat biology and taxonomy, developing SOPs focused on these topics, Involved in fieldwork, taxonomic identification of bats collected and administration of museum vouchers, comparison of morphological and genetic identification of bat species, co-analyze data, report and publish data. Co-supervision of students, assess risk mitigation strategies and development of threat reduction policies. **Staff:** Teresa Kearney (Research scientist/taxonomist – Involvement in all of the above).

#### **F. CREDENTIALS (See detailed bio sketches of key staff for additional information):**

**University of Pretoria (UP)** is a leading research-intensive university and is recognized nationally and internationally for the quality of its research and the extent of its research outputs. UP is also ideally situated in the executive capital of South Africa, Pretoria, in close proximity to the International airport (O.R Tambo) ensuring ease of travel to enhance collaborations and student exchange. One Health and zoonotic diseases is an important research theme and the Centre for Viral Zoonoses was established in 2016 to enhance multidisciplinary collaboration between the faculty of

Health Sciences, Natural and Agricultural Sciences and the only Veterinary Science faculty in South Africa. The UP has solid strength in the zoonosis research field and has in the last number of years made a series of significant financial and other contributions to support this research. Recently the Future Africa Institute was established to facilitate interdisciplinary research and this include state of the art training and meeting facilities. UP is also ideally situated close to several important collaborative networks including NICD, Onderstepoort Veterinary Institute (ARC-OVI), NDOH, DALRRD (DAFF) and DEFF. UP has a financial and grant management infrastructure and has successfully managed USA federal funding. Infrastructure include a biosafety level 3 laboratory, ultra-low temperature freezers in a biobank with back-up generator power, molecular and serological laboratories and Sanger DNA sequencing and next generation sequencing facilities on site. It also include information technology and bioinformatics infrastructure. Several established field sites exist as well as basic infrastructure and equipment to sample bats. **PI: Prof. Wanda Markotter** is the Director of the Centre for Viral Zoonoses and since January 2016 she is also occupying a South African Research Chair in “Infectious Diseases of Animals (Zoonoses)” funded by the South African government. She is a virologist who is involved in a multidisciplinary research programme on disease ecology in bat species in South Africa and other African countries leading to several high impact research outputs. Experience include molecular and serological diagnostics and fieldwork to collect samples. Her research group consist of support staff, postdoctoral fellows and several post graduate students that also have extensive experience in this field. She plays a key role in national governmental committees including the National Rabies Advisory Group and National One Health forum steering committee.

**EcoHealth Alliance (EHA)** is a scientific organization, working with local partners in over 30 countries at the nexus of health, biodiversity conservation and international development. EHA has a staff of 35 in New York, including scientists (e.g. social scientists, veterinarians, ecologists, analysts, IT experts, and economists), administration, and communications staff. EHA has an extensive record of publishing high quality, peer-reviewed papers, journals, briefing documents and reports, including seminal work on emerging infectious diseases and bat borne viral zoonoses with particular expertise in modelling of host-virus dynamics and human behavioural analyses. EHA’s ability to produce highly utilized and understandable science-based outputs will contribute significantly to achieving project goals and provide objective methods for tracking project utilization of project findings. In 2014, EHA became the first foreign NGO to sign a Memorandum of Agreement (MOA) with the Government of Malaysia. The MOA is to study zoonotic disease in populations exposed to wildlife and includes three sectors of government: Ministry of Health, The Department of Wildlife and National Parks, and The Department of Veterinary Services. **Co-PI: Dr. Jonathan Epstein** is a veterinary epidemiologist and the Associate Vice President at EHA. He is a technical lead for surveillance and outbreak response under the USAID Emerging Pandemic Threats: PREDICT program, a \$100 million effort focused on predicting and preventing pandemic diseases. Dr. Epstein is recognized internationally for his expertise on the ecology of emerging zoonotic viruses and currently directs research and surveillance programs in West Africa, South and Southeast Asia, and China. He has led investigations of NiV, EBOV, SARS CoV and MERS CoV in Asia, the Middle East, and Africa. He has also served as a consultant for WHO, FAO, OIE, and the Institute of Medicine.

**Uniformed Services University (USU)** is a US federal government health science university that trains military physicians through medical school, military masters of public health and military & civilian doctoral candidates in varying disciplines including emerging infectious diseases, and microbiology. USU hosts the Center for Global Health Engagement chapter, which has a mission to support the Department of Defense Global Health Engagement. USU has a world renowned health science faculty who have close ties with the proximally located Walter Reed Army Institute of Research and Naval Medical Research Centers. The Department of Microbiology and Immunology includes 12 full-time Faculty members, and has an overall focus on mechanisms of infectious diseases

and the host response/immunology. Faculty interests and active research programs at USU are diverse, with many nationally- and internationally-known investigators researching areas of viral immunology, vaccine and antiviral therapeutics, and animal model development. USU is also physically located directly across from the main NIH campus in Bethesda, Maryland. The overall broad scientific environment at both USU and the NIH is highly conducive to productive collaborations.

**National Institute for Communicable Diseases (NICD), Centre for Emerging Zoonotic and Parasitic Diseases (CEZPD)** The NICD is a national public health institute of South Africa, providing reference microbiology, virology, epidemiology, surveillance and public health research to support the government's response to communicable disease threats. The NICD serves as a resource of knowledge and expertise of communicable diseases to the South African Government, Southern African Development Community countries and the African continent. The institution assists in the planning of policies and programmes to support and respond to communicable diseases. CEZPD was established by the amalgamation of six former NICD sections: Special Bacterial Pathogens Reference Laboratory, Special Viral Pathogens Reference Laboratory, Arbovirus Reference Laboratory, Electron Microscopy, Parasitology Reference Laboratory and Vector Control Reference Laboratory. The CEZPD operates the only suit biosafety level 4 (BSL4) facility on the African continent, which places it both strategically and critically in a position to assist in the response of highly dangerous emerging and re-emerging zoonotic pathogens.

**Department of Agriculture, Land Reform and Rural Development (DALRRD previously DAFF), RSA together with KwaZulu Natal, Limpopo and Western Cape Department of Agriculture and Rural Development** and specifically the Animal Health section aim to manage risk associated with animal health by promoting, preventing and controlling animal diseases including zoonoses. This includes formulating policies and rendering epidemiological services for early warning and monitoring of animal diseases. Provincial departments and specifically the state veterinarians are involved in sampling animals.

**National Department of Health (NDoH), RSA** aim to improve the health status through the prevention of illnesses and the promotion of healthy lifestyles and to consistently improve the healthcare delivery system by focusing on access, equity, efficiency, quality and sustainability. The Directorate of Communicable Diseases include zoonoses and include multisector committees to report surveillance data and mobilize outbreak responses. This also include a National One Health forum including all stakeholders.

**National Department of Environment, Forestry and Fisheries (DEFF), RSA** aim to ensure an environment that is not harmful to people's health or wellbeing, and to have the environment protected for the benefit of present and future generations. To this end, the department provides leadership in environmental management, conservation and protection towards sustainability for the benefit of South Africans and the global community.

**Central Veterinary laboratories (CVL), Mozambique,** CVL is a technical department of the Directorate of Animal Science (DCA), of the Agrarian Research of Institute of Mozambique (IAM) and is the national reference laboratory. The role is to perform animal diseases diagnostics and epidemiological studies; to identify and propose research area on animal diseases; to develop research methodologies and standardized techniques for animal diseases and zoonotic diseases; to guarantee the specialized training and follow-up of laboratory technicians and to provide technical assistance to the regional and provincial laboratories. There is a One Health Technical Working Group (TWG) established which includes different stakeholders: Ministries of Health, Agriculture and Food Security, Fisheries, Environmental and Wildlife.

**Central Veterinary laboratories (CVL), Department of Veterinary Services and Wildlife services Zimbabwe,** CVL is a branch under the Directorate of the Division of Veterinary Technical Services of the Department of Veterinary Services. Veterinary Services falls under the Ministry of Lands, Agriculture, Water, Climate, and Rural Resettlement. The role is to provide diagnostic support

for zoonotic diseases and diseases of economic interest in animals, epidemiological disease investigations and surveillance of diseases as well as Food safety monitoring and Port Health Services.

**AfricanBats NPC**, is registered within South Africa as a Not for Profit Company. The vision is to have a functioning, integrated program for education, capacity building, research and management for the conservation of bat populations in Africa. Activities include the publication of African Bat Conservation News and the African Chiroptera Report. AfricanBats NPC has been doing capacity building through workshops and training courses, attended by post-graduate students and emerging scientists undertaking research on bats. Research projects have focused on bat monitoring, bat cave conservation, bat systematics, taxonomy and life histories, bat in protected areas and anthropocene bats.

**Ditsong National Museum of Natural History (DNMNH)**, formerly known as the Transvaal Museum was founded in 1892 and it has, since acted as custodian and documentation centre of South Africa's natural heritage. The Museum's collections and exhibits include fossils, skeletons, skins and mounted specimens of amphibians, fish, invertebrates, reptiles and mammals. It is one of the largest in South Africa and the largest collection of bat specimens in South Africa and extensive taxonomic expertise.

### **III. WORK TO BE PERFORMED**

The project will focus on capacity building in the Southern African region (Table 2) and biosurveillance (Table 3) as summarized and 3 and explained below.

*Capacity building* will focus on South Africa and neighboring countries. Pathogens do not respect borders and a regional approach is needed for South Africa to effectively detect, predict and respond to infectious disease threats. The main activities will be: 1) training representatives from Southern African countries in development of effective surveillance strategies, standard operating protocols, biosafety, data analysis, disease modelling, field and laboratory investigations, effective reporting and communication following a One Health approach; 2) establish diagnostic technologies to detect filo-, henipa- and coronaviruses for the region at a central facilities in South Africa; and 3) build capacity between stakeholders including governmental representatives through joined meetings including development of mitigation and threat reduction strategies to inform policy. Although the biosurveillance part of the project will be focused on South Africa, capacity building will include training of colleagues from Mozambique and Zimbabwe. Trainees, representing animal, human, environmental health and academia, will be selected from each country in line with a One Health focus by the different stakeholders. Theoretical and practical training will take place in South Africa through workshops, at field sites and diagnostic laboratories. In addition to developing emerging researchers and postdoctoral fellows, projects will be developed for at least 4 PhD, 4 MSc and 4 honors students, including students from neighboring countries, with co-supervision between partners. Fellows and students will spend time with different team members to learn laboratory and analytical techniques. By including colleagues from neighboring countries, we will develop a workforce that can then initiate long-term surveillance programs in the respective countries. These projects will be supported in the long-term by the regional diagnostic capacity developed in South Africa in two institutions and access to these facilities for testing to the region. Both these institutions invest in staff and infrastructure independent of this project and funding. The South African Research Chair of Prof. Markotter is also a long-term commitment from the South African government [Department of Science and Innovation (DSI)] and the academic institution (UP). To also ensure sustainability there is close collaboration with all ministries and capacity building is focused on emerging researchers to ensure long-term continuity

Activity	Location	Month and year	Duration in days	Chairs/ Trainers	Attendees	Proposed activities
Project Stakeholder meeting	UP, Pretoria, RSA	June Y1	3	Markotter and Epstein	<p><b>~ 30 attendees</b>  <b>At least one representative of each stakeholders mentioned below</b></p> <p>South Africa:  <i>UP, NICD, DALRRD, nDOH, DEFF, AfricanBats, DNMNH</i></p> <p>Mozambique  <i>CVL Moz, Ministry of Health, Academia, Ministry of Enviromental and Wildlife</i></p> <p>Zimbabwe  <i>CVL Zim, Ministry of Health</i></p> <p>USA  <i>EHA, USU, DTRA representatives</i></p>	<p><b>Y 1</b>                      Introduction to the project, roles and responsibilities, timelines                      Planning of surveillance strategies, standardized SOPs , standardize reporting policy                      Reporting of results and engagements with government (including between countries)                      Planning and design of human behavioral studies, communication strategy and awareness                      Biosafety training including packaging and shipping of samples                      Establishment of SABRENET</p>
	UP, Pretoria, RSA Set up a video conference, Moz and Zim representatives will meet with South African colleagues in South Africa and USU and EHA will dial in from the USA	June Y2	1			<p><b>Y 2, 3 and 4</b>                      Share and discuss results and progress, reporting, publications                      Agree on activities for the next year                      Identify trainees and student involvement                      Develop mitigation and prevention policies, threat reductions based on preliminary results                      Draft a plan for sustainability of biosurveillance for the region and decide on implementation timelines</p>
	New York, USA	June Y3	3			<p><b>Y 5</b>                      Analyze and discuss all results, finalize mitigation strategies and policies for threat reduction                      Finalize the plan for sustainable biosurveillance in the region.                      Prepare final report and publications</p>
	UP, Pretoria, RSA Set up a video conference, Moz and Zim representatives will meet with South African colleagues in South Africa and USU and EHA will dial in from the USA	June Y4	1			
	UP, Pretoria, RSA	June Y5	3			
Modelling and data analysis workshop	UP, Pretoria, RSA	June Y1	2	Olival, Ross, (EHA)	<p><b>~ 30 attendees</b>  <b>At least one representative of each stakeholders mentioned above</b></p>	<p>Epidemiology                      Risk analysis                      GIS                      Hotspot mapping                      Niche modelling                      Introduction to disease modelling</p>
Introduction to bat biology and taxonomy training	UP, Pretoria, RSA	June Y1	4	Kearney (DNMNH), Seamark (African Bats), Phelps (EHA), Markotter (UP)	<p><b>~ 15 attendees</b>  <b>At least one representative of each stakeholders mentioned above</b></p>	<p>Introduction to bat biology, physiology, ecology, taxonomy, echolocation and environmental monitoring. The focus will be on Southern African bat species. Will include practical taxonomic exercises and sampling at both insectivorous and frugivorous bat roosts.</p>
Bat field sampling training	Field sites in South Africa, Mozambique and Zimbabwe	Y1-Y4 various months	14	Markotter (UP), Postdocs (UP), Kearney (DNMNH) Seamark (African Bats), Phelps (EHA)	<p><b>At least one representative of each stakeholders mentioned above</b>                      A strong focus on training students and staff that will be involved in fieldwork</p>	<p>There will be continuous field training. This will consist of each trainee (Identified by the stakeholders) joining at least 2 field visits a year (part of the biosurveillance activity).</p>
Laboratory diagnostic training	UP and NICD laboratories, RSA	Y1-Y5 various months	21	Markotter (UP), Weyer (NICD), Moolla (NICD) Laing (USU) Postdocs (UP and NICD)	<p><b>At least one representative of each stakeholders mentioned above</b>                      Focus will be on training students and staff involved in diagnostic testing</p>	<p>There will be continuous laboratory diagnostic training. This will consist of trainees visiting the diagnostic laboratories (NICD and UP), receive training and perform sample processing, testing and analyses of results.</p>

**Biosurveillance for Viral Zoonoses around Bat-Livestock-Human interfaces in Southern Africa / Markotter & Epstein CBEP-Thrust Area 6, CC WMD**

Activity	Location	Month and year	Days	Chairs/ Trainers	Attendees	Proposed activities
Data interpretation workshop *	EHA, New York UP, RSA EHA, New York UP, RSA EHA, New York	Feb Y1 Feb Y2 Feb Y3 Feb Y4 Feb Y5	5	Markotter (UP), Epstein (EHA)	Markotter (UP), Epstein (EHA) E. Laing (USU) Postdocs UP, NICD, EHA	A smaller team that will do in depth data analysis that can then be discussed and analyzed by the broader group (Stakeholder meeting)

\*Depending on data collected, additional people will attend the data analysis workshops.

**Biosurveillance** activities will be focused in South Africa with limited fieldwork collections in Mozambique and Zimbabwe (Y4). Activities will already start at the beginning of Y1 since ethical approvals and Department of Agriculture and Rural Development (Previously DAFF) Section 20 to perform biosurveillance in Southern Africa is already approved. Minor amendments will be applied for. Due to the proposed project start date (June 2020) no retrospective sample testing will be performed but previous results generated will be part of data analysis.

**Sampling strategy:** Targeted longitudinal surveillance in bats, as well as sampling in potential spillover hosts (cattle, goats, donkeys, and pigs), will be implemented in South Africa and once-off biosurveillance of bats in neighboring countries. The surveillance strategy has been designed based on species previously associated with high consequence pathogens in the literature as well as host and other ecological factors that may play a role in spillover (See background for detail). Cross sectional studies will focus on *Rousettus*, *Rhinolophus*, *Miniopterus* and molossid bat species at several sites in South Africa (Figure 1) to determine the nucleic acid and seroprevalence of filo, henipa- and potentially zoonotic coronaviruses (Table 3). Prevalence depends on many factors, including sample type, seasonality, specific species targeted, target virus and sensitivity of the assay with studies reporting prevalence ranging from 0-100% and the prevalence of nucleic acids is usually much lower than the presence of antibodies. We assumed a nucleic acid and seroprevalence of 10% and sample sizes of individual bats were selected to detect positives with a 95% confidence interval based on estimated population sizes (Markotter, personal communication) and seasonality. Sampling in bats will be non-destructive where blood, swabs (oral and rectal) and urine samples will be collected and this sample strategy has proven to be successful in previous studies (Anthony et al., 2017a). Limited voucher specimens will be collected to confirm species identification where necessary. In addition, will we implement longitudinal surveillance in both *Rousettus* and *Miniopterus* spp. (implicated as filo- and henipavirus hosts), including during birthing periods to investigate seasonality of virus shedding. *Miniopterus* spp. move between Highveld roosts in urban areas during winter months and maternity summer roosts, and therefore several roosts are included to sample representative individuals over the study period. *Rousettus* roosts occur in different biomes in South Africa, and representative roosts are included specifically Black Rock and Table Mountain. Roost type differs and therefore caves, tree roosts, crevices and man-made structures are included in the selected sites and chosen because of a potential bat-animal human interphase. Matlapitsi is in a rural savanna area with free roaming livestock, vegetable and fruit farming. People visit the cave for cultural reasons, and there are fruit trees in-between human dwellings where fruit bats feed. Movement of *R. aegyptiacus* between Matlapitsi and Black Rock has been reported (>500 km) (Jacobsen and Du Plessis, 1976); Black Rock is in a tropical rainfall area, located inside a protected conservation area (Isimangaliso Wetland park), with human settlements and livestock within the foraging distance of the bats; The Table Mountain roost is located in the Table Mountain National Park, representing the fynbos biome and a winter rainfall with tourists visiting the area; Madimatle cave, Limpopo, South Africa is a maternity roost for *Miniopterus* spp., co-roosting with *Rhinolophus* spp. It is an important cultural site frequently visited by people travelling back and forth between this cave and major metropolitan cities in the most populated province in South Africa, Gauteng. It is also surrounded by wildlife farming areas. One-off sampling in Mozambique and Zimbabwe will focus on the cave dwelling *R. aegyptiacus* (implicated as a filo- and henipavirus host) and insectivorous bats co-roosting including know roosts such as Chinoyi caves.

**Biosurveillance for Viral Zoonoses around Bat-Livestock-Human interfaces in Southern Africa / Markotter & Epstein CBEP-Thrust Area 6, CC WMD**

**Table 3: Summary of sampling sites, bat species targeted, sample numbers and sample frequencies.**

Site name (Fig 1)	<i>Rousettus aegyptiacus</i> <sup>#</sup>			<i>Miniopterus</i> spp <sup>#</sup>			<i>Mollosids and Rhinolophus</i> spp <sup>#</sup>		
	Year of sampling and frequency	Sample numbers	Estimated population sizes	Year of sampling and frequency	Sample numbers	Estimated population sizes	Year of sampling frequency	Sample numbers	Estimated population sizes
Matlapitsi Limpopo, RSA*	Y1, Y2, Y3 Monthly	120/mo 1440/year Total=4320	Varies between 6000-20000 with lower numbers during the winter months	Y1, Y2, Y3 Seasonally (4 x/year)	120/visit 480/year Total=1440	Varies between 1000-2500 individuals	Y1, Y2, Y3 Seasonally (4 x/year)	120/visit 480/year Total=1440	Populations sizes are unknown but can be between 1000-2500 individuals
Black Rock KZN, RSA*	Y2 and Y3 Seasonally (4 x/year)	120/visit 480/year Total =960	Varies between 6000-10000 with lower numbers during the winter months	Y2 and Y3 Seasonally (4 x/year)	120/visit 480/year Total=960	Varies between 1000-2500 individuals	Y2 and Y3 Seasonally (4 x/year)	120/visit 480/year Total=960	
Table Mountain Western Cape, RSA	Y2 and Y3 Seasonally (4x/year)	120/visit 480/year Total=960	A small population of about 1000-3000 individuals	Y2 and Y3 Seasonally (4 x/year)	120/visit 480/year Total=960	Varies between 1000-2500 individuals	Y2 and Y3 Seasonally (4 x/year)	120/visit 480/year Total=960	
Madimatle Limpopo RSA*	<i>R. aegyptiacus</i> not present	N/A	N/A	Y1, Y2, Y3 Monthly for Oct – Feb	120/mo for 5 months 600/year Total=1800	Varies between 1000 in the winter months and 500 000 during birthing periods	Y1, Y2, Y3 Seasonally Only 5 month, 2 seasons	120/visit 240/year Total=720	
Other Miniopterus sites (Highveld) X 2 (Mamelodi and Gladysvale)	<i>R. aegyptiacus</i> not present	N/A	N/A	Y1, Y2, Y3 Monthly for March – Sept	120/mo for 7 months 840/year Total=2520	Varies between 1000-2500 individuals	Y1, Y2, Y3 Seasonally Only 7 month, 2 seasons	120/visit 240/year Total=720	
Mozambique*	Y4 Twice/year	200/visit 400/year Total=400	Unknown but <i>R. aegyptiacus</i> population estimated to be 2000-5000	Y4 Twice/year	200/trip 400/year Total=400	Unknown Varies between 1000-2500 individuals	Twice/year (Y4)	200/trip 400/year	
Zimbabwe*	Y4 Twice/year	200/visit 400/year Total=400	Unknown but <i>R. aegyptiacus</i> population estimated to be 2000-5000	Y4 Twice/year	200/trip 400/yea Total=400	Unknown Varies between 1000-2500 individuals	Twice/year (Y4)	200/trip 400/year Total=400	
<b>Total bats sampled</b>		<b>7040</b>			<b>8480</b>			<b>5600</b>	
					<b>21 120</b>				

# Population densities of the bat species differ significantly and is different for the same species between sites and seasons. Estimations are indicated in the table.

\*Sites that will be targeted for once of human behavior studies and collection of human and livestock serum for sero-surveillance. Only human questionnaire-based studies will be performed in Mozambique and Zimbabwe.

Human behavior (KAP analysis) and collection of human serum samples (n=150/site) will be implemented at three sites in South Africa in Y3 (Table 3) where potential human and livestock contact is a possibility. Sampling more than 100 per site will allow us to detect seropositivity with a 95% confidence at a seroprevalence of 3% assuming populations of 500. Livestock samples, including cattle, goats, pigs and donkeys (n=150/species/site), will also be collected in Y3 at South African sites. Only questionnaire-based human studies will be performed in Mozambique and Zimbabwe in Y4.

**Collection of samples and testing:** Sample collection will be performed in full personal protective equipment including disposable tyveks, double latex gloves, leather gloves, respiratory protection

(PAPRs) and gumboots. Oral and rectal swabs, urine and blood will be collected in duplicate. One sample set will be pooled for testing. All samples will be collected in inactivation buffer, DNA/RNA shield (ZymoResearch), at the site of collection, therefore avoiding any transport or storage of potential infectious samples (since viruses, bacteria, fungi and parasites are inactivated) and requirement of high biocontainment laboratories for processing of samples. This also protects the quality of nucleic acids by neutralizing nucleases and eliminates the need for cold-chain, if necessary. DNA/RNA shield abides by Center for Disease Control's (CDC) guidelines for pathogen inactivation and has been validated by various research groups to inactivate both enveloped and non-enveloped viruses such as parvoviruses, Chikungunya Virus, and West Nile Virus, Dengue Virus, Ebolavirus, Herpes Simplex Virus-1, Herpes Simplex Virus-2, Influenza A, Rhinoviruses, and MERS-coronavirus (Nowotny and Kolodziejek, 2014). Serum will be inactivated using 60°C for 15 min. This has been shown to be effective in inactivating viral pathogens (Van Vuren and Paweska, 2010).

**Ecological and environmental data:** Environmental (weather, rainfall and humidity) and ecological data of the bats (age, reproductive status, sex and measurements) will be collected, as well as population size estimates. We will employ marking and tracking technologies such as tattooing, pit tags (RFID), and telemetry systems to monitor virological status in individuals recaptured over time but also to determine foraging patterns (home ranges, distances traveled and habitat selection) and estimate population sizes. There is limited information about the habitat use and foraging patterns of *R. aegypticus*, and tracking this to estimate spillover risk will be a key component of this project. Movement data has been useful in understanding host and virus ranges and where bats may interact with people and livestock (Epstein et al., 2009; de Jong et al., 2013). EHA (Epstein) and the Movement Ecology laboratory (Hebrew University of Jerusalem) have extensive experience in using telemetry in fruit bats and will collaborate with UP on this specific part of the project.

**Diagnostic testing of samples:** Testing for viral antibodies and nucleic acids from all bats samples collected will be performed at UP and NICD, RSA. This will include follow up DNA Sanger sequencing of all positive amplicons. Molecular detection technologies are already established with some improvements needed (Table 4) and synthetic RNA controls will be used as positive controls and to determine sensitivity of the assays. In addition, these assays are conventional nested RT-PCRs, and the assay times are extensive. Given the scope of the proposed project and the high number of samples that will be tested, we aim to adapt these assays to use randomly primed cDNA, which can be used as template for all virus specific assays. This will save cost and processing time. Assays will be optimized on a SYBR Green real-time PCR platform, which will drastically improving throughput by reducing the processing times for sample testing, limits contamination risk and save on costs. Additional characterization of gene regions using Sanger (UP) and high throughput genome sequencing (UP) will be performed on all novel sequences identified. Luminex technology will be established in partnership with USU and will be transferred to both NICD and UP. This will include coupled antigens and controls for henipa- and filoviruses (Marburg and Ebola) and proteins are available for Hendra, Nipah, Cedar, Mojiang, Ghana henipavirus, Ebola virus, Sudan, Reston, Bundibugyo, Tai forest, Cueva, Lloviu, Marburg, Ravn, Mengla and Bombali virus. Currently, there are no antigens available for coronaviruses and cross reactivity complicates the value of such an assay and will therefore be excluded. Negative *R. aegyptiacus* sera available from previous experimental infections are available (NICD) to be used as additional controls to establish and verify cut-off values. NICD is the reference laboratory for human sample testing as well as for filovirus diagnostic testing and therefore the technologies will be established at both NICD and UP.

**Data analyses, reporting and communication strategy:** Data analyses will include statistics, bioinformatics, epidemiology and disease modelling. This will be done annually, including all stakeholders (Table 3). It will also include retrospective results generated before this project started. Standard operating procedures will be established for reporting and will include developing risk mitigation and prevention strategies. A communication strategy will be developed at the start of the project that will include education and awareness materials, also targeting communities.

**Biobank and database:** A secure and up to date database that will be shared by all partners will be established. UP has developed an in-house database that can function on a web-based system and can be adapted for this project. The PACS system is also available to manage sample information. For storage of samples the current biobank infrastructure at UP will be expanded.

**Table 4: Detail of nucleic acid detection methods that will be used in this study**

<b>Paramyxoviruses</b>						
<i>Respiro-, Morbilli-, and Henipavirus</i>	Hemi-nested RT-PCR (RMH assay)	Tong et al., 2008	10-100 copies of RNA (Tong et al., 2008); [Two-step protocol 10 copies of RNA (Bruck, 2019)]	Partial polymerase (L) gene	611 bp (first round); 494 bp (nested round)	The sensitivity and specificity of the assays were evaluated against a range of paramyxoviruses including several human viruses such as measles ( <i>Morbillivirus</i> ) and mumps virus ( <i>Orthorubulavirus</i> ), as well as the zoonotic bat-borne Hendra and Nipah viruses ( <i>Henipavirus</i> genus) amongst others. These assays have been widely applied for biosurveillance in bats which led to the detection of viruses such as Ghanaian bat henipavirus (Drexler et al., 2012), bat mumps orthorubulavirus (Drexler et al., 2012) and viruses related to other human pathogens such as human parainfluenza virus 2 (Mortlock et al., 2019). Additionally, the family wide PAR assay has been successfully used in the USAID PREDICT program for paramyxovirus biosurveillance.
<i>Avula- and Rubulavirus</i>	Hemi-nested RT-PCR (AR assay)	Tong et al., 2008	10-100 copies of RNA (Tong et al., 2008); [Two-step protocol 300 copies of RNA (Mortlock et al., 2019)]	Partial polymerase (L) gene	272 bp (first round); 224 bp (nested round)	
<b>Assay comment:</b> Both the selected assays (RMH and AR) are very sensitive and capable of detecting a diversity of paramyxoviruses. The family wide assay (PAR) was is much less sensitive (500-1000 copies of RNA), hence the selection of the two more specific and sensitive assays for biosurveillance. All three assays were developed and published in 2008 and included the then known diversity of bat-borne paramyxoviruses (Hendra, Nipah, Menangle and Tioman viruses). However, these assays have not yet been updated or evaluated against more recently described bat- and wildlife-borne viruses such as Sosuga, Cedar, Mojiang and Ghanaian bat henipavirus. We aim to evaluate the sensitivity of these established assays against more recently described bat-borne viruses such as Sosuga, Cedar, Ghanaian bat henipavirus and the presumed rodent-borne Mojiang virus and update the primers if necessary.						
<b>Filoviruses</b>						
Diversity targeted	Assay type	Reference	Sensitivity	Targeted gene region	Size of amplicon	Potential to detect zoonotic viruses
Ebola- and Marburg virus and new diversity (Bombali and Mengla)	Qualitative real-time RT-PCR (probe based)	Panning et al., 2007; Rieger et al., 2016 (RealStar® Filovirus Screen RT-PCR Kit)	Panning et al., 2007: Virus dependent (500-500 RNA copies); RealStar kit: ~ 10 RNA copies	Partial polymerase (L) gene	293 bp	Capable of detection of all Ebola- and Marburvirus strains, limited for detection of other viruses/strains (Rieger et al., 2016; Emperador et al., 2019)
	Hemi-nested RT-PCR	Yang et al. 2019, 2017; He et al. 2015	Not determined	Partial polymerase (L) gene	214-478 bp	Capable of detection of Ebola virus strains and Mengla virus (not evaluated for detection of other filoviruses)
	Qualitative real-time RT-PCR (probe based)	Kemenesi et al. 2018	Not determined	Partial polymerase (L) gene	73 bp	Capable of detection of Lloviu virus (not evaluated for detection of other filoviruses)
	RT-PCR	Goldstein et al. 2018	Not determined	Partial polymerase (L) gene	680 bp	Capable of detection of Bombali virus (not evaluated for detection of other filoviruses)
	Quantitative real-time PCR (probe based)	Forbes et al. 2019; Jääskeläinen et al. 2015	6 RNA copies for <i>Zaire ebolavirus</i>	Partial polymerase (L) gene	108 bp	Capable of detection of <i>Zaire ebolavirus</i> and Bombali virus (not evaluated for detection of other filoviruses)
<b>Assay comment:</b> Most diagnostic assays target the <i>Ebola-</i> and <i>Marburgvirus</i> genera and to allow for detection and differentiation, most of these assays target the more variable genes i.e. glycoprotein (GP) and the RNA-dependent RNA polymerase (L) (reviewed in Emperador et al., 2019). Genomic sequences of filoviruses of different genera differ from each other by more than 55% complicating assay selection for use in family-wide targeted surveillance and a combination of several assays (as listed) will be required to allow detection of the complete diversity. Although established assays have been reported to be successful for detection of novel filoviruses (for example Forbes et al. 2019), the majority has not been fully validated or evaluated for detection of all members of the <i>Filoviridae</i> family with important information regarding specificity and sensitivity lacking. Therefore, several assays will be required for surveillance; the Panning/kit assay will be used for detection of Ebola- and Marburgvirus strains in combination with the other assays listed to cover the entire diversity (i.e. Bombali-, Lloviu- and Menglaviruses).						

**Biosurveillance for Viral Zoonoses around Bat-Livestock-Human interfaces in Southern Africa / Markotter & Epstein CBEP-Thrust Area 6, CC WMD**

Coronaviruses						
Diversity targeted	Assay type	Reference	Sensitivity	Targeted gene region	Size of amplicon	Potential to detect zoonotic viruses
Coronaviruses - focused on the mammalian infecting <i>Alpha</i> - and <i>Betacoronavirus</i> (includes SARS coronavirus) genera	Hemi-nested RT-PCR	Geldenhuis et al., 2018	The nested assay is capable of detecting 50 copies of synthetic control RNA (Nkambule, 2019)	Partial region of the RNA dependent RNA polymerase (RdRp) gene	443 bp (first round); 268 bp (nested round)	Capable of detecting the range of human coronaviruses (synthetic controls); detected a MERS-related coronavirus from an insectivorous bat species (Geldenhuis et al., 2018); SARS-related coronaviruses from Horseshoe bats in Rwanda (Markotter et al., 2019)
<p><b>Assay comment:</b> Members of the <i>Coronaviridae</i> family are highly diverse, which complicates sequence detection of all species with one nucleic acid detection assay. The RNA dependent RNA polymerase (RdRp) gene region (or nsp 12) is situated within ORF 1b of the genome, and is highly conserved and a number of nucleic acid detection assays (Stephensen et al., 1999; Poon et al., 2005; Woo et al., 2005; Watanabe et al., 2010; de Souza Luna et al., 2007; Tong et al., 2009; Gouilh et al., 2011; Geldenhuis et al., 2013; Geldenhuis et al., 2018) use a region located between approximately 14,800 and 15,600 nt depending on the genome (in reference to SARS coronavirus AY714217) for coronavirus RNA detection. Since the majority of assays use the same region, it allows overlapping sequence regions to be compared when investigating partial genes. Assays reported in Watanabe et al., 2010 and Quan et al., 2010 are used in the PREDICT project (Anthony et al., 2017a; Anthony et al., 2017b; Wacharapluesadee et al., 2015; Lacroix et al., 2017), though the sensitivity of these assays have not been reported in literature. The Geldenhuis et al., 2018 assay is a hemi-nested RT-PCR assay that is a multiplexed assay focused on diversity of alpha- and betacoronaviruses and correspond to the same regions targeted in these assays. The primers of the Geldenhuis et al., 2018 assay was updated in 2017, and included the latest diversity of coronaviruses (including human and major bat coronavirus lineages).</p>						

**IV. SUMMARY OF TASKS AND PERFORMANCE SCHEDULE**

Table 5: Summary of the tasks that will be performed for the duration of the project. Detailed tasks are indicated in the attached Statement of work (SOW).

TASK	Y1	Y2	Y3	OY4	OY5	TASK	Y1	Y2	Y3	OY4	OY5
<b>1. Build and enhance capacity in Southern Africa to conduct biosurveillance for filo-, henipa- and coronaviruses</b>						<b>3. Conduct targeted observational and human behavior studies</b>					
1.1. Project stakeholder workshop						3.1. Design the study and questionnaires					
1.2. Establishment and sustaining a Southern African Bat Research network (SABRENET)						3.2. Apply for necessary ethical approvals and obtain community permissions					
1.3. Modelling and data analysis workshop						3.3. Collect and analyze data					
1.4. Introduction to bat biology and taxonomy						<b>4. Conduct targeted serological surveys in people and livestock</b>					
1.5. Bat field sampling training						4.1. Scoping visits to potential study sites					
1.6. Establishment of luminex serology technology at UP and NICD						4.2. Apply for necessary permits and ethical approvals					
1.7. Laboratory diagnostic training						4.3. Collection of samples					
1.8. Data interpretation workshop						4.4. Test and analyze data					
<b>2. Implement biosurveillance in bats in Southern Africa and testing of samples</b>						<b>5. Reporting and Communication</b>					
2.1. Cross sectional and longitudinal surveillance in bat species in South Africa						5.1. Discuss results, finalize and compile an annual report including all stakeholders					
2.2. Nucleic acid testing of samples and DNA sequencing of positives.						5.2. Develop a communication plan and implement it					
2.3. Serological testing of serum samples collected from bats and data analysis						5.3. Present at scientific conferences and prepare manuscripts for publication					
2.4. Characterization of additional genes or genome regions of positive samples, verify serological positive results						5.4. Annual report to all governmental partners and stakeholders					
2.5. Enter all data and results into a database and analyze						5.5. Annual report to DTRA					
2.6. Once off surveillance of bats in Mozambique and Zimbabwe						5.6. Attend DTRA technical review

**Abstract**

Nipah virus (NiV) is an emerging bat-borne zoonotic virus that causes near-annual outbreaks of fatal encephalitis in South Asia – one of the most populous regions on Earth. In Bangladesh, infection occurs when people drink date palm sap contaminated with bat excreta. Outbreaks are sporadic and the influence of viral dynamics in bats on their temporal and spatial distribution is poorly understood. We analyzed data on host ecology, molecular epidemiology, serological dynamics, and viral genetics to characterize spatio-temporal patterns of NiV dynamics in its wildlife reservoir, *Pteropus medius* bats, in Bangladesh. We found that NiV transmission occurred throughout the country and throughout the year. Model results indicated that local transmission dynamics were modulated by density-dependent transmission, acquired immunity that is lost over time, and recrudescence. Increased transmission followed multi-year periods of declining seroprevalence due to bat population turnover and individual loss of humoral immunity. Individual bats had smaller host ranges than other *Pteropus* spp., although movement data and the discovery of a Malaysia-clade NiV strain in eastern Bangladesh suggest connectivity with bats east of Bangladesh. These data suggest that discrete multi-annual local epidemics in bat populations contribute to the sporadic nature of Nipah virus outbreaks in South Asia. At the same time, the broad spatial and temporal extent of NiV transmission, including the recent outbreak in Kerala, India, highlights the continued risk of spillover to humans wherever they may interact with pteropid bats, and the importance of limiting opportunities for spillover throughout *Pteropus*'s range.

**Significance**

Nipah virus (NiV) is a zoonotic virus and WHO priority pathogen that causes near-annual outbreaks in Bangladesh and India with >75% mortality. This work advances our understanding of transmission of NiV in its natural bat reservoir by analyzing data from a 6-year multidisciplinary study of serology, viral phylogenetics, bat ecology and immunology. We show for the first time that outbreaks in *Pteropus* bats are driven by increased population density, loss of immunity over time and viral recrudescence, resulting in multi-year inter-epidemic periods. Incidence is low, but bats carry NiV across Bangladesh and can shed virus at any time of year, highlighting the importance of routes of transmission to the timing and location of human Nipah virus outbreaks.

70 **Introduction.**

71 Outbreaks of zoonotic diseases are often sporadic, rare events that are difficult to predict, but can have  
72 devastating consequences (1). Emerging viral zoonoses of wildlife that have become pandemic include  
73 HIV/AIDS, 1918 H1N1 influenza virus, SARS coronavirus, and the current COVID-19 pandemic caused by  
74 SARS-CoV-2 (2-5). Bats are important hosts for many zoonotic viruses including Ebola virus, SARS-CoV,  
75 SARS-CoV-2 and Nipah virus; the ecological drivers and transmission dynamics of these viruses in their  
76 reservoir hosts are poorly understood (6-12). A better understanding of the transmission dynamics of  
77 zoonotic pathogens in their natural reservoirs may help anticipate and prevent outbreaks (10, 13).

78 Nipah virus (NiV) is an emerging zoonotic paramyxovirus (genus *Henipavirus*) that has  
79 repeatedly spilled over from bats to cause outbreaks in people and livestock with high case fatality rates  
80 across a broad geographic range. To date, human Nipah virus infections have been identified in India,  
81 Bangladesh, Malaysia, Singapore, and the Philippines (14-18). It has caused repeated outbreaks in  
82 Bangladesh and India, with a mean case fatality rate greater than 70% (14, 19, 20). A single genus of  
83 frugivorous bats (*Pteropus*) appears to be the main reservoir for henipaviruses throughout Asia and  
84 Australia (21-25). This includes *Pteropus medius* (formerly *Pteropus giganteus* (26)), the only pteropid  
85 bat present in Bangladesh and India (16, 27-30). Nipah virus has several characteristics that make it a  
86 significant threat to human and animal health: 1) its bat reservoir hosts are widely distributed  
87 throughout Asia, and occur within dense human and livestock populations, leading to widespread  
88 frequent spillover events and outbreaks; 2) it can be transmitted directly to humans by bats or via  
89 domestic animals; 3) it can be transmitted from person to person; 4) spillover has repeatedly occurred in  
90 highly populous and internationally connected regions, giving it pandemic potential; 5) it is associated  
91 with high mortality rates in people; and 6) there are currently no commercially available vaccines to  
92 prevent infection or drugs to mitigate disease (31-33). As a result, the World Health Organization has  
93 listed Nipah virus among the ten most significant threats to global health (34). In May 2018, an outbreak  
94 of Nipah virus encephalitis with a 91% mortality rate occurred in a new location - Kerala, India - more  
95 than 1,200 km southwest of previous Indian and Bangladeshi outbreaks (35). A single case was  
96 subsequently reported in Kerala in 2019, and while local *P. medius* populations have been implicated as  
97 the local source of infection, the route of spillover in both instances remains unknown (35, 36).

98 In Malaysia and Bangladesh, consumption of cultivated food resources contaminated with bat  
99 excreta such as mangoes in Malaysia and date palm sap in Bangladesh and northeastern India have been  
100 identified as the predominant cause of spillover to pigs and people, respectively (37). Human outbreaks  
101 occur almost annually in Bangladesh and the seasonal timing (November-April) and spatial distribution  
102 of outbreaks coincide with patterns of raw date palm sap consumption in a region termed the "Nipah  
103 belt" (38). However, there is variability in the geographic locations and number of spillover events, as  
104 well as the number and magnitude of human outbreaks that occur each year (39, 40). Spillover has also  
105 occurred outside the predominant season and region of date-palm sap consumption (41). Whereas no  
106 human outbreaks have been reported in eastern Bangladesh despite date palm sap harvesting and  
107 consumption, human outbreaks have been reported in Kerala, India where date palm sap is not  
108 cultivated (38). These observations suggest an alternate route of spillover in certain locations, and a  
109 critical need to understand the mechanisms of underlying viral infection dynamics in bats and the extent

110 of genetic diversity within the virus – each of which may influence the timing, location and epidemiology  
111 of human outbreaks (38).

112 Previous research on the transmission dynamics of Nipah and Hendra viruses in *Pteropus* spp.  
113 bats has produced mixed and sometimes contradictory findings. Nipah virus, like Ebola, Marburg,  
114 Hendra and some bat coronaviruses, is associated with seasonal spikes in infection that coincide with  
115 annual or semi-annual synchronous birth pulses (21, 42-48). Seasonal periods of Nipah virus shedding  
116 were observed in *P. lylei* in Thailand and seasonal spikes in NiV (or a related henipavirus) seroprevalence  
117 coinciding with pregnancy periods were observed in *Eidolon dupreanum* in Madagascar (49, 50), but not  
118 in *P. vampyrus* or *P. hypomelanus* in Peninsular Malaysia (25). Hendra virus prevalence in Australian  
119 pteropid bats has shown multi-year inter-epidemic periods during which little virus can be detected,  
120 followed by periods of markedly increased viral shedding (51-53). It has been hypothesized that multi-  
121 year periodicity in the incidence of henipavirus infections could arise from a build-up and waning of herd  
122 immunity in the reservoir host, with re-introduction of virus via immigration or recrudescence or viral  
123 persistence (11, 54-56).

124 There is a paucity of data related to henipavirus-associated immune dynamics in free-ranging  
125 pteropid bats, including the duration of immunity in adults and juveniles, which limits our understanding  
126 of population-level viral dynamics. Experimental infections of *Pteropus* bats with Hendra and Nipah virus  
127 show that bats mount an antibody response following infection with Hendra and Nipah virus (57-59).  
128 Waning of anti-Nipah virus antibodies was observed in recaptured wild *Eidolon helvum*, a bat related to  
129 *Pteropus* spp., in Madagascar (60). Passive transfer and waning of maternal antibodies also occurred in  
130 captive *Pteropus* species, and along with loss of immunity in adults, could contribute to the loss of herd  
131 immunity in wild populations (61). Some pteropid bat species are migratory and interconnected colonies  
132 form a metapopulation which could allow for viral re-introductions into susceptible colonies (10, 25, 62,  
133 63). In addition, NiV recrudescence has been observed in wild-caught *P. vampyrus* and possibly also in  
134 *Eidolon helvum* (64-66). Either of these phenomena could allow NiV to persist regionally during periods  
135 of high local immunity. However, no study has yet shown evidence in open, free-ranging bat populations  
136 that examines the influence of these factors on NiV transmission dynamics.

137 Here we examine the distribution, dynamics, genetic diversity, and underlying drivers of NiV  
138 infection in *Pteropus medius* in Bangladesh to improve our understanding of human outbreak patterns.  
139 Specifically, we analyze the spatial, temporal and demographic variation in serological dynamics and  
140 viral shedding in bats over a six-year period to determine the spatio-temporal drivers and dynamics of  
141 virus transmission. We also analyze the movement patterns of individual bats and analyze NiV  
142 phylogenetics to understand patterns of spatial mixing and virus strain diversity.

143

## 144 **Results**

145 *Comparative Nipah seroprevalence and virus infection study in bats inside and outside the Nipah belt and*  
146 *concurrent longitudinal bat study inside the Nipah belt.*

147 In a cross-sectional spatial study conducted between January 2006 and July 2012, we caught and  
148 tested 883 *P. medius* (~100 per district) from eight colonies in different districts across Bangladesh. We  
149 detected anti-Nipah IgG antibodies in all colonies (**Figure 1**). Seroprevalence varied by location ( $\chi^2 =$

150 55.61,  $p < .001$ ). In most locations adult seroprevalence exceeded juvenile seroprevalence; in Tangail and  
151 Rajbari seroprevalence was similar across ages. Viral detection in individuals was rare; overall, we  
152 detected NiV RNA in 11/2088 individuals and in three pooled oropharyngeal samples (representing five  
153 bats, but which could not be resolved to an individual) (**Table 1**). We detected viral RNA in individual  
154 bats in Faridpur and Rajbari and from pooled samples from Thakurgaon and roost urine samples from  
155 Cumilla. Of the 11 PCR positive individuals, three had IgG antibodies (**Table S1**). We also detected virus  
156 in pooled urine collected from tarps placed below bats at roosts associated with human outbreaks in  
157 Bhanga and Joypurhat. The viral prevalence in Rajbari in January 2006 was 3.8% (95% CI: 0% -11%;  
158  $n=78$ ). In Faridpur, which is adjacent to Rajbari and where we conducted an intensive longitudinal study  
159 (see below), viral prevalence estimates ranged from 0% to 3% (95% CI: 0%-10%;  $n=100$  at each of 18  
160 sampling times) (**Table 1**). Nipah virus RNA was detected in bats from inside (Rajbari, Thakurgaon, and  
161 Faridpur) and outside (Cumilla) the Nipah Belt. There was no significant difference between NiV  
162 detection rates from individual bats by the two main sample types: urine/urogenital swabs, 0.37%  
163 ( $n=2,126$ ) and oropharyngeal swabs, 0.15% ( $n=1973$ ) ( $\chi^2= 1.92$   $p=0.17$ ). The estimated detection rate  
164 from pooled urine samples, collected from tarps placed underneath roosts) across the entire study was  
165 2.5% ( $n=829$ ), which was significantly higher than either sample type collected from individual bats ( $\chi^2 =$   
166 55.6,  $p < 0.001$ ).

167

#### 168 *Factors associated with NiV IgG serostatus in P. medius*

169 There was no statistical difference between seroprevalence in bats inside the Nipah Belt and  
170 outside (95% odds ratio (OR) 1.2, highest posterior density interval (HDPI) 0.47-3.1). Adults had higher  
171 seropositivity than juveniles (OR 2.4, 1.7-3.6 HDPI), and males greater than females (OR 1.6, 1.0-2.4  
172 HDPI) (**Figure 2**). There was weak evidence that seroprevalence was higher in pup-carrying (OR 4.0, HDPI  
173 0.6-34) and pregnant (1.5 times, HDPI 0.85-2.8) individuals than other females. Neither mass, forearm  
174 length nor the M:FA ratio ( a proxy for age ) consistently correlated with seropositivity. However, bats  
175 with poor body condition (an assessment of pectoral muscle mass by palpation) were less likely to be  
176 seropositive (Poor/Fair body condition OR = 0.69, HDPI 0.49-0.96). Finally, serostatus was strongly  
177 correlated in mother-pup pairs; 39 of 41 pups with seropositive mothers were seropositive, and 32 of 39  
178 pups with seronegative mothers were seronegative.

179

#### 180 *Longitudinal NiV serodynamics in P. medius, Faridpur district (2006-2012)*

181 We sampled bats quarterly from a single population in the Faridpur district. We also  
182 microchipped a total of 2,345 bats between 2007 and 2012. We used generalized additive models  
183 (GAMs) to characterize changes in NiV seroprevalence over time. There were significant fluctuations in  
184 adult (>24 mo.) and juvenile (6 – 24 mo.) seroprevalence over the six-year study period (**Figure 3A**).  
185 Juvenile seroprevalence ranged from 0% to 44% (95%CI 37%-51%), and decreased over the first year of  
186 life for bats born in each year (“yearlings”), consistent with loss of maternal antibodies in juveniles. A  
187 more pronounced decrease occurred from mid-October to mid-December than other parts of the year.  
188 However, the GAM indicating this had only slightly better fit ( $\Delta AIC < 1$ ), than one with a linear decrease  
189 over the whole year (**Figure 3B**).

190 Adult seroprevalence ranged from 31% (95% CI: 20%-46%) to 82% (95% CI: 77%-87%) with three  
191 cycles of clear variability over the course of the study (**Figure 3A**). We found no evidence of regular

192 seasonal fluctuations; a GAM with annual cyclic terms fit worse than one without ( $\Delta AIC > 10$ ). Viral RNA  
193 was detected during periods of increasing, decreasing, and stable seroprevalence.

194 We fitted a series of age-stratified compartmental susceptible-infected-recovered models to  
195 examine different biological processes influencing serodynamics, including density- vs. frequency-  
196 dependent transmission, recrudescence vs. immigration of infected individuals, and seroreversion (loss  
197 of antibodies) in both juveniles and adults (see Methods and (**Figure 4**)). Density-dependent models  
198 were a far better fit to the data than frequency-dependent models (difference in log-likelihood 10.0;  
199  $\Delta AIC = 20.0$ ), suggesting that movements of bats and fluctuations in colony size alter spatio-temporal  
200 variation in the risk of NiV infection in bats. In Faridpur (see “Domrakhandi/Khaderdi” in **Figure S1** )  
201 during the period of sampling, the roost population declined from approximately 300 bats to 185, which  
202 decreased transmission potential in the fitted model:  $R_0$  in adult bats was estimated to decrease from  
203 3.5 to 2.1 as the number of bats in the colony decreased. As a result, over the six-year study period, the  
204 fitted model predicted that the threshold for herd immunity (i.e. the seroprevalence below which the  
205 reproductive ratio  $R_t > 1$  ) for adults fell from 72% (when bat counts were highest - in 2006) to 52%  
206 (when bat counts were lowest).

207 The fitted model suggests that serodynamics in juveniles were strongly driven by inheritance  
208 and loss of maternal antibodies. The estimated duration of maternal antibodies was 17.6 weeks (95% CI:  
209 13.7-25.0), which was much quicker than the loss of antibodies in adults (290.8 weeks, 95% CI: 245.0-  
210 476.4) (**Table S2**). Finally, models with recrudescence fit the data better than models without  
211 recrudescence (**Table S2**; difference in log-likelihood 32.6;  $\Delta AIC = 65.1$ ), and models with recrudescence  
212 fit the data better than models with immigration ( $\Delta AIC = 3.76$ ).

213

#### 214 *Mark-recapture and seroconversion/seroreversion*

215 There were 56 recapture events over the study period (**Table S3**). Thirty-one bats were  
216 recaptured at a nearby roost other than the original capture location. This network of roosts or “roost  
217 complex” formed a polygon covering approximately 80 Km<sup>2</sup> and included 15 roosts sampled during the  
218 longitudinal study (**Figure S2A and S2B**). Ten instances of seroconversion (change from IgG negative to  
219 IgG positive) and nine instances of seroreversion (positive to negative) were observed (**Table S3**). The  
220 mean time between positive and negative tests in *adults* (excluding juveniles with maternal antibodies)  
221 was 588 days (n=6) (range: 124-1,082 days).

222

#### 223 *Home range and inter-colony connectivity analysis*

224 Home range analysis of satellite telemetry data from 14 bats (mean duration of collar data  
225 transmission = 6.25mo; range = 1-25mo; **Table S4**) showed that the majority of bats roosted within 10  
226 km of where the bats were originally collared, in the Faridpur (Nipah belt) colony, and within 7 km from  
227 where the bats in the Cox’s Bazaar colony were originally collared (315km east of Faridpur). The average  
228 foraging radius was 18.7 km (s.d. 21.5 km) for the Faridpur bats and 10.8 km (s.d. 11.9 km) for the Cox’s  
229 Bazaar bats (**Figure S2**). Home range analysis suggests that bats in Faridpur and Cox’s Bazaar (separated  
230 by approx. 310km) would have a <5% probability of intermingling (**Figure 5**). Home-range size was larger  
231 during the wet season than the dry season (2,746 km<sup>2</sup> vs. 618 km<sup>2</sup>) (**Figures S3 & S4**).

232

233

234 *NiV* phylogenetic analysis.

235 Phylogenetic analysis of NiV sequences from a 224nt section of the N gene (nt position 1290-  
236 1509 [position ref [gb|FJ513078.1](#) India]) suggests that strains from both India and Malaysia clades are  
237 present in bats in Bangladesh (**Figure 6**). This finding is supported by an additional analysis of near-  
238 whole N gene sequences (~1720 nt) from bats, pigs, and humans, including those from a subset of *P.*  
239 *medius* from this and a more recent study by our group (**Figure S5**) (67). Eleven 224nt N gene sequences  
240 obtained from bats between 2006 and 2012 (all from the Faridpur population) were identical. Overall,  
241 the N gene sequences identified from the Faridpur, Rajbari and Bhanga colonies between 2006 and 2011  
242 had 98.21%-100% shared nucleotide identity. Sequences from Rajbari district obtained five years apart  
243 (January 2006 and January 2011) had only a single nucleotide difference resulting in a synonymous  
244 substitution (G to A) at position 1304, which was found in four other bat NiV sequences from this study,  
245 as well as in the NiV isolate from *P. vampyrus* in Malaysia. Five human NiV N gene sequences from  
246 various locations within the Nipah belt over the same time period as our bat study show more  
247 nucleotide diversity than those from the Faridpur *P. medius* population. Human sequences throughout  
248 Bangladesh and from Kerala, India, all nested within the diversity found in *P. medius* (**Figure 6**). By  
249 contrast, the sequences found in *P. medius* from Cumilla, a location 150Km to the east of Faridpur,  
250 showed 80.8%-82.59% shared nucleotide identity with sequences from *P. medius* in Faridpur and  
251 clustered within the Malaysia group of NiV sequences. The two Cumilla sequences were identical to  
252 each other, and had up to 87.95% shared nucleotide identity to sequences from *P. lylei* in Thailand.

253

## 254 **Discussion**

255 Our findings suggest Nipah virus (NiV) circulation occurs in bat populations throughout the  
256 country. We observed that virus can be shed by bats at any time of year, and that viral dynamics are  
257 cyclical but not annual or seasonal. Our models fit to serological data suggest that these cycles may be  
258 driven by demographic and immunological factors; the waning of herd immunity through turnover or  
259 individual waning in bat populations allows heightened viral transmission when seroprevalence passes  
260 below a critical threshold. Previous studies from Bangladesh suggested that human Nipah virus (NiV)  
261 outbreaks occur primarily within a defined region in western Bangladesh, termed the “Nipah belt,”  
262 during a defined season (Nov-Apr) (41, 68). These observations raised the question of whether the  
263 timing and location of human infections are due solely to differences in the frequency and intensity of  
264 date palm sap consumption, or whether ecological factors such as the distribution and timing of bat viral  
265 infection also play a role (19, 38, 69). Our extensive survey of *Pteropus medius*, which is common across  
266 Bangladesh and throughout the Indian subcontinent, demonstrates that viral circulation within their  
267 populations is not limited to the Nipah belt (16, 27, 30).

268 A number of mechanisms have been proposed for the maintenance of acute viral infections in  
269 bat populations which are often formed of interconnected colonies, including synchronous birthing and  
270 subsequent loss of maternal antibodies (11, 43, 45), lowered immunity within pregnant females due to  
271 stress, nutritional stress and other factors (47), immigration of infected individuals from other colonies  
272 (62, 70, 71), and recrudescence within previously-infected individuals (11, 64, 72). However, little is  
273 known about how henipaviruses are transmitted among wild bats. *Pteropus* species are typically  
274 gregarious and their roosts, often comprising multiple hardwood trees, are highly socially structured,  
275 with individuals segregated by age, sex, and social dominance (69, 73, 74). Interactions among

276 individuals are often dependent on their grouping and the intensity of social interactions varies with  
277 specific behaviors such as mother-pup interactions, play (juveniles), territorial fighting (adult males), and  
278 mating (adults) (74). Our data and previous experiments show that henipaviruses can be shed orally,  
279 urogenitally, in feces, and in birthing fluids (59, 75). This suggests multiple mechanisms for transmission  
280 are possible, including mutual grooming, fighting, mating, exposure to excreta or birthing fluids, and  
281 ingestion of food contaminated by saliva. Roost size also increases seasonally during mating and birthing  
282 periods, which the fitted models suggest would increase transmission, if seroprevalence is below the  
283 herd immunity threshold (30, 73). While *P. medius* does not roost with other bat species, it does feed  
284 with other frugivorous bats, and it's possible that inter-species viral transmission occurs during feeding  
285 (76, 77). In Madagascar, henipavirus antibodies have been detected in multiple species of frugivorous  
286 bats, though it is unknown whether the same virus or antigenically related viruses was shared among  
287 them (60). While serological evidence suggests it is possible henipaviruses circulate in other frugivorous  
288 bat species, our findings as well as others (59, 78) suggest that in Bangladesh, *P. medius* is the main  
289 natural reservoir for Nipah virus. Henipaviruses other than Nipah may be circulating in *P. medius* (28).  
290 We assumed that the anti-IgG antibodies detected by the serological assays used in this study were  
291 specific to Nipah virus, but it is possible that the ELISA used in the cross-sectional study may have  
292 detected antibodies against unknown henipaviruses, which could elevate NiV seroprevalence estimates.  
293 An advantage of the Luminex assay used in the longitudinal study is that we could compare MFI values  
294 to multiple specific henipaviruses (Nipah, Hendra and Cedar) and differentiate between specific  
295 reactions to NiV and reactions to the other viruses, which could indicate antibodies against an unknown  
296 henipavirus. Hendra and Cedar viruses are enzootic in Australian *Pteropus spp.* and are not known to  
297 occur in Bangladesh, so we considered reactions to these viruses NiV-negative results.

298 Our modeling indicates that NiV is primarily driven by immunity and density-dependent  
299 transmission dynamics among bats, with cycles of higher seroprevalence dampening intra-colony  
300 transmission followed by waning of antibody titers within individuals and death of seropositive  
301 individuals. Waning humoral immunity against NiV has been consistently shown in henipavirus studies of  
302 African pteropodid bats (56, 60). Our recapture data provided the first reported evidence of the loss of  
303 detectable NiV IgG antibodies in individual free-ranging bats, which supports the fitted model suggesting  
304 limited duration individual immunity and the importance of population-level waning immunity. The  
305 consistently decreasing seroprevalence that we observed in juveniles suggests that they lose maternal  
306 antibodies over their first year (the fitted model estimates after 3-5 months), consistent with other  
307 studies of maternal antibodies against henipaviruses in pteropodid bats (47, 56, 61, 65). Our analysis do  
308 not support the hypothesis (45) that seasonal pulses of these new seronegative individuals are sufficient  
309 to drive new outbreaks because high seroprevalence in adults limited transmission in several years  
310 (Figure 4).

311 Nipah virus reintroduction into a colony may occur from a persistently infected individual (e.g.  
312 via recrudescence) or immigration of an infected individual. Our analyses suggested that recrudescence  
313 was a more important driver of transmission dynamics than immigration. Recrudescence of henipavirus  
314 infection has been observed for NiV in captive *P. vampyrus* (64), for henipavirus in captive *E. helvum* (56,  
315 66), and humans infected by NiV (79) and Hendra virus (80). It is difficult to know from serology alone  
316 whether wild-caught seronegative bats had been previously infected. Experimental infections comparing  
317 naïve to previously infected *Pteropus medius* that have sero-reverted would provide a better

318 understanding of how humoral immunity influences individual susceptibility to infection, and inform  
319 dynamics models attempting to explain viral maintenance within bat populations (60).

320 Our longitudinal study was limited to a single population of interacting subcolonies and bat  
321 populations across Bangladesh likely represent a dynamic metapopulation. Our roost count data and  
322 recapture data from microchipped bats showed how roost sizes can fluctuate, and that bats shift among  
323 local roosts. The fitted model strongly suggested that decreases in local roost counts substantially  
324 reduced local transmission potential of NiV. However, a larger study across multiple regional  
325 populations would be needed to understand how local shifts in bat colonies impact broader fluctuations  
326 in regional populations and spatial patterns of NiV transmission.

327 Understanding how bat populations connect across landscapes is important for understanding  
328 viral maintenance, and studying local and migratory bat movements can provide important ecological  
329 information related to viral transmission, including how bats move between different colonies (62, 81).  
330 Our satellite telemetry data suggest that *P. medius* exists as a metapopulation, like other pteropid  
331 species (11, 71). The numbers of individuals we collared represents a small sample size, however they  
332 are comparable to other bat satellite telemetry studies of related species, and our data suggest that bat  
333 dispersal in Bangladesh may currently be more localized than other species elsewhere. *Pteropus medius*  
334 appear to travel shorter distances and remain within a smaller home range (321.46km<sup>2</sup> and 2,865.27km<sup>2</sup>  
335 for two groups) than *P. vampyrus* in Malaysia (64,000 km<sup>2</sup> and 128,000 km<sup>2</sup>) and *Acerodon jubatus* in the  
336 Philippines, both of which are similarly sized fruit bats (62, 82). Pteropodid bat migration is primarily  
337 driven by seasonal food resource availability (63, 83-85). In Bangladesh, *P. medius* prefer to roost in  
338 human-dominated environments in highly fragmented forests as opposed to less populated, intact  
339 forested areas such as in national parks (86). The conversion of land to villages and farmland over recent  
340 human history has likely led to increased food availability for *P. medius* and may have reduced the  
341 impetus for long-distance migration (37). This may reflect a similar adaptation to anthropogenic food  
342 resources as observed over the last few decades in Australian *Pteropus* species (71). Home ranges were  
343 significantly smaller during the dry season which corresponds to winter months and the time when most  
344 female bats are pregnant, likely resulting in them flying shorter distances to conserve energy. Genetic  
345 analysis of *P. medius* across Bangladesh has shown that historically, there has been extensive gene flow  
346 and intermixing among populations, and we did observe a few instances of longer distance flights,  
347 however, the movement data indicated that overall these bats had much smaller home ranges (81). Less  
348 connectivity among bat populations across Bangladesh may influence NiV transmission by creating  
349 longer inter-epidemic periods and larger amplitude fluctuations in population level immunity in  
350 *Pteropus medius* compared to more migratory species (71). Bat movement and population connectivity  
351 may also influence the genetic diversity of NiV found in different locations.

352 The potential existence of a more transmissible or pathogenic strain of NiV already circulating in  
353 bats further underscores the need to strengthen efforts to prevent spillover. While the overall strain  
354 diversity among NiV has not been well characterized due to a dearth of isolates, two distinct NiV clades  
355 have been described: A Bangladesh clade, that includes sequences identified in India and Bangladesh;  
356 and a Malaysian clade, that comprises sequences from Malaysia, Cambodia, The Philippines and  
357 Thailand (18, 67, 87). Our findings of substantially different NiV sequences in Faridpur and Cumilla  
358 suggest that viruses from both clades are circulating in Bangladesh. Strains of NiV from these two clades

359 are associated with differences in pathogenesis, epidemiological and clinical profiles in humans and  
360 animal models and observed shedding patterns in bats (49, 88-92). Phenotypic variation in Nipah virus  
361 could influence human outbreak patterns by altering transmission to, or pathogenesis in, humans, and  
362 the likelihood of smaller outbreaks being identified or reported (93). Human-to-human NiV transmission  
363 via contact with respiratory and other secretions has been regularly observed in Bangladesh and India,  
364 including the recent 2018 outbreak in Kerala (14, 68, 94), whereas transmission among people was not a  
365 common feature of the Malaysia outbreak, despite close contact between cases and health care  
366 providers (95, 96). Nipah virus cases in Bangladesh have shown more strain diversity than in the  
367 Malaysia outbreak, which could be due to greater virus diversity in *P. medius* (97).

368         Until now, there have been very few Nipah sequences obtained from *P. medius*. We found that  
369 Nipah N-gene sequence from bats from the Faridpur population were nearly identical over time,  
370 compared to variation in N-gene sequences from bats and humans from other locations observed over  
371 the same time period (2006-2010). This suggests that there may be locally prevalent and stable NiV  
372 genotypes that persist within bat colonies. Human NiV genotype diversity is likely a reflection of the  
373 diversity of the NiV strains in the local bats that seed outbreaks (10). This is also supported by viral  
374 sequences obtained from human and bats associated with the 2018 NiV outbreak in Kerala, India, where  
375 human NiV sequences were most closely related to local *P. medius* sequences (98).

376         Connectivity of pteropid bats in Bangladesh with those in Southeast Asia could explain the  
377 observed strain diversity in our study. Historical interbreeding of *P. medius* with pteropid species found  
378 in Myanmar, Thailand, and Malaysia and our telemetry findings showing bats are capable of flying  
379 hundreds of kilometers, could explain the presence of a Malaysia clade NiV sequence in bats from  
380 Cumilla (81). NiV Bangladesh strains have also been found in *P. lylei* in Thailand (99). The N gene of the  
381 Cumilla NiV strain differs from those reported from bats in the Nipah belt by 20%, whereas NiV Malaysia  
382 and NiV Bangladesh differ by only 6-9% and are associated with different clinical profiles. Whole  
383 genome sequence would have allowed for better characterization of the Cumilla strain, however this  
384 was not obtained. Despite the short sequences used in our analysis, the N gene is generally conserved  
385 relative to other genes and is representative of the diversity across henipavirus genomes (87). We would  
386 expect the rest of the Cumilla viral genome to also be highly divergent, potentially even qualifying it as a  
387 different henipavirus species. It is therefore plausible that the clinical profile of a 20% divergent Nipah-  
388 related virus differs significantly from known strains. Sequence information from an isolated human NiV  
389 case in Cumilla has not been reported, so comparison to sequence we found in bats was not possible  
390 (41). Studies linking viral genotype to clinical outcomes in people would provide additional insight into  
391 the effect of strain diversity in bats on the potential for larger-scale human outbreaks.

392         Our study sheds light on the sporadic nature of human NiV outbreaks, with multi-year inter-  
393 epidemic periods in South Asia. PCR results show that overall NiV incidence in *P. medius* is low,  
394 consistent with previous studies of Hendra and Nipah virus (47, 52, 100, 101). The fitted model suggests  
395 that transmission increases when bat populations that have become susceptible through waning  
396 immunity (11). In the current study, observed seroprevalence patterns and the fitted model suggest that  
397 three periods of transmission occurred over the 6 years of sampling, each of which followed periods of  
398 low adult and juvenile seroprevalence. Viral detection in bats has coincided with some human  
399 outbreaks, supporting the hypothesis that spillover is a sporadic event (67, 98). In our study periods of  
400 low seroprevalence in bats were not always followed by outbreaks in humans. We detected NiV RNA

401 during periods of both increasing and high seroprevalence, consistent with recrudescence which was  
402 strongly supported by the fitted model and has been demonstrated in captive animals (64-66). This  
403 likely contributes to the sporadic variation in human outbreaks (e.g. spillover events) from year-to year  
404 in Bangladesh.

405 Overall, our results suggest that NiV outbreaks in humans stem from an interaction of four  
406 factors: 1) multi-year fluctuations in transmission intensity among bats driven by immunity and colony  
407 size/ density-dependent transmission; 2) relatively localized bat movements creating spatially variable  
408 transmission dynamics; 3) occasional shedding by previously infected bats due to recrudescence; and 4)  
409 highly seasonal contact between bats and humans via consumption of raw date-palm sap. The timing of  
410 multiple factors involved in driving transmission dynamics needs to align for intra-colony NiV  
411 transmission events and further align with human behavior and availability of a route of spillover for  
412 human outbreaks to occur, as previously hypothesized (102). We further conclude that NiV dynamics in  
413 bats combined with the seasonality and specific geography of date palm sap consumption in Bangladesh  
414 likely explains the sporadic nature of human outbreaks in the region (38).

415 These findings suggest that human NiV outbreaks in other regions of Bangladesh (and Asia)  
416 where *Pteropus* bats occur, are also likely to be sporadic and rare, leading to under-reporting or a lack of  
417 reporting. This is probably exacerbated by the fact that the clinical syndrome is similar to that of other  
418 common infections, such as Japanese encephalitis, malaria and measles (103). Understanding whether  
419 some NiV strains are capable of causing mild or asymptomatic cases will provide important insights  
420 about why outbreaks have not been detected in areas such as eastern Bangladesh or other parts of Asia,  
421 where host, virus, and potential routes of spillover exist. One reason is that mild or asymptomatic cases  
422 would be unlikely to be detected by current surveillance systems. About half of all Nipah outbreaks in  
423 Bangladesh between 2007 and 2014 were unreported, suggesting that many cryptic spillover events  
424 have occurred (104). The 2018 and 2019 spillover events in Kerala, India, which were linked to local *P.*  
425 *medius* colonies and which occurred in an area that does not cultivate date palm sap, further emphasize  
426 the point, but raise questions about the mechanism of spillover.

427 In the last two decades, the world has experienced large epidemics of bat-associated viruses,  
428 including Ebola in West Africa and DRC; SARS coronavirus, and SARS CoV2. The World Health  
429 Organization has listed Nipah virus and other henipaviruses as priority pathogens for vaccine and  
430 therapeutic research and development, along with Ebola viruses and coronaviruses. Surveillance for  
431 henipaviruses and antibodies in bats and people where they are in close contact will help determine  
432 spillover risk; characterize henipavirus genetic diversity; and understand the genetic determinants of  
433 NiV transmissibility and pathogenicity among humans. These measures may help target interventions  
434 that reduce spillover, substantially improving our ability to reduce the risk of a more transmissible strain  
435 of NiV emerging and causing a large-scale epidemic with significant human and animal mortality.

436

## 437 **Methods**

438 The study period was between January 2006 and November 2012. The study was conducted under Tufts  
439 University IACUC protocol #G929-07 and icddr,b AEEC protocol 2006-012 with permission from the  
440 Forest Department, Government of Bangladesh. Locations were selected based on whether the district  
441 had any previously recorded human NiV encephalitis clusters at the time of this study and was therefore  
442 inside the Nipah Belt (e.g. Rajbari, Tangail, Thakurgaon, and Kushtia) or whether they had not and were  
443 outside the Nipah Belt (e.g. Cumilla, Khulna, Sylhet, and Chattogram). The Thakurgaon study was  
444 conducted as part of an NiV outbreak investigation, and coincided with ongoing human transmission  
445 (105). Between 2006-2012, three different studies of *Pteropus medius*, with similar bat sampling  
446 protocols were performed: 1) a cross-sectional spatial study with a single sampling event in each of the  
447 eight locations listed above; 2) a longitudinal study of a Faripur bat colony with repeated sampling  
448 approximately every 3 months from July 2007 to November 2012; and 3) a longitudinal study of the  
449 Rajbari colony with repeated sampling at a monthly interval between 12 month period between April  
450 2010 and May 2011. Opportunistic sampling of *Pteropus medius* was also performed during this time  
451 period during NiV outbreak investigations [Bangha, Faridpur (Feb 2010), Joypurhat (Jan 2012), Rajbari  
452 (Dec 2009), West Algi, Faridpur (Jan 2010)]. Bats were captured using mist nets at locations within eight  
453 different districts across Bangladesh between January 2006 and December 2012 (**Figure 1**).

454

### 455 *Capture and sample collection*

456 For the country-wide cross-sectional and Faridpur longitudinal study, approximately 100 bats  
457 were sampled at each sampling event, which lasted 7-10 days. This sample size allowed us to detect at  
458 least one exposed bat (IgG antibody-positive) given a seroprevalence of 10% with 95% confidence. Bats  
459 were captured using a custom-made mist net of approximately 10 m x 15 m suspended between  
460 bamboo poles which were mounted atop trees close to the target bat roost. Catching occurred between  
461 11 pm and 5 am as bats returned from foraging. To minimize bat stress and chance of injury, nets were  
462 continuously monitored and each bat was extracted from the net immediately after entanglement.  
463 Personal protective equipment was worn during capture and sampling, which included dedicated long-  
464 sleeve outerwear or Tyvek suits, P100 respirators (3M, USA), safety glasses, nitrile gloves, and leather  
465 welding gloves for bat restraint. Bats were placed into cotton pillowcases and held for a maximum of 6  
466 hours before being released at the site of capture. Bats were sampled at the site of capture using a field  
467 lab setup. Bats were anesthetized using isoflurane gas (106) and blood, urine, oropharyngeal swabs, and  
468 wing membrane biopsies (for genetic studies) were collected. For some sampling periods, rectal swabs  
469 were collected but due to resource constraints, these samples were deemed to likely be lower yield than  
470 saliva and urine for NiV, and were discontinued during the study. For each bat sampled we recorded  
471 age, weight, sex, physiologic and reproductive status, and morphometric measurements as described  
472 previously (27). Bats were classified as either juveniles (approximately four to six months - the age by  
473 which most pups are weaned) to two years old (the age when most *Pteropus* species reach sexual  
474 maturity) or adults (sexually mature) based on body size and the presence of secondary sexual  
475 characteristics, pregnancy, or lactation - indicating reproductive maturity (27, 107).

476 Up to 3.0 mL of blood were collected from the brachial vein and placed into serum tubes with  
477 serum clot activator (Vacutainer, USA). Blood tubes were stored vertically on ice packs in a cold box  
478 and serum was allowed to separate overnight. Serum was drawn from the tube after 24 hours and

479 placed in a screw-top cryovial (Corning, USA) and stored in a liquid nitrogen dewar (Princeton  
480 Cryogenics, NJ, USA). Sterile pediatric swabs with polyester tips and aluminum shafts were used to  
481 collect urogenital and rectal samples, and larger polyester swabs with plastic shafts (Fisher, USA) were  
482 used to collect oropharyngeal samples. All swabs were collected in duplicate, with one set being placed  
483 individually in cryotubes containing lysis buffer (either tri-reagent or NucliSENS Lysis buffer,  
484 BIOMERIEUX, France) and the second set in viral transport medium. All tubes were stored in liquid  
485 nitrogen in the field then transferred to a -80C freezer.

486 During each sampling event, pooled urine samples were collected beneath bat roosts using  
487 polyethylene sheets (2' x 3') distributed evenly under the colony between 3 am and 6 am. Urine was  
488 collected from each sheet either using a sterile swab to soak up droplets, or a sterile disposable pipette.  
489 Swabs or syringed urine from a single sheet were combined to represent a pooled sample. Each urine  
490 sample was divided in half and aliquoted into lysis buffer or VTM at an approximate ratio of one part  
491 sample to two parts preservative.

492

#### 493 *Serological and molecular assays*

494 Sera from the cross-sectional survey were heat inactivated at 56°C for 30 minutes, as described  
495 (108) prior to shipment to the Center for Infection and Immunity at Columbia University (New York,  
496 USA) for analysis. Samples were screened for anti-NiV IgG antibodies using an enzyme linked  
497 immunosorbent assay (ELISA) as described in (27). Sera from the longitudinal studies were sent to the  
498 Australian Animal Health Laboratory and were gamma irradiated upon receipt. Because of the large  
499 sample size and development of a high throughput multiplex assay of comparable specificity and  
500 sensitivity, for these samples we used a Luminex<sup>®</sup>-based microsphere binding assay to detect anti-Nipah  
501 G IgG antibodies reactive to a purified NiV soluble G protein reagent, as described previously (109, 110).  
502 Samples resulting in a Median Fluorescent Intensity (MFI) value of 250 and below is considered negative  
503 for other bat species and previous studies have reported using a threshold of at least three times the  
504 mean MFI of negative sera to determine the cutoff (47, 111-113). For this study, MFI values of over 1000  
505 were considered positive for NiV antibodies, an approach considered appropriate for research purposes  
506 for bats.

507 Total nucleic acids from swabs and urine samples were extracted and cDNA synthesized using  
508 Superscript III (Invitrogen) according to manufacturer's instructions. A nested RT-PCR and a real-time  
509 assay targeting the N gene were used to detect NiV RNA in samples (114). A RT-qPCR designed to detect  
510 the nucleocapsid gene of all known NiV isolates was also utilized (115). Oligonucleotide primers and  
511 probe were as described (115). Assays were performed using AgPath-ID One-StepRT-PCR Reagents  
512 (ThermoFisher) with 250 nM probe, 50 nM forward and 900 nM reverse primers. Thermal cycling was  
513 45°C for 10 min, followed by 45 cycles of 95°C for 15 s and 60°C for 45 s. Cut-off values were cycle  
514 threshold ( $C_T$ )  $\leq 40$  for positive and  $CT \geq 45$  for negative. Results with  $C_T$  values between 40 and 45 were  
515 deemed indeterminate, i.e. not conclusively positive or negative. Samples with NiV RNA detected by real  
516 time PCR were confirmed by gel electrophoresis and product sequencing.

517 A subset of NiV-positive samples was processed by high-throughput sequencing (HTS) on the Ion  
518 Torrent PGM platform in order to obtain additional NiV genomic sequence. Libraries were prepared  
519 according to the manufacturer's instructions, and 1 million reads allocated per sample. HTS reads were  
520 aligned against host reference databases to remove host background using bowtie2 mapper, and host-

521 subtracted reads primer trimmed and filtered based on quality, GC content and sequence complexity.  
522 The remaining reads were de novo assembled using Newbler (v2.6) and mapped to the full length NiV  
523 genome. Contigs and unique singletons were also subjected to homology search using MegaBlast  
524 against the GenBank nucleotide database, in case variance in parts of the genome precluded efficient  
525 mapping. From these data, N gene consensus sequences were constructed using Geneious v 7.1, and  
526 used for phylogenetic analyses.

527

#### 528 *Phylogenetic analysis*

529 All *P. medius* NiV sequences have been submitted to Genbank and accession numbers are  
530 included in **Figure 6**. Sequence alignments were constructed using ClustalW in Geneious Prime software  
531 (116). Phylogenetic trees of NiV N-gene sequences were constructed using Neighbor-Joining algorithms  
532 and figures constructed in FigTree 1.4.2.

533

#### 534 *Satellite telemetry and home range analysis*

535 We developed a collar system to attach 12g solar-powered Platform Terminal Transmitters (PTT)  
536 (Microwave Telemetry, Colombia, MD, USA) to adult bats using commercial nylon feline collars with the  
537 buckle removed and 0-gauge nylon suture to attach the PTT to the collar and to fasten the collar around  
538 the bat's neck. Collars were fitted to the bat such that there was enough space to allow for normal neck  
539 movement and swallowing, but so that the collar would not slip over the head of the animal (**Figure S6**).  
540 PTTs were programmed with a duty cycle of 10 hours on and 48 hours off. Data was accessed via the  
541 Argos online data service (argos-system.org; France). A total of 14 collars were deployed as follows: Feb  
542 2009: 3 males, 3 females from a colony in Shuvarampur, Faridpur district; Feb 2011: 3 males, 2 females  
543 from the same colony; and April 2011 Cox's Bazaar, 3 bats from a colony in Cox's Bazaar, Chattogram  
544 district. Bats were selected based on size such that the total weight of the collar (~21g) was less than 3%  
545 of the bat's body mass (Table S3).

546 The individual telemetry dataset was combined for each region and its aggregate utilization  
547 distributions (UD) computed in R using package 'adehabitatHR' (117). Population-specific home range is  
548 represented by the \*95% area enclosure of its UD's volume. The volume of intersection between the  
549 colonies quantifies the extent of home range overlap. To evaluate the potential for contact with the  
550 Cox's Bazaar colony, we calculated the most likely distance moved ('mldm') for each sampled bat at  
551 Faridpur where the population was more intensively monitored. Movement distance was measured in  
552 kilometers with respect to a center location (w) shared by the whole colony. This information was used  
553 to predict how likely an animal was to use the landscape.

554

#### 555 *Statistical approach – cross-sectional study*

556 We fit a Bayesian generalized linear model with a logit link and a Bernoulli outcome to identify  
557 potential predictors which influenced a bat's serostatus. We included age, sex, age- and sex-normalized  
558 mass and forearm length, mass:forearm ratio, body condition, and whether the bat was pregnant,  
559 lactating, or carrying a pup, using weak zero-centered normal priors for all coefficients. We included  
560 location of sampling as a group effect (similar to a random effect in a frequentist context) nested within  
561 Nipah Belt or non-Nipah Belt regions. We fit the models and performed posterior predictive checks in R  
562 3.4.3, using the **rstanarm** and **rstan** packages.

563

564 *Statistical approach – longitudinal study*

565 We fit binomial general additive models (GAMs) (118) to the time series of adult and juvenile  
566 seroprevalence in the longitudinal study. We included annual, synchronous birthing that occurred  
567 between March and April. We assumed that pups weaned from their dams at 3 months, and became  
568 independent flyers, and that maternal antibodies waned after 6 months at which point pups  
569 transitioned into the “juvenile” class (30, 61). We assumed that juveniles became sexually mature at 24  
570 mo., and entered the “adult” class based on other pteropid species (30, 47, 119). For juveniles, we  
571 modeled the birth cohort of bats as separate random effects in a pooled model of juvenile  
572 seroprevalence starting from June of their birth year; June being the earliest month we sampled free-  
573 flying juveniles in any cohort. We determined the cohort year of juveniles by using cluster analysis to  
574 group individuals by weight, assuming those in the smallest group were born in the current year and  
575 those in the larger group were born the previous year. 92% of juveniles captured were yearlings. For  
576 adults, we analyzed seroprevalence of adults as a single pool over the entire course of the study. We  
577 tested models with and without annual cyclic effects.

578 Where time series had significant temporal autocorrelation (adults only), we aggregated data by  
579 week. We determined periods of significant increase or decrease as those where the 95% confidence  
580 interval of the GAM prediction’s derivative did not overlap zero. We fit the models and performed  
581 checks in R 3.4.3, using the **mgcv** package.

582 To examine the importance of different biological mechanisms in transmission, we fit an age-  
583 structured (adult and juvenile) maternally immune (M)-susceptible (S)-infected (I)-recovered (R) model  
584 with recrudescence (R to I) and loss of immunity (R to S) to the seroprevalence data on a weekly  
585 timescale:

$$\frac{dS_J}{dt} = -S_J(\beta_{JJ}I_J + \beta_{AJ}I_A) - \mu_J S_J + bN_A(t-5)\frac{S_A}{N_A} - bN_A(t-52)\frac{S_J}{N_J}(1-\mu_J)^{52} + \lambda M_J$$

$$\frac{dI_J}{dt} = S_J(\beta_{JJ}I_J + \beta_{AJ}I_A) - \gamma I_J - bN_A(t-52)\frac{I_J}{N_J}(1-\mu_J)^{52}$$

$$\frac{dR_J}{dt} = \gamma I_J - \mu_J S_J - \mu_J R_J - bN_A(t-52)\frac{R_J}{N_J}(1-\mu_J)^{52}$$

586 
$$\frac{dM_J}{dt} = bA(t-5)\frac{R_A}{N_A} - \lambda M_J - \mu_J M_J - bN_A(t-52)\frac{R_A}{N_A}(1-\mu_J)^{52} \lambda^{52}$$

$$\frac{dS_A}{dt} = -S_A(\beta_{AA}I_A + \beta_{JA}I_J) - \mu_A S_A + \tau R_A + bN_A(t-52)\frac{S_J}{N_J}(1-\mu_J)^{52}$$

$$\frac{dI_A}{dt} = S_A(\beta_{AA}I_A + \beta_{JA}I_J) - \gamma I_A - \mu_A I_A + bN_A(t-52)\frac{I_J}{N_J}(1-\mu_J)^{52} + \Delta R_A$$

$$\frac{dR_A}{dt} = \gamma I_A - \mu_A R_A + bN_A(t-52)\frac{R_J}{N_J}(1-\mu_J)^{52} - \tau R_A - \Delta R_A$$

587 We included a class M for the density of juvenile bats with maternal antibodies to allow for the biological  
588 possibility that maternal antibodies are lost at a much higher rate than antibodies acquired following  
589 infection. The subscripts J refer to juveniles and A to adults,  $\beta$  is the transmission rate,  $\gamma$  is the recovery

590 rate,  $\mu$  is the mortality rate,  $\tau$  is the rate of loss of adult immunity,  $\lambda$  is the rate of loss of maternal  
591 antibodies(61),  $\Delta$  is the adult recrudescence rate (R to I),  $b$  is the birth rate (pups join the juvenile  
592 population after 5 weeks). Juveniles transition to adults after 52 weeks. We included terms for loss of  
593 antibody in adults ( $\tau$ , S to R), and viral recrudescence ( $\Delta$ , R to I) based on previous studies on captive bats  
594 that demonstrated the existence of these processes without providing enough data to characterize them  
595 precisely (64, 65). We fit this deterministic model to the seroprevalence data by maximum likelihood,  
596 which assumes that deviations from the model are due to observation error. We estimated the confidence  
597 intervals around maximum likelihood parameter estimates using likelihood profiles using the *profile*  
598 function in package *bbmle* in R v3.2.2.

599 We used model fitting and model comparison to examine the need for several of the biological  
600 processes in the model above that could influence NiV dynamics. First, we examined both density and  
601 frequency-dependent transmission by comparing the fit of the model above to one with transmission  
602 terms that have population size ( $N_A$  or  $N_J$ ) in the denominator. Second, we examined the confidence  
603 intervals of the parameters describing viral recrudescence, loss of antibodies in adult bats, and loss of  
604 antibodies in juvenile bats. If the confidence bounds for these parameters included zero, then these  
605 biological processes are not needed to explain the serological dynamics. Finally, we examined the  
606 confidence bounds for parameters describing the loss of maternal and non-maternal antibodies ( $\tau$  and  
607  $\lambda$ ), to determine if the rate of loss of these two types of immunity were different. We note that this  
608 model structure has similarities to a susceptible-infected-latently infected(L)-infected (SILI) model (if  
609 latently infected individuals are seropositive), but the model above differs in allowing for the possibility  
610 of individuals to transition from the R class back to the S class.

#### 611 *Code availability*

612 SIR model code written in R is available upon request.

613

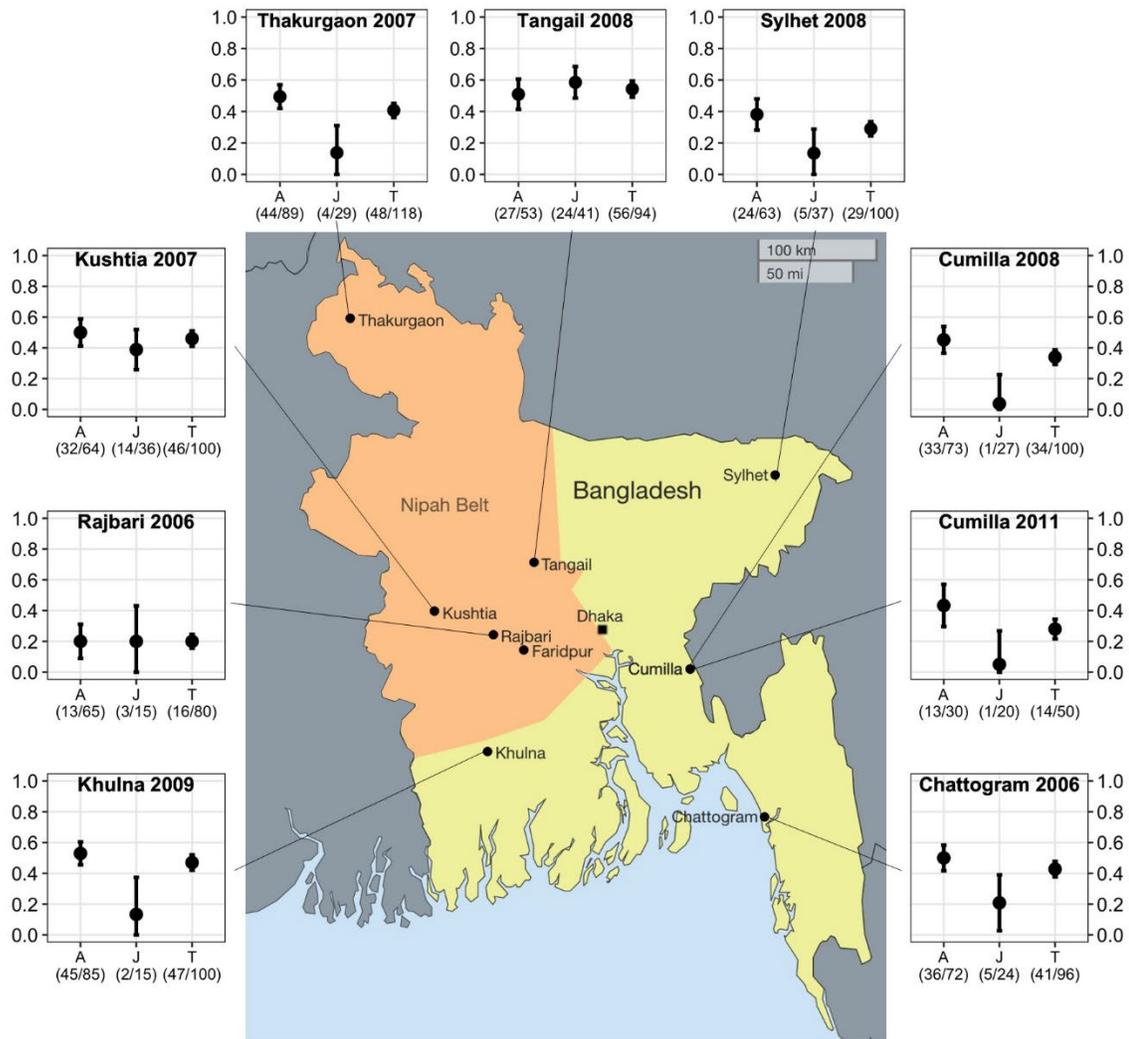

#### 614 *Data availability*

615 All molecular sequences are available via Genbank. The datasets generated during and/or analyzed  
616 during the current study are available from the corresponding author on reasonable request.

617

618

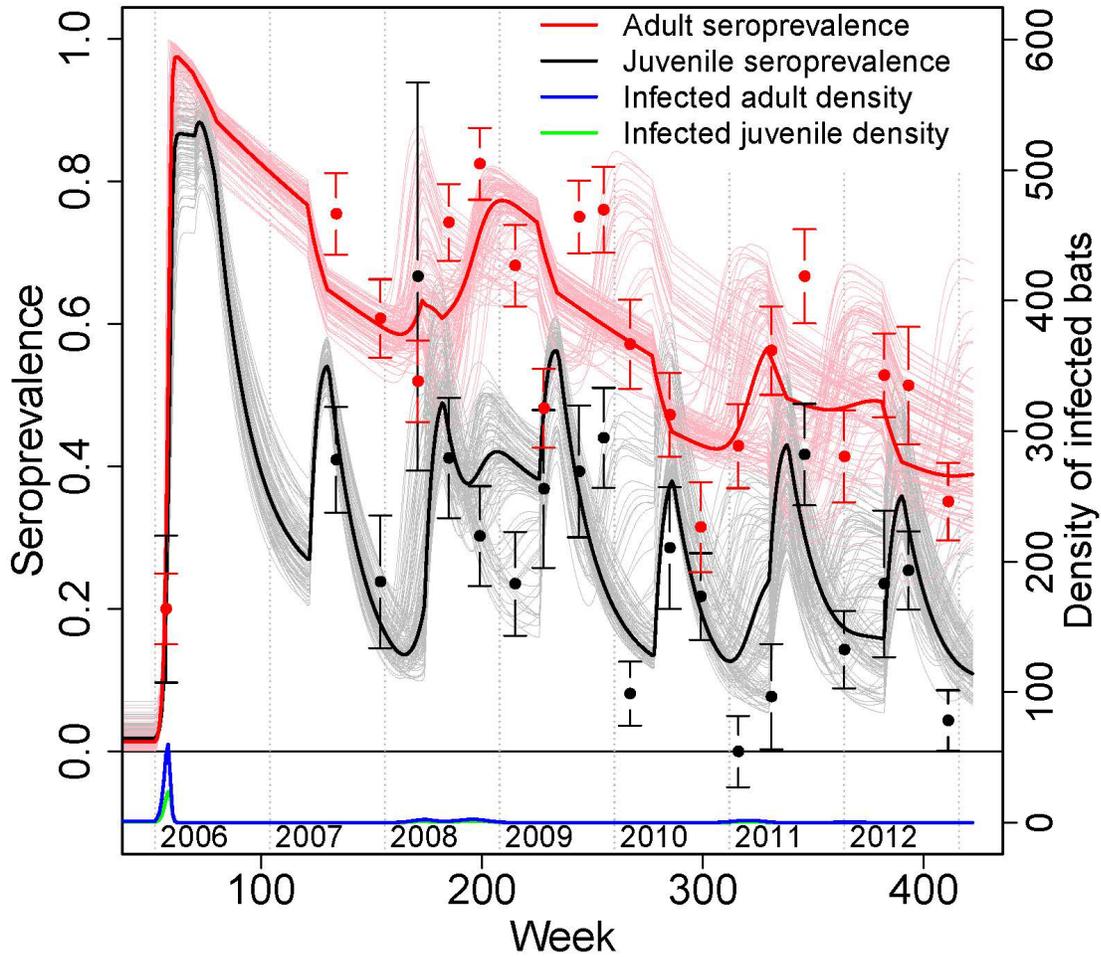

**Figure 1.** Map showing age-stratified seroprevalence in *Pteropus medius* colonies, Bangladesh. Bats from eight colonies were sampled and tested for anti-NiV IgG antibodies: four within the “Nipah belt” (orange shaded) and four outside. Seroprevalence of adults (A), juveniles (J) and total seroprevalence (T) are shown with 95% CI error bars. The shaded region represents the “Nipah belt” where previous human NiV outbreaks have been reported.

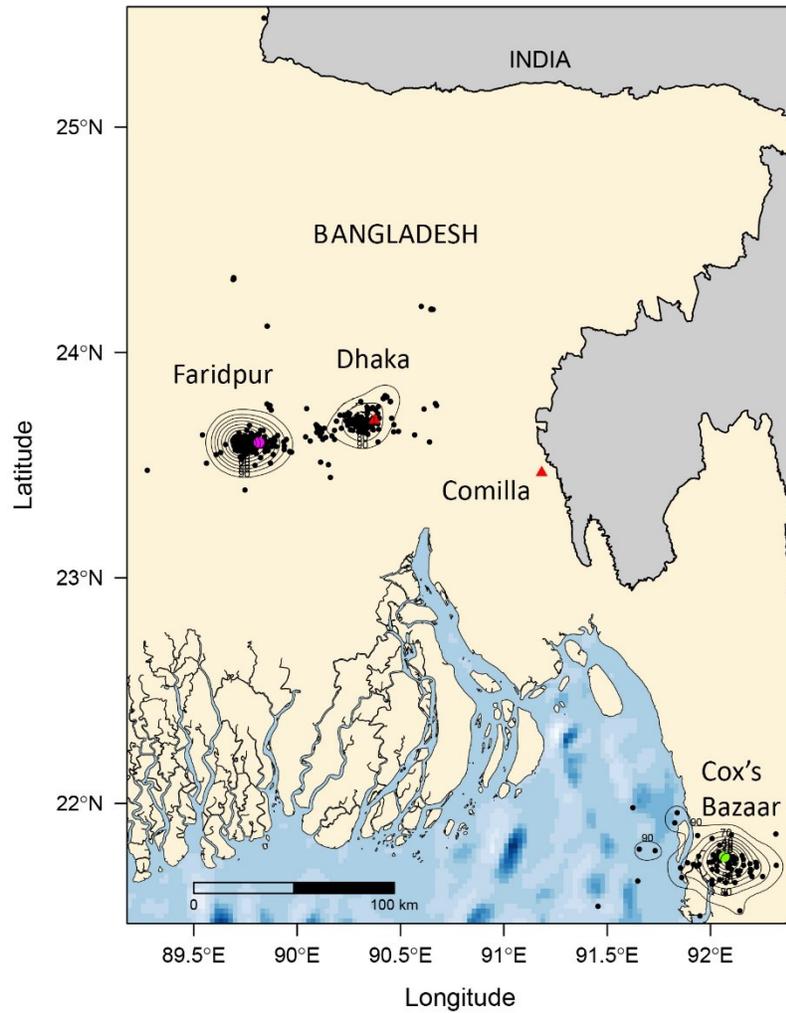

641  
 642 **Figure 2.** Results of Bayesian GLM of factors affecting Nipah serostatus in bats in cross-sectional study. Bars  
 643 indicate odds ratios and 50% (inner) and 95% (outer) credible intervals for model parameters. Factors with  
 644 asterisks (\*) have 95% CIs that do not overlap 1. Model intercept (predicted probability of seropositivity for a  
 645 juvenile, female, bat outside the Nipah belt of mean size and good body condition) was 0.26, (95% CI 0.12-0.56).  
 646 Random effect of location (not shown) had an estimated SD of 0.63 (95% CI 0.29-1.27)  
 647

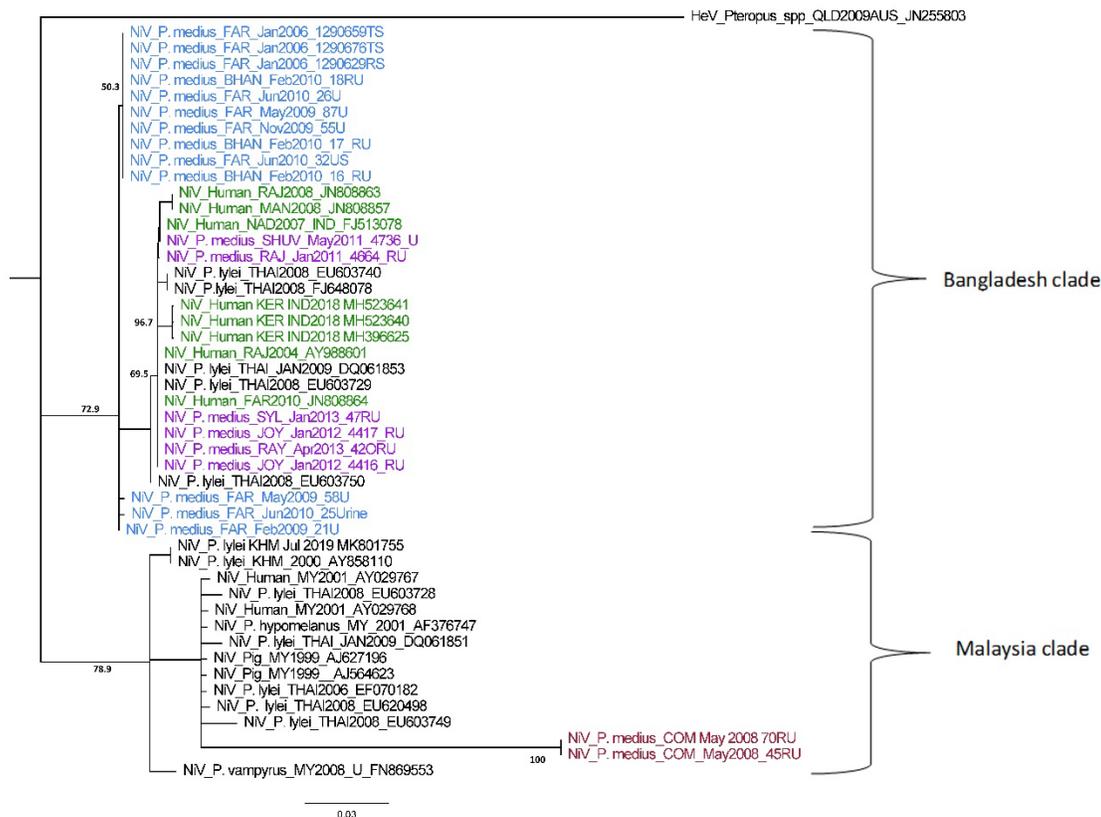

648  
 649 **Figure 3 A & B.** Serodynamics of the Faridpur bat population, measured and fit to a GAM. (A) Adult seroprevalence  
 650 over time, with measured values and 95% CI in blue, and mean GAM prediction and 95% shown with line and  
 651 surrounding shaded areas. Point from Feb 2006 (purple) shown separately due to ELISA vs Luminex measure.  
 652 Periods of significant change (where GAM derivative 95% does not overlap zero) are shown in red (increasing) and  
 653 green (decreasing). Periods of increase indicate viral circulation events in the adult population; these do not occur  
 654 with consistent periodicity or seasonality. Counts of primary human cases from local district (dark gray), and bat  
 655 viral viral detections (orange, see Table 1) are shown on bottom for comparison. (B) Juvenile seroprevalence during  
 656 the first year of life (“yearlings”). All years’ measurements are collapsed onto the scale of a single year overlain to  
 657 show yearling dynamics. Measured values and 95% CI shown in blue, and mean and 95% CI for the GAM model  
 658 pooled across cohorts shown with line and surrounded shaded areas. GAM realizations for individual years in grey,  
 659 overall effect in black. The period of significant decline in the GAM is shown in red. Juvenile seroprevalence  
 660 decreases over the course of the year, and is not distinguishable from a simple linear decrease ( $\Delta AIC < 1$ , dotted  
 661 line).

662  
 663 **Figure 4.** Longitudinal data and fitted model for NiV serological dynamics in adult and juvenile bats. Red and black  
 664 points show observed data ( $\pm 1$  SE) and solid lines show the fitted model (thick lines show the trajectory for the  
 665 model with maximum likelihood parameter estimates; thin lines show realizations for parameter estimates drawn  
 666 from the estimated distributions) for the fraction of adults and juveniles seropositive for NiV (left axis), and the  
 667 model-estimated number of infected adult and juvenile bats (bottom panel and right axis). See Methods for details  
 668 of model structure.  
 669  
 670

671  
 672 **Figure 5.** Satellite telemetry and home range analysis. Location data from satellite collars (n=14) placed on 11 bats  
 673 from Faridpur and 3 bats from Cox's Bazaar, Chattogram collected between 2009 and 2011, were used to calculate  
 674 local and long-range movement patterns and home range for these two groups.  
 675

7/21/2020

Dear Editor,

We are pleased to provide a revised manuscript entitled: *Nipah virus dynamics in bats and implications for spillover to humans* and a detailed response to reviewers' comments. We thank the reviewers for their overall enthusiasm for the study and their constructive comments which have allowed us to significantly improve the manuscript. We have responded to each of their comments, as detailed below. Our manuscript has even more relevance at a time when the world is experiencing a severe pandemic due to what is likely a bat-origin zoonotic virus, and hope that this study provides insight that will inform future ecological studies of zoonotic viruses, including coronaviruses, in bats.

We look forward to the review of our revised manuscript and hope that it is now considered acceptable for publication in PNAS.

Sincerely,

(b) (6)

Dr. Jonathan Epstein  
EcoHealth Alliance

Specific responses to reviewers:

*Reviewer 1*

- 1) **The methods section uses jargon** –We agree with Reviewer 1 that the methods included many technical terms. We have tried to reduce jargon where possible.
- 2) **What is the nature of recrudescence and of antibody disappearance in bats? Some of these questions could be answered by experimental studies.** We have added background describing what is known about antibody response to NiV infection in bats and the loss of antibodies in adults and juveniles, based on experimental data. Lines 124 - 131
- 3) **Are colonies species specific?** In Bangladesh, where this study took place, *Pteropus medius* is the only endemic species of *Pteropus* bat and they do not co-roost with other bat species. We have clarified this in lines 85-86. We also discuss *Pteropus* ecology in more detail in lines 273-285, including interspecies interactions.
- 4) **In the abstract the term "epidemic" is used rather than "epizootic".** While epizootic is the technical term for circulation among animals, readers may be more familiar with the term epidemic, so in our effort to reduce jargon, we have stayed with this term and made sure that there is appropriate context to clarify whether we're discussing an outbreak among bats or in people. (see lines 398-404).

- 5) **Lines 91-92, regarding pandemic potential, I would not use this term because some observers, probably most, think the pandemic potential is low. This might be a controversy well avoided.** We removed the word pandemic from the abstract, but left it in the introduction. S. Luby describes the pandemic potential of henipaviruses in (Luby. *Antiviral Research* (100) 1. 2003.). Given that we know so little about other henipaviruses in bats, and there is already evidence for variation in transmissibility among humans between Bangladesh and Malaysia strains, we believe that the possibility that there are or could be more transmissible strains is valid.
- 6) **Explain the movement data more and in general expand on speculation in the discussion / strengthen the conclusion.** We have added more discussion of the localized movement findings and speculation in the discussion. We have also strengthened the language in the conclusion.
- 7) **Figures: Figure 1. Improve coloring and visibility of error bars; Figure 3 needs a clearer explanation; Figure 4 is difficult to read. Do peaks of juvenile prevalence follow declines of adult prevalence? Fig. 5 expand on discussion of movement data.** We have updated figures 1-4 to improve readability and captions for 3 and 4 have been updated for clarity. Peaks of juvenile prevalence reflect seasonal birthing where pups are born with maternal antibodies then lose them after about 5-6 months. Our longitudinal data and mechanistic model shown in Figure 4 show that adults lose seroprevalence over time, but spikes in adult seroprevalence are independent of spikes in juveniles, which appear to be due to maternal antibodies. We address this in the discussion section in lines 201-310. We have expanded our discussion of movement data.

## Reviewer 2

- 1) **Statistical support for higher adult seroprevalence? And, could test be non-specific?** Figure 3 shows that adults had a statistically significant greater seroprevalence than juveniles. The ELISA used is specific to Nipah virus and the Luminex multiplex assay contained specific antigens from other henipaviruses (Nipah, Hendra, and Cedar virus). We agree that it's possible for either assay to cross-react with antibodies against other unknown henipaviruses circulating in *P. medius*. The Luminex assay allows us to determine whether there may be reactivity to non-Nipah henipaviruses based on the ability to compare quantitative outputs for multiple henipavirus antigens. We added this to the discussion in lines 289-297.
- 2) **Fig 4: Are spikes in juveniles observed before spikes in adults reflective of juveniles transitioning into adults?** We don't think so, because adults showed independent patterns of spikes in seroprevalence not associated with annual seasonal spikes in juveniles. We believe the spikes in juveniles are consistent with synchronous birthing patterns where pups are born with then lose maternal antibodies.

3) **Figure 5: Is sample size adequate to represent full range? Do *P. medius* interact with other bats? Does range change with season? Could other species serve as reservoirs?**

We discuss the small but illustrative sample size in lines 331-2, and that these sample sizes are comparable to other satellite telemetry studies in pteropodid bats. We compare them to range data from pteropid species in Malaysia which showed greater range of movement. *P. medius* do not roost with other bat species, however they do feed in the same locations as two other frugivorous bats: *Rousettus leischenaulti* and *Cynopterus horesefidi*. These bats have been screened for henipaviruses under different studies, and have not been found to be hosts. We cannot rule it out, but the majority of evidence (experimental, virus isolation, PCR detection and serology) globally is that *Pteropus* bats are the primary reservoir for henipaviruses, which we discuss. Seasonal data is presented in the results section (lines 229-230). Host range does contract in the dry season, as we show in suppl. Fig S3 & S4 and added a line in the discussion to suggest a reason for the finding (lines 343-4).

- 4) **Fig 6. Is the 224nt fragment representative of the whole genome?** The Nucleocapsid gene was used because it is among the most conserved regions of the henipavirus genome, and past published data indicate that N gene genetic tree has a high concordance with whole genome phylogeny. This was also confirmed in our current study. While we, unfortunately, could not get whole genome sequences from our positive samples, we were able to obtain whole and near-whole N gene sequences (1,592 nt) from a subset of the samples in this study and from the isolates described in (Anderson et al. 2019), and we generated a phylogenetic tree using these sequences (Fig. S5). This tree supports the relationships we see in the tree we use in Figure 6. Further, in Anderson et al., 2019, we constructed a tree using whole NiV genomes from bat and human isolates. Some of the bat isolates are included in our N gene trees. We see consistent relationships among the bat and human whole genome sequences in Anderson et al., and the N gene sequences in Fig 6. in this paper. We are therefore confident that the N gene reflects the relative phylogenetic relationships that would be seen among whole genome sequences. Finally, it should be noted that recombination has not been observed in paramyxovirus genomes and this also explains the concordance of phylogeny between individual genes (except the most variable regions) and the whole genome sequences.

The question of how divergent the Comilla strain would be across its whole genome is an excellent one. The sequence we have from the N gene suggests this virus is more closely related to viruses in the Malaysia clade than those from Bangladesh. The serological assays used in our study would not differentiate between Nipah virus strains from the Malaysia or Bangladesh clade.

**Subject:** Update on PNAS Nipah paper: resubmitted  
**Date:** Tuesday, July 21, 2020 4:27:06 PM  
**Attachments:** [Nipah dynamics in bats Epstein et al 2020 revised w figs.docx](#)  
[Nipah dynamics in bats Epstein et al 2020 response letter final.pdf](#)

---

Hi everyone,

I hope everyone is staying safe and healthy. I wanted to update you on the status of our PNAS paper. I was finally able to finish responding to the reviewers' substantive though positive comments, and have resubmitted the revised manuscript. Thank you to those of you who helped with specific questions the reviewers had. I've attached the revised manuscript and the response letter to the Editor, for your records.

I don't know what the timing of review will be given that PNAS says they're backed up and prioritizing COVID-19 papers, but hopefully it won't be too long. Mostly, thank you all for your continued patience, and here's hoping for a positive response.

Cheers.

Jon

## PROJECT SUMMARY/ABSTRACT

Southeast Asia is one of the world's highest-risk EID hotspots, the origin of the SARS pandemic, Nipah virus, and repeated outbreaks of influenza. This is driven by high diversity of wildlife and rapidly expanding demography that brings human and wildlife populations closer. This proposal will launch the **Emerging Infectious Diseases - South East Asia Research Collaboration Hub (EID-SEARCH), a collaboration among leaders in emerging disease research in the USA, Thailand, Singapore and the 3 major Malaysian administrative regions. These researchers have networks that span >50 clinics, laboratories and research institutions across almost all SE Asian countries and will use the EID-SEARCH as an early warning system for outbreaks involving exchange of information, reagents, samples and technology, and a collaborative power-house for fundamental and translational research. The EID-SEARCH will also act as **a significant asset to scale-up and deploy resources in the case of an outbreak in the region.** This EIDRC will conduct research to: **1) Identify, characterize and rank spillover risk of high zoonotic potential viruses from wildlife,** by analyzing previously-archived wildlife samples, conducting targeted wildlife surveillance, and using serology & PCR assays to identify novel viruses. These will be characterized to assess risk of spillover to people, and a series of *in vitro* (receptor binding, cell culture) and *in vivo* (humanized mouse and collaborative cross models) assays used to assess their potential to infect people and cause disease; **2) Collect samples and questionnaire data from human communities that live in EID hotspots and have high cultural and behavioral risk of animal exposure (e.g. wildlife hunting, bat guano collection).** These will be tested with serological assays to identify evidence of novel virus spillover, and analyzed against metadata to identify key risk pathways for transmission; **3) Identify and characterize viral etiology of 'cryptic' outbreaks in clinical cohorts.** We will conduct syndromic surveillance at clinics serving the populations in Aim 2, enroll patients with undiagnosed illness and symptoms consistent with emerging viral pathogens, and test samples with molecular and follow-up serological assays to identify causal links between these syndromes and novel viruses.**

This research will advance our understanding of the risk of novel viral emergence in a uniquely important region. **It will also strengthen in-country research capacity** by linking local infectious disease scientists **with an international collaborative network that has proven capacity to conduct this work and produce significant findings.** The large body of high impact collaborative research from this EIDRC leadership team provides proof-of-concept that EID-SEARCH has the background, collaborative network, experience, and skillset to act as a **unique early warning system for novel EIDs of any etiology threatening to emerge in this hottest of the EID hotspots.**

## II. Research Strategy:

**1. Significance:** Southeast Asia is a critical hotspot for emerging diseases due to its high biodiversity of wildlife and their viruses, and the presence of key ecological and socioeconomic drivers of emergence (**Fig. 1**) (1). These include dense human populations living in networks of rural and urban communities, with strong cultural and occupational connection to wildlife and livestock farming and trading, and intimate connection to global travel networks (2). The region is undergoing rapid environmental and demographic change, both of which increase the risk of disease emergence and spread. Pathogens that emerge in this region often spread and sometimes enter the USA (e.g. prior influenza pandemics, SARS) and threaten global health security.

**Fig. 1:** Southeast Asia, and in particular, parts of Thailand and Malaysia are hotspots of risk for disease emergence (**left**), and predicted high diversity of 'missing' or as-yet undiscovered viruses, yellow = highest diversity (**left**). From (1-3).

Not surprisingly novel viruses, including near-neighbors of known agents, have emerged in the region leading to often unusual clinical

presentations (**Table 1**). This adds to a significant background burden of repeated Dengue virus outbreaks in the region (20), and over 30 known *Flavivirus* species circulating throughout S. and SE Asia (21). The events in Table 1 are dominated by three viral families: coronaviruses (CoVs), paramyxoviruses (PMVs - particularly henipaviruses) and filoviruses (FVs), which are initial examples of our team's research focus and capabilities. These viral groups have led to globally important emerging zoonoses (4, 5, 22-31), causing tens of thousands of deaths, and costing billions of dollars (32-34). Furthermore, near-neighbors of known pathogens in these families have been reported throughout the region, including by members of our consortium: henipaviruses in bats in Thailand, Cambodia, Philippines, Laos, Indonesia, China, Malaysia, Bangladesh and India (35-41); a novel henipavirus, Mòjiāng virus, in wild rats in Yunnan (14); serological evidence of FVs in bats in Bangladesh (42) and Singapore (43); Nipah- and Ebola-like viruses in *Hipposideros*, *Cynopterus* and *Rhinolophus* species in Malaysia (Hughes *et al.*, in prep.); evidence of novel FVs in bats in China (44-46), including Měnglà virus

Viral agent	Site, date	Impact	Novelty of event	Ref.
Nipah virus	Malaysia, Singapore 1998-9	~246 human cases, ~40% fatal	2 <sup>nd</sup> emergence of a zoonotic henipavirus, 1 <sup>st</sup> large outbreak	(4-6)
Melaka & Kampar virus	Malaysia 2006	SARI in family group, individual	1 <sup>st</sup> disease due to bat-origin reoviruses, also Singapore, Vietnam etc.	(7-10)
Reston filovirus	Philippines 2008	Seropositive people killed pigs,	No prior FVs in pigs	(11)
Thrombocytopenia Syndrome virus	E. Asia 2009	100s of deaths in people	Novel tick-borne zoonosis with large caseload	(12)
Reston filovirus	Shanghai 2011	PCR positive pigs	Further evidence of pig RESTV infection	(13)
Mòjiāng virus	Yunnan 2012	Death of 3 mineworkers	1 <sup>st</sup> evidence of rodent origin henipavirus in people	(14)
Nipah-like virus	Philippines 2015	Killed horses	No prior horse infection for NiV, known for HeV	(15)
SARSr-CoV & HKU10-CoV	S. China 2015	Seropositive people	1 <sup>st</sup> evidence human infection HKU10 & SARSr-CoV	(16)
SADS-CoV	China 2017	>25,000 pig deaths seronegative people	Novel emergence of bat-origin CoV	(17)
Nipah virus	Kerala 2018, 2019	Killed 17/19 people 2018, 1 infected 2019	1 <sup>st</sup> outbreak of NiV outside Bangladesh, W. Bengal focus	(18, 19)

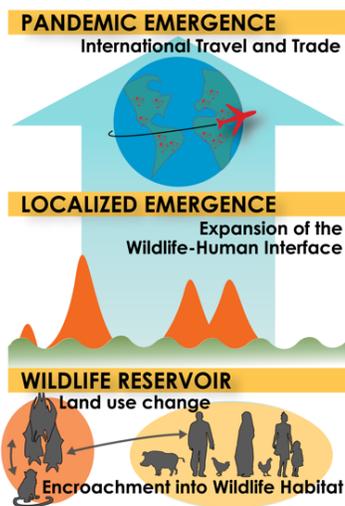

that appears capable of infecting human cells (47); novel PMVs in bats and rodents consumed as bushmeat in Vietnam (48); a lineage C  $\beta$ -CoV in bats in China using the same cell receptor as MERS-CoV to infect human cells *in vitro* (49); MERSr-CoVs in bat guano harvested as fertilizer in Thailand (50), and directly in bats (Wacharapluesadee *et al.*, in prep.); 172

**Table 1:** Recent emergence events in SE

Asia indicating potential for novel pathways of emergence, or unusual presentations for known or related viruses.

novel  $\beta$ -CoVs (52 novel SARSr-CoVs) and a new  $\beta$ -CoV clade (“lineage E”) in bats in S. China that occur throughout the region (24, 49, 51, 52); 9 novel wildlife-origin CoVs and 27 PMVs in Thailand, and 9 novel CoVs in Malaysia reported by us from USAID-PREDICT funding (51, 53). These discoveries underscore the clear and present danger of zoonotic events in the region. The wide diversity of potentially pathogenic viral strains also has significant potential use in broadly active vaccine, immunotherapeutic and drug development (49).

Most high-impact zoonotic viruses originate in wildlife reservoirs, sometimes spilling over first into livestock ‘amplifier’ hosts, or directly into localized human populations with high levels of animal contact (**Fig. 2**). Efforts to prevent emerging zoonoses have targeted these high-risk populations in regions prone to disease emergence (31, 54). However, these regions tend to be in the developing world, where nations often lack the resources to investigate novel zoonotic events, or wildlife reservoirs of zoonoses, and prioritize more immediate public health concerns such as Dengue virus or NTDs (20). Zoonotic disease surveillance and control is also hampered by inadequate information on basic disease ecology (e.g. range of wildlife reservoirs, risk factors for spillover) and pathogen biology (viral diversity, pathogenesis), and by logistical challenges sharing novel diagnostics, animal models, samples and reagents at sites where outbreaks begin (55). Countermeasure and vaccine development is challenged by the small number of isolates available, and the presence of closely-related strains, some with evidence of transmission to people but with unknown pathogenicity. For example, using NIH and other funding, we found serological evidence of exposure to African henipaviruses in 3-4% of a sample of people in Cameroon, with a significant risk factor being butchering of bats; and serological responses to bat SARSr-CoVs in 6/209 (2.87%) and bat HKU10-CoV in 2/412 (0.5%) people living close to a bat cave in Yunnan, all novel viruses with unknown clinical impact (16, 56). We discovered two novel bat-borne reoviruses, Melaka and Pulau viruses, and showed that 14/109 (13%) of people living in close proximity to bat roosts on Tioman Island, Malaysia were exposed to these viruses (7) as well as 12/856 (1.4%) of a random sample screened in Singapore (8). Previous studies in the Philippines found farmers and butchers who had contact with sick pigs tested positive for Reston ebolavirus antibodies but had not experienced illness (11), and it was our team that discovered Philippine bats as natural reservoir hosts for Reston virus (57). In preliminary screening in Malaysia with funding from DTRA we found serological evidence of exposure to henipaviruses (Hendra, Nipah and Cedar) in 14 bats and 6 human samples, and Ebola (Zaire and Sudan)-related viruses in 11 bats, 2 non-human primates (NHP) and 3 human samples (Hughes, in prep.).

Even when spillover leads to outbreaks of illness and mortality, they are often unreported, undiagnosed or misdiagnosed. We initiated targeted syndromic surveillance of encephalitis patients in Bangladesh clinics and showed that Nipah virus (NiV) causes repeated annual outbreaks with an overall mortality rate of ~70% (58). NiV has been reported in people in West Bengal, India, which borders Bangladesh (28), in bats in Central North India (59), and now in people in Kerala, South India in 2018 and 2019, raising the specter of future spillover at other sites in the region (18, 60).

**Fig. 2: Our Early Warning Approach:** Most zoonotic viruses emerge from wildlife hosts, sometimes via livestock (**lower panel**), to cause small scale outbreaks (green) or larger chains (red) of human-to-human transmission (**middle**). In some cases, these spread more widely via air travel (**upper**). Our EIDRC proposal targets each stage: SA1 examines the diversity and spillover potential of viral threats in targeted SE Asian wildlife; **SA2** seeks evidence of their spillover into focused high-risk human populations; **SA3** identifies their capacity to cause illness and to spread more widely. Figure from (54).

Under a current NIAID R01, we have shown that we can use analytical approaches to target surveillance of wildlife and people and identify likely sites of spillover. We used phylogenetic analysis of bat hosts and their CoVs to identify a key cave complex in SW Yunnan Province that harbors all the genetic elements of SARS-CoV (61), as well as a series of SARSr-CoVs that can infect human cells *in vitro*, cause SARS-like clinical signs in humanized mice, and evade vaccine treatment and therapeutics (24, 49, 51, 52, 62-64). We conducted risk factor surveys and biological sampling of human populations living close to this cave and found serological evidence of spillover in people highly exposed to wildlife (16). **This work provides proof-of-**

**concept for an early warning approach that we will expand in this EIDRC to target other viral groups in one of the world's most high-risk EID hotspots.**

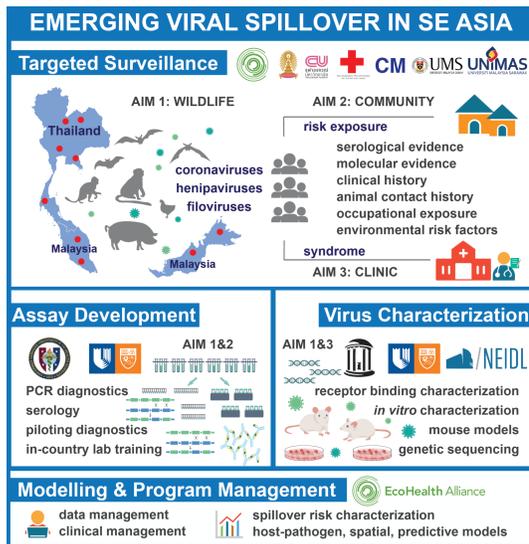

The overall premise of this EIDRC proposal is that there is substantial evidence that: 1) diverse CoVs, henipaviruses and FVs related to known human pathogens are circulating in wildlife reservoirs in Southeast Asia; 2) these viruses likely spillover regularly to people, are often unreported or misdiagnosed, and their clinical manifestations and potential to cause pandemics are unknown and underestimated; and 3) our strategy for targeted surveillance and detection of spillover and illness in at-risk human populations can be used as an 'early warning system' to conduct public health interventions and disrupt disease emergence. To scale-up this approach, we propose to launch EID-SEARCH (the **E**merging **I**nfectious **D**iseases - **S**outh **E**ast **A**sia **R**esearch **C**ollaboration **H**ub), to better understand, and respond to, the risk of zoonotic viral emergence in Southeast Asia. We will initially focus on the diversity of known and novel CoVs, henipaviruses, and FVs in wildlife reservoirs. We will use this work to build our center's interactive network throughout the region, bridge barriers, provide early focal point for basic and translational studies, develop sample handling and storage routines, communication networks, cohort management, infrastructure development, and cross-training in surveillance and novel diagnostic platforms. We will develop and transfer technology to test these viruses' capacity to infect human cells and mouse models, develop new specific and sensitive serological and molecular diagnostic tools, conduct surveillance of human communities with high risk of exposure to wildlife, and clinical cohorts to identify evidence of spillover of viruses causing previously 'cryptic' clinical syndromes in people. We will test the capacity of novel viruses to infect human cells and/or mouse models, and thus assess potential for spillover and spread which will feed into our risk models. Our group also has extensive experience in other viruses, including vector-borne flaviviruses, and alphaviruses, and will use this experience to provide robust long-term surveillance, diagnostics, and basic science opportunities. While the current proposal focuses its basic and applied research agendas on this group of viral EID, we note that the EID-SEARCH is poised to rapidly respond to any outbreak. **Thus, FVs, henipaviruses and CoVs are examples of sentinel surveillance systems in place that illustrate EID-SEARCH's capacity to identify and initiate a rapid response targeting any novel microbial pathogen that emerges in this region.**

**2. Innovation:** Previous work by our consortium has developed strategies to target surveillance in wildlife and people to better anticipate and identify early spillover events and pre-empt outbreaks of emerging viruses. In the EID-SEARCH we scale up this approach in a central research "hub" made up of leading laboratories, clinics and surveillance sites in three critically high-risk EID hotspot countries in SE Asia. EID-SEARCH's reach is expanded through its regional network of collaborators that covers nearly all of the greater SE Asia region. The innovation of the EID-SEARCH is in: 1) Its multidisciplinary approach that combines modeling to target geographic and taxonomic sampling targets with on-the-ground zoonotic disease surveillance in human and wildlife populations; 2) the biological characterization approach that identifies how likely viruses are to be able to infect people, and enables evaluation of existing countermeasure technologies; an approach that is grounded in our successful work on SARS-CoVs; and 3) the strategic sampling of both high-risk communities with extensive animal contact at the front-lines of viral spillover and syndromic clinical cohorts that present with signs of novel viral emergence, to identify risk of viral spillover in an early warning system approach (**Fig. 2**). **In Aim 1, we will target viruses in archived and newly collected wildlife samples, and characterize their risk of spillover to people.** We will use spatial and phylogeographic analyses to identify the geography and species of wildlife to test samples from, and to further characterize viruses we have recently discovered. We will use *in silico* methods (novel ecological-phylogenetic risk ranking and mapping of receptor binding domains), cell culture, and animal models to assess their potential for spillover into high-risk human populations. **In Aim 2, we will conduct targeted cross-sectional serological surveys of human communities with high levels of animal contact to find evidence of viral spillover, and identify occupational and other risk factors for zoonotic virus transmission.** We will use serological tests targeting viruses identified in Aim 1 to identify the baseline spillover of known or novel CoVs, henipaviruses and FVs in these populations. Serological findings will be analyzed together with subject metadata (including a simple animal-contact survey, location data, viral sequence/isolates etc.) to identify zoonotic risk factors and routes of exposure from specific wildlife or vector species. **In Aim 3, we will use syndromic surveillance of clinical human cohorts to identify evidence of viral etiology for otherwise 'cryptic' outbreaks.** We will enroll and

collect biological samples from patients in local clinics and hospitals who present with syndromes previously linked to known viral agents and live within communities at high risk for disease emergence. We will conduct molecular and follow-up serological diagnostic assays to identify likely viral etiology of syndromes that may represent otherwise cryptic events. Where viruses are identified, we will attempt to isolate or molecularly re-derive them, and use survey data, ecological and phylogenetic analysis to identify likely reservoir hosts and inform intervention programs. Our US partner BSL-4 laboratory, NEIDL, will attempt isolation and characterization of viruses requiring BSL-4 of containment (e.g. novel filoviruses, close relatives of Hev/NiV).

**3. Approach: 3.1. Research team:** The EID-SEARCH builds on long-term collaboration among world leaders in emerging virus research with proven experience collaborating internationally on field, lab and human surveillance research (**Fig. 3**). Over the past two decades, our consortium partners have conducted high profile research on EIDs within the region and globally, including identifying the wildlife reservoirs for NiV and Hendra virus (HeV), MERS- and SARS-CoVs (24, 27, 59, 61, 65-67), discovering SADS-CoV (17), and developing an array of serological, molecular, *in vitro* and *in vivo* approaches to characterizing high-risk CoVs, henipaviruses, and FVs (62-64, 68-81). Our team has substantial experience conducting human surveillance in the community and during outbreaks (Sections 2.2.a., 2.2.b., 2.2.c, 3.2.a, 3.2.b), including: USAID-PREDICT, and DTRA-funded viral surveillance of indigenous communities in Peninsular Malaysia and syndromic surveillance of hospital patients in Sabah (Co-I Hughes); collection of >2,000 serum samples from healthy blood donors and sanitation workers, febrile and influenza like illness (ILI), and diarrheal stool samples from children under 5 years of age across Borneo Malaysia (Co-I Kamruddin); collaboration on the MONKEYBAR project with the

London School of Hygiene and Tropical Medicine to analyze risk and prevalence of the zoonotic malaria *Plasmodium knowlesi* through case control and cross-sectional studies in Sabah villagers (n=~800, 10,000 resp.) and clinical observational studies to determine the etiology of central nervous system infections and acute undifferentiated febrile illness in Sabah. (Co-Is William, Rajahram, Yeo); and community-based surveillance of hundreds of bat-exposed villagers in Thailand (Co-Is Wacharapluesedee, Hemachudha). As a proof-of-concept of how our team can rapidly scale up resources for diagnostics and surveillance in the face of a new EID, in 2016, we discovered a novel bat-origin HKU-2 CoV (82, 83) killing >20,000 pigs in S. China, designed PCR and serological assays, surveyed pig farmers for evidence of exposure, and conducted experimental infections, pathogenesis and molecular studies, **all in the span of 3 months** (17, 84).

**Fig. 3:** EID-SEARCH scope, core institutions, and roles.

The administration of this center (**Section 4.1.**) will be centralized at EcoHealth Alliance (EHA) led by PI Daszak, who has >20 years' experience managing international research collaborations on emerging zoonoses, and has collaborated with all partners in the EIDRC consortium for 5-20 yrs on NIAID- and USAID-funded research. He will oversee all activities in this EIDRC, supported by Deputy lead, Dr. Olival – who has managed human and wildlife disease surveillance projects in SE Asia for >10 years, and a **Core Executive Committee (Section 4.1.a)**. Co-Is Olival and Zambrana are leaders infectious disease analytics, and head the modeling and analytics work for USAID-PREDICT. Co-Is Wang, Baric, Broder, Anderson, and Laing have developed a unique array of *in vitro* cell culture, serological and molecular reagents to identify and characterize emerging viruses in people and animals (henipaviruses and other PMVs, CoVs, FVs and many others). Co-Is Wacharapluesedee, Hemachudha, and Hughes and collaborators have coordinated clinical and community surveillance of people, and of wildlife and livestock within Thailand and Malaysia for the past 15 years, in collaboration with Ministries of Health, Agriculture and Environment. Finally, this consortium has extensive external funding from NIH, DoD, USAID, DHS and other USG agencies supporting laboratory, analytical and field studies directly related to the current proposal, and will bring substantial leverage to our EIDRC.

**3.2. Geographical focus:** The three core (hub) countries for this proposed EIDRC are Thailand, Malaysia and Singapore, three contiguous EID hotspot countries that stretch through one of the most significant foci of EID origins globally. Our proposed work includes sampling wildlife and people in Thailand, Peninsular Malaysia, Sarawak and Sabah, and thus contains overlapping wildlife biogeography with India, Bangladesh, Myanmar, SW China, Laos, Cambodia, Vietnam, Philippines, and Indonesia. It encompasses diverse cultural and socioeconomic backgrounds which have correspondingly diverse and intensive interactions with wildlife reservoirs and the global travel network. We have already begun sampling of wildlife hunters, livestock workers, wildlife farmers and market workers, rural villagers living close to high risk wildlife species, people otherwise highly exposed to animals in these countries, and clinical cohorts, as part of current/prior NIH, DTRA, and USAID funding. Our core member's extensive network of collaborators in clinics, research institutes and public health laboratories in almost every other Southeast Asian country positions the EID-SEARCH within a much larger catchment area for emerging zoonoses and will allow us to rapidly scale up to include additional sites in response to an outbreak or shift in research priorities. We will conduct regular meetings with key research, public health and community leaders, including >50 leading laboratories/institutions in 10 countries (**Section 4.2**) to maintain these collaborative relationships with the core members of our consortium (**Fig. 4**).

We will use these, and our annual meetings, to share information on novel research and diagnostic approaches, pathogens that are of key pandemic potential, regions or populations at high risk of spillover, and information from the greater network on likely outbreaks of novel disease. This platform will coordinate sample sharing and diagnostic platforms and help build a rapid response to outbreaks across the region.

**Fig.4 :** Map of Southeast Asia indicating three hub countries for this proposed EIDRC (**Red**: Thailand, Singapore, Malaysia) and countries in which Key Personnel have existing collaborating partners via other funded work (**Green**), indicating that EID-SEARCH provides access to key collaborators and sites throughout the region.

**3.3. Capacity for linkage with other NIAID studies, and scaling up to respond to outbreaks:** EID-SEARCH US-based partners include senior scientists with significant experience on NIAID-funded projects, extensive collaborations with other NIAID-funded scientists, and previous experience working with NIAID leadership through workshops, review of programs (e.g. PI Daszak's role in NIAID CEIRS external review), and work on study sections. These contacts ensure that the EID-SEARCH senior leadership will be ready and able to rapidly set up data, sample and reagent/assay sharing protocols with NIAID researchers, the other EIDRCs, the EIDRC CC and other NIAID research centers. EID-SEARCH in-country partners include senior medical doctors and infectious disease specialists at national and regional hospitals in each country and administrative state in this proposal. On news of potential outbreaks, **EID-SEARCH will rapidly mobilize its core staff and their extensive collaborative network across almost all SE Asian countries (Fig. 4) (Sections 4.1.a, 4.2. 4.3)**. The core analytical approach can be used to rapidly identify sampling sites and targets to harvest vectors, vector borne arboviruses, birds and mammalian species that harbor most other viral threats. Through existing projects such as the USAID PREDICT Project and DTRA-funded biosurveillance projects, EHA is currently partnered with hospitals and researchers across South and Western Asia, West and Central Africa, and Latin America. Our partners already have capacity to conduct human and wildlife sampling and testing for novel viral agents, so expanding in geography or scale is readily achievable given sufficient resources.

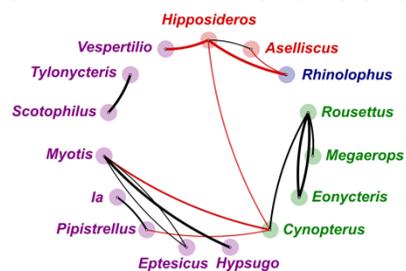

**Aim 1: Identify, characterize and rank spillover risk of high zoonotic potential viruses from wildlife.**

**1.1 Rationale/Innovation:** The vast majority of emerging zoonotic pathogens are linked directly or indirectly to wildlife host, particularly from important mammalian groups like bats, rodents and NHPs (3). Our previous work on wildlife origin viruses demonstrates that zoonotic viral emergence tends to occur in specific regions with high diversity of wildlife that harbor viruses of zoonotic potential, and human populations that have close contact to these wildlife (**Fig. 1**) (2, 3). In Aim 1 (**see Fig. 9 for overview**), we will strategically conduct EID

surveillance by applying risk analytics to prioritize the regions, wildlife species, and human populations that have a particularly high risk of viral spillover. We will target high-risk zoonotic host reservoirs (bats, rodents and NHPs) in these regions and apply novel predictive models to estimate viral diversity and host range to identify wildlife species that have been ignored or under-sampled by previous zoonotic disease surveillance efforts. We will strategically collect specimens from these species and screen them, together with some of the tens of thousands of recently collected samples we have archived, for known and novel agents. We will begin screening using conserved PCR assays to identify known and novel viruses in high risk RNA viral families, *Coronaviridae*, *Paramyxoviridae*, and *Filoviridae*. We will expand to other groups of pathogens, including arboviruses, pending available resources and priorities established with the EIDRC coordinating center (EIDRC-CC) and other regional EIDRCs. Using risk ranking algorithms and a series of ecological and virological risk factors, we will triage the wildlife viruses we discover for further genomic characterization and viral isolation. On this subset of viruses, we will then use *in vitro* and *in vivo* approaches (viral rescue, cell lines, gene edited humanized transgenic mice and the collaborative cross genetic reference mouse population) previously developed and widely used by our team to predict capacity of novel viruses to infect people and spillover (63, 85-88). These high-risk viruses and their close relatives will be targets for human community serosurveys and clinical sampling in Aims 2 and 3, respectively.

**1.2 Preliminary data: 1.2.a. Geographic targeting:** EHA has led the field in analyzing where the highest risk of zoonotic spillover is across the globe, identifying SE Asia as a major EID hotspot (1, 2). These hotspots are sites where high wildlife biodiversity, human population density and rapid ecologic change collide (**Fig 1**). Using host and ICTV viral data for all known mammalian viruses, and generalized additive models to correct for sampling bias, we are able to predict the relative number of yet-to-be-described viruses that a species harbors (3). This demonstrates substantial undiscovered viral diversity in mammals across Southeast Asia, and particularly in regions of Thailand, Singapore and Malaysia (**Fig. 1**). Separately, we found that factors driving spillover (host diversity, climate) differ from those driving spread in human populations (population density, bushmeat hunting, livestock production) (89). We therefore analyze capacity for viral spread as a separate risk factor, using our unique demographic and air travel and flight data modeling software (90, 91). In the current proposed work, we will use all the above approaches to target wildlife sampling (archival and new field collections) in Aim 1, to inform sites for human sampling in Aim 2, and to assess risk of spread in Aim 3.

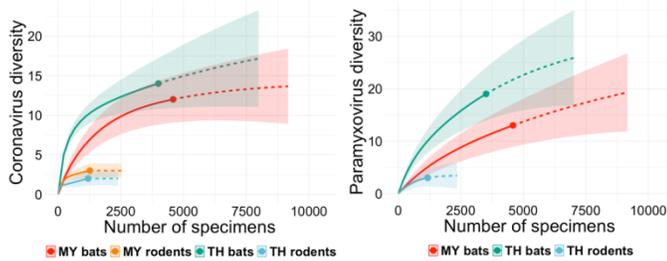

**1.2.b. Reservoir host species targeting:** Our analysis of all known mammalian host-viral associations demonstrates that bats, rodents and NHPs represent the three most important reservoirs for zoonoses, responsible for the highest proportion of known and predicted viral diversity of zoonotic potential (3). Thus, the bulk of our proposed wildlife sampling and testing will consist of these three taxa with a focus on bats, because this group is the known or hypothesized reservoir for the majority of high-impact zoonotic CoVs, PMVs and FVs (50, 92-94). Bats have the highest proportion of predicted zoonotic viruses in any mammalian group (2), and are exceedingly diverse in Southeast Asia (~500 species). To further prioritize taxonomic sampling targets within these diverse geographic hotspots, we used a novel Bayesian phylogeographic algorithm to identify host genera and species that are the most important centers of evolutionary diversity for a given viral group, e.g. bat genera for  $\beta$ -CoVs (**Fig. 5**) (51). This approach will be extended to other mammal taxa and viral families of interest, allowing us to identify the reservoir hosts of specific zoonotic viral groups, where viral diversity is likely highest.

**Fig 5:** Preliminary analysis of sequence data collected under prior NIH funding, identifying SE Asian bat genera with the highest  $\beta$ -CoV evolutionary diversity. We will apply this Bayesian discrete phylogeographic model to identify taxonomic and geographic centers of viral diversification and sharing for relevant PMV, CoV, FV and other virus clades. Line thickness proportional to probability of virus sharing between two genera. Inter-family switches in red.

Finally, we have designed a strategy to estimate sampling gaps, using a viral 'mark-recapture' approach we previously published (95, 96) (**Fig. 6**). Using prior data for bat, rodent and NHP viral discovery vs. sampling rates, we can identify the likely total viral diversity for specific host groups in a region, and use this to estimate sample sizes to discovering the majority of unknown viruses within a specific family or genus. **In the current**

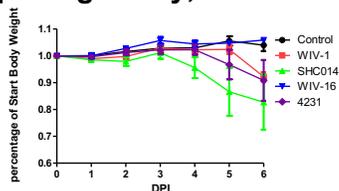

**proposal**, we will use these analyses to estimate geographic and species-specific sampling targets **to more effectively identify new strains to support experimental infection studies and risk assessment.**

**Fig. 6:** Estimated CoV (**left**) and PMV (**right**) diversity in bats and rodents from Thailand and Malaysia, using data from PCR screening and RdRp sequences from >10,000 specimens in bats and 4,500 in rodents. Bats have 4X more viral species than rodents, controlling for sampling effort. We estimate that additional collection of 5k-9k bat specimens and testing of our archived bat and rodent specimens alone will identify >80% of remaining CoV and PMV viral species in these key reservoirs, yielding >800 unique viral strains.

**1.2.c. Sample testing to identify known and novel viruses:** We have conducted extensive wildlife surveillance for novel viruses across Southeast Asia in prior NIAID funded work and as part of the USAID PREDICT project. Under the 10-year PREDICT program globally, we identified 912 novel and 210 known viruses, more than the total number of viruses previously recognized in mammals by the ICTV (97). This work included collecting nearly 300,000 individual mammal samples from 14 EHA-led PREDICT countries, and PCR-screening of more than 60,000 individual specimens (53). In southern China alone, we identified 178  $\beta$ -CoVs, of which 172 were novel, discovered a new  $\beta$ -CoV clade, “lineage E” (41), diverse HKU3r-CoVs (179 sequences) within a ‘sister’ clade to the SARS-CoV lineage, and a new bat-origin SADS-CoV, responsible for killing >25,000 pigs in Guangdong Province (17). We have collected 28,957 samples from bats, rodents and NHPs in Thailand and 47,178 in Malaysia, **but have only tested a minority of these using PCR.** We have identified 100 novel viruses in Thailand and 77 in Malaysia. **Furthermore, we have only sequenced a small segment of one gene for all novel viruses found. We have archived duplicate samples which are now available for use in this project**, including fecal, oral, urogenital, serum samples, and biopsies from bats, rodents, and NHPs. In the current proposed work, we will attempt to sequence, isolate and characterize those viruses that our analyses below suggest are most likely to be able to infect humans.

**1.2.d. In vitro & in vivo characterization of viral potential for human infection:** Using Coronaviridae as an example, we have conducted *in vitro* and *in vivo* experiments to characterize the pathogenic potential of novel SARSr-CoVs from bats. We isolated three SARSr-CoVs from bat feces: WIV1, WIV16 and Rs4874, with Spike (S) protein sequences that diverged from SARS-CoV by 3-7% (24, 61, 98). We conducted full-length genome sequencing of 12 other novel SARSr-CoVs, some highly similar to outbreak SARS-CoV in the most variable genes (61). Using our reverse genetics system we constructed chimeric viruses and rederived full length recombinant SARSr-CoV from in silico sequence. All 3 SARSr-CoV full length isolates and the two chimeric viruses replicated efficiently in Vero E6 cells and in HeLa cells expressing hACE2, civet and bat ACE2, but not in those without ACE2 (24, 61, 98). We used the SARS-CoV reverse genetics system (72) to generate a chimeric virus with a mouse-adapted SARS-CoV backbone expressing SHC014 S protein with 10% sequence divergence from SARS-CoV S. This and the other full length and chimera viruses replicated in primary human airway epithelium, using the human ACE2 receptor to enter into cells (62). Thus, **SARSr-CoVs with diverse variants of SL-CoV S protein without deletions in their RBD can use human ACE2 as receptor for cell entry.** The Baric lab has a well-established hACE2 and DPP4 transgenic mouse model that **we used to assess the capacity of novel SARSr-CoVs and MERS-CoV to infect humans and cause disease (85, 99).** Infection of bat SARSr-SHC014 or WIV1 caused SARS-like clinical signs in the transgenic hACE2 mouse model **that weren’t reduced by immune-therapeutic monoclonals that attenuate SARS-CoV pathogenicity, nor after challenge following vaccination against SARS-CoV (62) (Fig. 7).** We repeated

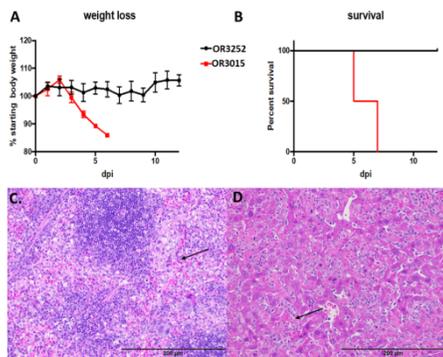

this virus characterization approach with chimeras using HKU3r-CoV S proteins that are ~25% divergent from SARS-CoV S, **and found that they are unable to use the ACE2 receptor.** Additionally, we were unable to culture HKU3r-CoVs in Vero E6, or human cell lines.

**Fig. 7:** Body weight change in hACE2 transgenic mice after SARSr-CoV infection, demonstrating that bat-origin SARSr-CoVs cause similar clinical signs to outbreak SARS-CoV strain (4231) (62, 63).

A similar approach to the above pipeline for CoVs will be applied to novel henipaviruses we discover during our research. The broad mammalian tropism of HeV and NiV (68) is likely mediated by their usage of highly conserved ephrin ligands for cell entry (19, 100). A third isolated henipavirus, Cedar virus does not cause pathogenesis in animal models. **Co-Is Broder and Laing** have developed a reverse genetics system and rescued a recombinant CedV to test ephrin receptor usage/tropism and pathogenicity during henipavirus infections (77). CedV is unable to use the Ephrin-B3 receptor (77, 101) which is found in spinal cord and may underlie NiV encephalitis (102) and that pathogenesis also involves virulence factors V and W proteins. The putative henipaviruses, Ghana virus and Mòjiāng virus, predict V and W protein expression, with GhV able to bind to ephrin-B2, but not -B2 (103), and the receptor for MoJV remains unknown (104) but is likely ephrin-B2 (105). Our group has also used similar methods to test the hypothesis that novel Filoviruses discovered in wildlife are able to infect people. NiV, EBOV and MERS-CoV all infect primary microvascular endothelial cells, which are available at Co-I Baric's lab for EID-SEARCH collaborators (71, 106). Primary human lung endothelial cells are highly susceptible to Ebolavirus infection (107), and Huh7 cells can be used to isolate virus from clinical samples (108) offering advantages for reverse genetic recovery of novel FVs (109). The three filovirus genera, *Ebolavirus*, *Marburgvirus* and *Cuevavirus*, use Niemann–Pick type C1 (NPC1) protein as cell entry receptor (110). For novel filoviruses, cell culture would be carried out under BSL-4, however they can readily be characterized following identification of their encoded GP sequences which can be pseudotyped into recombinant GP-bearing vesicular stomatitis virus (VSV) pseudovirions (111). These pseudovirions can be safely used to characterize the tropism and entry filoviruses mediated by GP without a need for BSL4 containment. **Co-Is Wang and Anderson** used cells originating from various mammalian species to determine spillover and/or zoonotic potential of MLAV, a newly discovered Asian filovirus (47). Despite the low amino acid sequence identity (22–39%) of the glycoprotein with other filoviruses, MLAV is capable of using NPC1 as entry receptor. Cells from humans, monkeys, dogs, hamsters and bats were able to be infected with a MLAV pseudovirus, implying a broad species cell tropism with a high risk of interspecies spillover transmission.

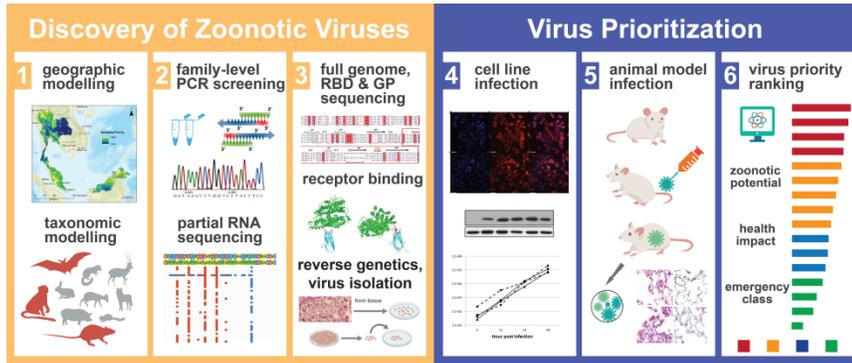

**Mouse models.** For novel viruses across all families, we will use the UNC collaborative cross mouse that captures 90% of the diversity within all mouse groups to assess the most suitable model for further experiments (112). We have used this model for CoV, FV (Ebola), Flaviviruses, and alphaviruses infections. Clinical signs such as weight loss, hemorrhage, encephalitis, and, acute or chronic arthritis were recapitulated in these mice following SARS, EBOV, West Nile virus and Chikungunya infections, respectively (86-88, 113-116). Note that CC OR3015 shows hemorrhagic disease phenotypes after EBOV infection (**Fig. 8**). **Bat Models.** Duke-NUS has developed two models for bat *in vivo* studies: a colony of *Eonycteris spelaea* (cave dwelling small fruit bat) and a bat mouse model, which contains the bat immune system in an immunodeficient mouse (117). In a proof of concept study, **Co-Is Wang and Anderson** infected *E. spelaea* bats with MERS-CoV to demonstrate their susceptibility and suitability for infection with a bat borne virus under BSL3 containment. These bats and the bat mouse model will serve to complement and expand studies from the UNC collaborative cross mouse, pending further funding from EIDRC CC.

**Fig. 8:** EBOV Infection in Collaborative Cross Mouse. **Panel A/B:** Wt EBOV in two different CC lines demonstrate different disease patterns. **Panel C/D:** Hemorrhagic phenotypes on d. 6 (arrow) in spleen and liver, resp. From (86).

**1.3. General Approach:** We will conduct analyses to geographically- and taxonomically-target testing of samples from wild mammals that are most likely to harbor known high-profile zoonotic pathogens, or close relatives with potential to infect people. This includes selecting from tens of thousands of samples collected on recent projects and stored in freezers in our laboratories, and new sampling of wildlife in high risk locales. We will use viral family level PCR assays to identify and partially characterize viruses, then follow up sequencing of relevant receptor binding proteins to assess homology and predict binding affinity, then attempt to isolate and

biologically characterize viruses that phylogenetic and other data suggest have high spillover and pandemic potential. We will follow this with *in vitro* binding assays and cell culture experiments, and *in vivo* animal model infections to assess their potential to infect people and cause disease (**Fig. 9**). EHA will lead the study design, targeted sampling, and data analysis; Co-Is Hughes and Wacharapluesadee will lead field sampling and in-country testing; Duke-NUS, UNC, USUS will lead the serological and PCR diagnostic development and the *in vitro* and *in vivo* analyses, as well as cross-training and tech transfer to the hub labs in Thailand and Malaysia. This will include via support of one Malaysian Ph.D student, Mei-Ho Lee (CM Ltd.) who has worked with the EID-SEARCH collaborators for 9 years. The focus of her study will be infection potential of novel CoVs and PMVs already found in bats in Malaysia under preliminary data for this proposal.

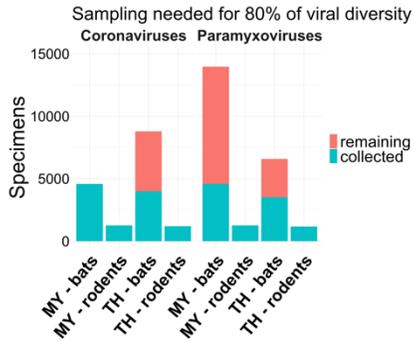

**Fig. 9:** Aim 1 will use analytical tools to target selection of archived and newly collected samples, conduct PCR and sequencing of novel viruses, recover by reverse genetics, and assess zoonotic potential using *in vitro* and *in vivo* models and analyses.

**1.4 Wildlife samples: 1.4.a. Geographic and taxonomic targeting for newly collected wildlife samples:** We will prioritize sites within each country that rank highest for both the risk of zoonotic

disease emergence (2) and the predicted number of 'missing' zoonotic viruses (3). Our preliminary analysis (**Fig. 1**) suggests priority areas include: the Kra Isthmus (S. Thailand) and adjacent forests in N. Peninsular Malaysia, NW Thailand (near the Myanmar-Laos border), and lowland rainforests of Sarawak and Sabah. In each of these 'hottest of the hotspots' regions, we will identify 2-4 distinct sampling sites based on the geographic distribution of key hosts we prioritize for additional wildlife sampling. We will priority rank bat, rodent, and NHP species using host trait-based models (3). We will also identify species predicted to be centers of evolutionary diversity for CoVs, PMVs, and FVs using ancestral host reconstruction of available sequence data and Bayesian discrete phylogeographic models (118-120). We will leverage our strong collaborations with wildlife experts in Malaysia and Thailand, including many of whom are based at our core partner institutions, to ground-truth geographic and taxonomic model outputs with local expert knowledge to ensure the sampling plan is realistic based on current species distributions, population size estimates, seasonality, and accessibility to sites. Most zoonotic viruses are naturally carried by multiple wildlife host species, and there are strong, predictable relations between host phylogeny and viral taxonomy (3). We will use a combined network analysis and phylogeographic model to rapidly predict and prioritize new (unsampled) hosts for important, novel viruses we discover during our research. We have shown this relatively simple model (using just wildlife species range overlap and phylogenetic similarity between host species) is both generalizable to estimate host range for all mammalian and avian viruses *and* robust – accurately predicting hosts 98% of the time when cross-validated using data from known viruses (121).

**1.4.b. Sample size justifications for testing new and archived wildlife specimens:** We calculate initial sample sizes targets using our preliminary data on average PCR prevalence from screening tens of thousands of bat, rodent and NHP specimens for CoV and PMVs based on previous studies in Malaysia and Thailand. We will refine these sample size targets, in real-time, over the course of our project using viral discovery curve analyses (**Fig. 6**) to either scale-up or scale-back new sampling and testing of archived specimens for each species depending on viral capture rates. We will only collect additional specimens projected from each prioritized taxa to achieve statistically robust sample sizes and to complement our archived specimens. For example, *Rousettus* spp. bats, known FV reservoirs, were not adequately sampled under PREDICT research in Thailand. Preliminary analysis indicates that, for all viral target families, we will require ~14,000 new samples to identify 80% of remaining viral species diversity in our study region, ~5,000 samples from Thailand and ~9,000 samples from Malaysia (**Fig. 10**). Viral strain diversity from a sampling effort this size is expected to number in the hundreds of strains. For example, given ~6% prevalence of CoVs in bat species previously sampled under the PREDICT project, a target of 14,000 individuals would yield ~800 PCR positive individuals,

representing, an estimated ~600 novel sequences/strains. Similarly, for PMVs, which have an average PCR detection prevalence of ~1.5%, sampling of 14,000 individuals would yield ~200 positives and an estimated 150 unique strains. Filovirus estimates are not feasible yet due to the small number of positive samples in prior

studies, but will be estimated as the project begins. From each mammal, we will collect serum, whole blood, throat swabs, urine and fecal samples or rectal swab using our previously-validated nondestructive methods. We will sample sites at different time-points throughout each year, and sample an equal number of males and females to account for seasonal or sex-specific differences viral shedding (**See Vertebrate Animals**) (122, 123). Dead or animals euthanized due to injury will be necropsied.

**Fig. 10:** Stacked bar plot showing number of currently-archived specimens (blue) and new specimens required (orange) to discover 80% of predicted number of CoVs and PMV species from high-risk bat and rodent taxa in Malaysia and Thailand.

**1.4.c. Sample collection, testing, viral isolation:** Wildlife will be captured and sampled using previously published techniques, by personnel wearing appropriate personal protective equipment (Tyvek suits or dedicated long external clothing, double nitrile gloves, leather gloves, an N95 or p100 respirator, and safety glasses) (53, 93, 95, 96, 122, 124). All samples will be placed in a vapor phase liquid nitrogen dry shipper immediately upon collection, and then transferred to a -80C freezer once back in the lab, until testing. Viral RNA will be extracted from bat fecal pellets/anal swabs. RNA will be aliquoted, and stored at -80C. PCR screening will be performed with pan-coronavirus (125, 126), filovirus (127) and paramyxovirus primers (128), in addition to virus specific primers where additional sensitivity is warranted in key viral reservoirs, i.e. Nipah virus or MERS virus specific primers (129, 130). PCR products will be gel purified and sequenced. We will attempt isolation on samples that contain viruses of interest (determined in **Aim 1.5 below**), using Vero cells and primary cell culture from the wildlife taxonomic order (bat, rodent and NHP cell lines). Over 70 bat cell lines are maintained at Duke-NUS from five different bat species. These include primary lung, brain, bone marrow, heart, kidney, intestine, liver, lymph node, muscle, spleen, PBMC and ovary/testes from *Eonycteris spelaea*, *Cynopterus bracyhotis*, *Rhinolophus Lepidus*, *Myotis muricola* and *Pteropus alecto* bats. In addition we have 8 immortalized cell lines, including those derived from lungs, therefore suitable for the isolation of respiratory viruses.

**1.4.d. Moving beyond RNA viruses:** To detect pathogens from other families, such as non-RNA viruses, we will combine conserved PCR assays with NGS. We will perform either unbiased NGS, or use a pan-viral enrichment library to sequence full-length genomes (131). We will conduct this work via EID-CC research projects or as part of outbreak detection/investigation in the region from DNA viruses or other agents.

**1.4.e. Sequencing Spike Glycoproteins:** Based on earlier studies, our working hypothesis is that zoonotic CoVs, FVs and henipaviruses encode receptor binding glycoproteins that elicit efficient infection of primary or continuous human cell lines (e.g., lung, liver, etc.) (16, 61, 62). Characterization these for SARSr-CoVs suggest that viruses up to 10%, but not 25%, different in the spike glycoprotein use human and bat ACE2 receptors for docking and entry. Uneven sampling gaps (e.g., no strains were found with 10-25% spike variation) prevent a thorough understanding of the transition point where the most divergent strains lose human ACE2 receptor usage. Our viral discovery curves (**Fig. 6**) suggest further sampling will reveal a rich diversity of as-yet-undiscovered SARSr-CoVs and strains of other viruses that fill in the phylogenetic tree between currently-described viruses. In this aim we will use phylogenetic and viral discovery analysis to specifically target bat species and regions that are under-sampled to allow sufficient power to identify and characterize missing strain diversity for potential zoonoses. We will sequence the S proteins of novel SARSr-CoVs to prioritize viruses for experimental work in Aim 3 to test this hypothesis. Likewise, we will test the hypothesis that phylogenetic related zoonotic receptor binding protein genes of MERS-related, Ebola-related and NiV/HeV-related viruses will also program efficient entry via human and ortholog receptors. For all novel virus strains, we will sequence the complete entry spike genes by amplifying overlapping fragments using degenerate primers as shown previously (24, 61). **Reverse Genetics:** Full-length genomes of selected CoVs, FVs or henipaviruses (representative across subclades) will be sequenced using NEBNext Ultra II DNA Library

Prep Kit for Illumina and sequenced on a MiSeq sequencer. PCR or Minlon sequencing will be performed to fill gaps in the genome. The full length spike gene sequences, including the amount of variation in the receptor binding residues that bind the appropriate human receptor will be used to select strains for Aim 3 experiments. We will sequence full length genomes of high risk strains that are antigenically distinct and escape SARS or MERS-CoV cross neutralization, synthetically reconstruct a small subset (1-2) and evaluate growth in Vero, BHK and Huh7 cells (63, 132). From full length sequences, synthetic clones will be ordered to recover recombinant viruses using reverse genetics as described by our groups (62, 63, 77, 109, 133, 134). Recombinant virus growth will be accessed in Vero, BHK, Huh7 and select bat cells and recovered viruses used for downstream studies. Virus strain prioritization is described below.

**1.5. Assessing risk for spillover. 1.5.a. Capacity to infect human cells:** We will use a series of cell cultures to assess the capacity of target viruses to enter human cells. For CoVs, FVs and henipaviruses, we will use primary human ciliated airway epithelial cells (HAE) and lung endothelial cell cultures derived from the lungs of de-identified transplant recipients. HAE are highly differentiated and grown on an air-liquid interface for several weeks prior to use (62, 63, 132). We will prepare HAE and lung endothelial cultures from three different patient codes in triplicate in collaboration with the tissue procurement facility at the Cystic Fibrosis Center at UNC. Cultures will be inoculated with chimeric bat SARSr-CoVs or novel FVs or henipaviruses to assess efficient replication. At 72 hpi, cultures will be fixed for immunofluorescent staining using antisera to the SARS-CoV conserved nucleocapsid protein (N) or to structural genes of the other viruses (64, 71). SARSr-CoVs that differ significantly in S protein sequence (11-24%) from epidemic SARS-CoV yet replicate *in vitro*, will also be evaluated for sensitivity to neutralization in Vero cells by PRNT50 assays using broadly SARS-CoV cross reactive human mAbs S227.14, S230.15, S215.17, and S109.8 (63, 135) or monoclonal antibodies targeting the Ebola or Marburg E glycoprotein (Available through BEI), or NiV/HeV glycoproteins (136). As controls or if antisera is not available, the S genes of novel SARSr-CoV or spike entry genes of other novel viruses under investigation will be inserted into VEE 3526 replicon vectors (VRP3526-S), packaged and used to vaccinate mice (137). Polyclonal sera against test bat-SARS virus or other spike genes will be harvested and tested for ability to cross neutralize SARS-CoV, GD03, WIV-1, SHC014, WIV-16, other novel SARSr-CoV and HKU3-SRBD by PRNT50 assay (63, 138, 139). Using PRNT50 titers with sera (n=4 each) among these viruses, antigenic cartography (140) will allow comparison of antigenic vs. phylogenetic distance, identifying the transition at which SARSr-CoV strains escape SARS-CoV based vaccines, informing immunotherapeutic and vaccine design strategies (141-143). Similar approaches will be applied to novel MERS-related viruses, other CoV, FVs or henipaviruses. While most wildlife-origin viruses with unknown transmission potential or pathogenicity in people uncategorized, we use BSL-3 for isolation as standard, and cell culture for potentially BSL-4 pathogens will be undertaken at collaborating institute NEIDL. To facilitate this, duplicate samples in culture medium from animals PCR +ve for FVs and very close relatives of NiV or HeV will be shipped to NEIDL (**See letter of support**) for culture, characterization and sharing with other approved agencies including NIH Rocky Mountain Laboratories where PI Daszak and Co-Is Baric have ongoing collaborations. Similarly, some duplicate samples of animals PCR +ve for CoVs will be shipped to UNC for further characterization by Co-I Baric. Where feasible and appropriate, training opportunities at NEIDL and UNC for in-country staff will be given, thereby enriching hands-on collaboration across sites.

**1.5.b. Host ACE2, DPPR, Niemann-Pick C1 (NPC1) and EphrinB2/EphrinB3 receptors:** We will sequence relevant host receptors for select mammalian wildlife species we find positive for strains of high-priority CoV clades, and all new henipaviruses and FVs. Of particular interest is homology across 18 bat and human orthologue ACE2 contact interface residues that engage the SARS RBD as a potential indicator of SARSr-CoV cross species transmission potential and growth in human cells (70). Likewise, variation in the NPC1 receptor has been shown to alter EBOV ability to infect in humans and bats, so this can be structurally mapped for prediction and downselection of strains (144). Signatures of positive selection in bat NPC1 were concentrated at the virus-receptor interface, with the strongest signal at the same residue that controls EBOV infection in *Eidolon helvum* cells. Thus NPC1 is a genetic determinant of FV susceptibility in bats, and some NPC1 variations likely reflect host adaptations to reduce FV replication and virulence (145). NiV and HeV use ephrin B2 or ephrin B3 as a receptor, and variation affects its ability to use human vs bat receptor molecules (103, 146).

**1.5.c. Host-virus evolution and predicting receptor binding:** We will use Bayesian and Maximum Likelihood phylogenetic analyses of RNA-dependent RNA polymerase (RdRp) sequences from PCR screening, receptor binding glycoproteins, and/or full genome sequence data (when available) to reconstruct the evolutionary history of the novel bat SARSr-CoVs, bat MERSr-CoV, FVs and henipaviruses that we identify. We will run co-phylogenetic analyses to map out instances of host-switching (147, 148) and ancestral state reconstruction analyses (Fig. 4) to identify the most important species for shaping evolutionary diversity for these viruses (51, 149), allowing for more targeted future surveillance and spillover mitigation interventions. For receptor binding glycoprotein sequence data from characterized viruses, we will apply codon usage analyses and codon adaptation indices, as used recently on henipaviruses (150), to assess the relative contributions of natural selection and mutation pressure in shaping host adaptation and host range.

**1.5.d. Viral strain prioritization:** Of the expected 100-200 novel SARSr-CoV strains, and approximately 600 total CoV strains, we will down-select to prioritize for further characterization based on S genes that are: i) different from SHC014, WIV1, SARS-CoV with diversity ranges of 10-25%; ii) have virus S RBD that could use human/bat receptors; iii) have recombinant chimeric spikes indicative of gene flow between clade I and II strains; iv) have bat ACE2 or DPP4 receptors that might select for spike RBDs that can use human receptors for entry (15/18 conserved residues in human/bat ACE2 molecules that bind SARSs-CoV S RBD domains are likely more efficient receptors than 3/18 conserved sites). Using structural models based on the SARS S glycoprotein, the extent and location of antigenic variation will be annotated onto the structure, further resolving the locations of highly evolving and conserved structural motifs/epitopes that function in protective immunity (135, 151-153). For novel henipaviruses, we will examine the receptor-binding proteins (e.g. envelope attachment (G) proteins) for sequence and structural homology with particular attention to conservation of amino acids that mediate ephrin receptor binding. We will prioritize strains that are predicted to interact with ephrin-B2 and expression V/W proteins to determine whether these viruses represent zoonotic threats. Using the recombinant Cedar virus (rCedV) platform, we will be able to rescue rCedV that express heterotypic G proteins to explore receptor utilization and tissue dissemination in animal models. We will assess ability to infect human cells using a continuous lung epithelial cell line, Calu3, which our group has previously used to generate data on NiV and HeV growth curves and a variety of host expression changes after infection (154). We will also use primary human airway cultures and microvascular endothelial cells to assess human infection for FVs, henipaviruses and MERSr- and SARSr-CoVs (155) (156). There is some evidence for NiV and HeV replication in mouse lung, low level titers in young animals, 10 fold higher titers in aged mice (157, 158). Thus it is likely these models could be improved in the collaborative cross mouse resource at UNC. We have identified CC lines that are highly vulnerable to wildtype SARS and others that develop hemorrhagic disease following mouse adapted Ebola infections (86-88).

**1.5.e. Animal models:** We will use transgenic mouse models and the UNC Collaborative Cross model to assess spillover potential of viruses. For work on CoVs, we will follow the protocols in the transgenic mouse model used by the Baric lab previously. Briefly, in the BSL3 lab, 10- to 20-week old hACE2 or hDPP4 transgenic mice will be intranasally inoculated with  $5 \times 10^4$  PFU of full length wildtype rbat CoV, or chimeric SARSr-CoV or MERSr-CoV encoding different bat CoV spike proteins respectively, then monitored daily for weight loss, morbidity, and clinical signs of disease. Mice will be euthanized at 2, 4, and 6 dpi (endpoint of 14 dpi), organs harvested and virus quantified by plaque assay or genome (mRNA1) RT-PCR. After 7 days in formalin, tissues for histopathology will be removed from the BSL3 and stained with H&E, and for immunohistochemistry using polyclonal antibodies against the N protein. We will conduct limited evaluation of existing countermeasures using therapeutic monoclonal antibodies *in vitro*. Existing SARSr-CoV or MERS-CoV mAbs (159, 160) will be diluted in DMEM starting at 1:20, and serial dilutions mixed with an equal volume of 50 PFU of chimeric bat SARSr-CoVs encoding different spike proteins and RFP indicator genes, then incubated on Vero E6 cells at 37°C for 1 h. Antibody neutralization titers will be evaluated by plaque quantification at 4-5dpi. In select instances, hACE2 transgenic mice will be injected with SARS-CoV mAbs, and infected with chimeric bat SARSr-CoVs. Clinical signs and morbidity will be assessed and tissue pathology examined and compared with mice without treatment of mAbs to determine the therapeutic effect on SARSr-CoV infection, and protection of SARSr-CoV by wildtype SARS-S based vaccines assessed as described (132, 161). We will sequence full length genomes of high risk strains that are antigenically distinct and escape SARS or MERS-

CoV cross neutralization, synthetically reconstruct a small subset (1-2), recover full length viruses and evaluate the ability of nucleoside analogues to inhibit growth in HAE cultures and/or *in vivo* (63, 132). For the Collaborative Cross model, we will infect six to eight mice from 6-8 Collaborative Cross mouse lines (10 weeks of age) with six test viruses/yr, intranasally or by subcutaneous infection with  $1 \times 10^4$  virus. Animals will be followed for weight loss, morbidity, mortality and other clinical disease symptoms (e.g., hunching, hindleg paralysis). One half the animals will be sacrificed at day 3 and day 7 pi. to evaluate virus growth in various organs, and organ pathology. In highly vulnerable lines, additional experiments will be performed using more animals, evaluating virus growth, clinical disease symptoms, respiratory pathology, tropism and organ pathology through day 28 pi. We anticipate that some CC lines will prove highly vulnerable to select wildtype viruses, because of host susceptibility combinations that promote severe disease outcomes.

**1.6. Potential problems/alternative approaches: Challenges with logistics or obtaining permission for wildlife sampling in sites we select.** We have a >20-year track record of successful field work in Malaysia, and >10 years in Thailand, and have strong established partnerships with local wildlife authorities and communities to ensure access. We have existing permissions in place which will be renewed at the start of this project. Due to the abundance of wildlife habitats in the region, if access to a site is withdrawn, we will rapidly identify a suitable, complementary site with similar bat species composition and abundance. Finally, we have already collected tens of thousands of wildlife samples from the region and will focus on these while waiting for permission. **We may not identify novel viruses in our sample wildlife species due to seasonality of viral shedding or other factors.** We have calculated sample sizes based on realistic detection rates from our extensive preliminary data, and are confident that we will detect and identify large numbers of potentially zoonotic pathogens, particularly for CoVs and PMVs. We acknowledge that FV strain diversity may be harder to capture, given relatively low seroprevalence in bat populations – suggesting lower levels of viral circulation (42, 43). However, our team was the first and only group to sequence FV RNA from Asian wildlife species (46, 47, 57), and we are confident that with our targeted sampling and testing strategy offers the best chance globally to identify additional strains of Ebola and related viruses. The sampling regions we have selected are subtropical, and our previous data, and even published studies in temperate regions (162), do not suggest a strong pattern of seasonality in CoV shedding, and where seasonal patterns do occur, i.e. for henipaviruses in Thailand (163), or can be predicted from wildlife serology data, we will be sure to conduct sampling at different timepoints throughout the year to account for this.

**Aim 2: Identify evidence and analyze risk factors for viral spillover in high-risk communities using novel serological assays.**

**2.1 Rationale/Innovation:** Rapid response requires early detection. Assessing the spillover of rare or novel zoonotic agents will require targeted surveillance of high-risk communities that interface frequently with wildlife that harbor high risk emerging viral strains. To enhance the low statistical probability of identifying these rare events, In Aim 2 we will target rural human communities inhabiting regions identified in Aim 1 as having high viral diversity in wildlife, that also engage in practices that increase the risk of spillover (e.g. hunting and butchering wildlife). We will initially identify 4 subsites in each of Thailand, Peninsular Malaysia, Sarawak, and Sabah for sampling. We will design and deploy human risk factor questionnaires, and specific and sensitive serological assays to identify the baseline frequency, and causes of, spillover of known and related novel viral pathogens in these populations. **We will use the results to test a key hypothesis: that hunting wildlife increases the risk of exposure to novel viruses, compared to the rest of the community.** The alternative hypothesis is that seroprevalence in the general community is not statistically different to those who hunt and butcher wildlife, because exposure to wildlife pathogens is largely through inhabiting a biodiverse landscape where wildlife make indirect contact with people (e.g. via fomites). For participants who report symptoms related to 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; 5) hemorrhagic fever; or 6) unusual presentation of high fever with severe diarrhea; all within the last 10 days, an additional sample type will be collected, two nasal or oropharyngeal swabs. Samples will be marked for additional PCR-based assays to identify presence of known and novel CoVs, henipaviruses and FVs, and for isolation and biological characterization of potential pathogens, using the approach laid out in Aim 1.

**2.2 Preliminary data on high-zoonotic risk human community surveillance: 2.2.a Biological sample collection in SE Asia:** Our long-term collaboration in the region has included qualitative and quantitative survey data, and collecting large archives of banked human sera and other biological samples from high zoonotic-risk populations. For example, under the USAID-PREDICT project, EHA has collected 1,400 and 678 specimens in Malaysia and Thailand respectively from people living in zoonotic disease interfaces, all of which will be available for retrospective serological testing by EID-SEARCH which we have ensured is compliant with our existing IRB. Our core group has collected and tested many thousand additional specimens from other important community cohorts (**Table 2**), and some of these will continue under EID-SEARCH (**Section 2.4**).

Country, site	Lead	# enrolled, focus	Findings
Peninsular Malaysia	Hughes	9,800+ samples, Orang Asli indigenous pop., for PCR/serol.	25+ novel CoVs, influenza, Nipah ab+ve, FV ab+ve
Malaysia Sabah	Kamruddin	1,283 for serology	40% JE, 5% ZIKV ab+ve
Malaysia Sabah	William	10,800 for zoonotic malaria study	High burden of macaque-origin malaria
Malaysia Sabah	Hughes	150 bat cave workers	Ongoing
Malaysia Sarawak	Siang	500 Bidayuh and Iban people	8% PCR prevalence HPV in women
Malaysia PREDICT	Hughes	1,400 high zoonotic-risk communities for viral PCR, serology	Ongoing. Multiple known and novel CoVs, PMVs, others.
Thailand	Wacharapluesadee	100s of bat guano harvesters/villagers	Novel HKU1-CoV assoc. clinical findings
Thailand PREDICT	Wacharapluesadee	678 high zoonotic-risk communities for viral PCR, serology	Ongoing. Multiple known and novel CoVs, PMVs, others.
Singapore	Wang	856, for Melaka virus	7-11% MELV ab+ve

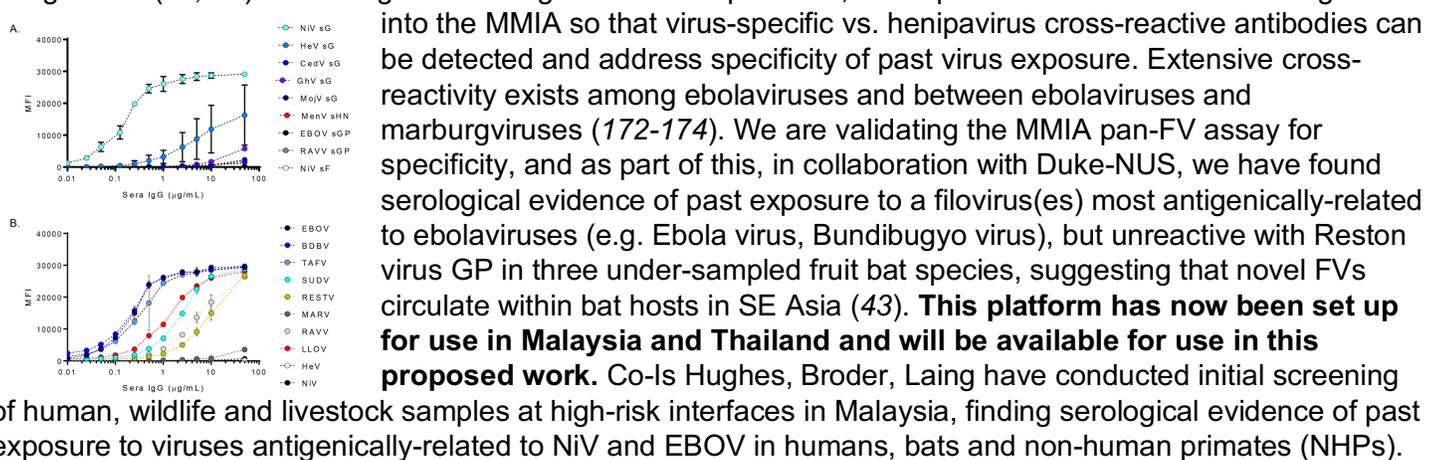

**Table 2:** Biological sample collection from healthy populations conducted by members of **EID-SEARCH** in our hub countries. Of particular interest is the access to indigenous communities in Peninsular Malaysia (Orang Asli) and Sarawak (Bidayuh, Iban people), and the bat guano harvesters in Thailand. These communities hunt, butcher and eat wildlife daily, and work in supremely high-risk zoonotic interfaces (e.g. bat caves). One of our indigenous community sites is experiencing an ongoing outbreak of unknown etiology that we are investigating currently (Section 3.2.a).

**2.2.b Human Contact Risk Factors:** EHA is the lead organization across all 27 USAID-PREDICT project countries for collecting data on, and analyzing the human aspects of, zoonotic spillover risk (164, 165). We conducted exploratory studies using standardized one-on-one semi-structured interviews and site observation data with people living in hotspot areas or engaged in high-zoonotic spillover risk activities, using these data to assess local social and cultural norms underlying wildlife contact (165). We then developed a risk factor survey to accompany human biological sampling to evaluate the type and frequency of animal contact, wildlife exposure in daily life, occupational risk in markets and long the wildlife value chain, and unusual illnesses reported over the past 12 months. We conducted cross-sectional studies in high risk populations in 27 countries, and study participants provided biological samples (oral/oropharyngeal swab, nasal/nasopharyngeal swab, urine sample/urogenital swab, fecal sample/rectal swab, whole blood, serum, plasma). For example, survey and biological samples were collected from: 1,585 participants from 7 sites in Yunnan, Guangxi, and Guangdong provinces, China; 1,400 participants from 4 sites in Malaysia; and 678 participants from 4 sites in Thailand. Samples were tested with novel serological assays and results analyzed against risk factors from survey data (16). In China, CoV-seropositive individuals were mostly farmers/peasants (8/9), living in Yunnan province (7/9), 41-60 yrs old (7/9), with domestic contact with rodents (6/9), that are male (6/9). Although these results are preliminary and don't provide detailed information on routes of exposure, they identify key subpopulations to target that would likely increase the opportunity for identifying evidence of spillover for other CoVs, PMVs and FVs. Data from PREDICT surveys have been used to help identify target populations in Aim 2, identify strategies to better target at-risk people, and conduct focused **human risk factor surveys and serosurveys to produce statistically significant findings for henipaviruses, CoVs and FVs.** In Aim 2, we will use combined biological sampling and risk factor surveillance in targeted populations within the community to 1) test the hypothesis that occupational (i.e. wildlife hunting) risk factors correlate with seropositivity to henipaviruses, FVs and CoVs; 2) assess possible health effects of infection in people; and 3) where recent

illness is reported, obtain biological samples for PCR testing and potential viral isolation and characterization. Obtaining this information could be a significant step in understanding the likelihood of recent 'hidden' spillover events and their public health impacts, as well as the risk of future emergence of viral disease.

**2.2.c. Risk factors for illness:** Our preliminary data in Thailand, Malaysia and other SE Asian countries revealed that frequent contact with wild (e.g. bats, rodents, NHPs) and domestic animals (e.g. poultry, swine) among local communities was associated with a high percentage of self-reported severe/acute respiratory illness (SARI/ARI) and Influenza-like illness (ILI) symptoms (**Section 3.2.b**). In addition, people involved in crop production, hunting and butchering of wildlife reported statistically significantly higher SARI and ILI symptoms (Li *et al.*, in prep.). **These preliminary data suggest a target population and sites for current proposal with the correct targets for serological surveillance and risk factor surveys in Aim 2 to produce statistically significant findings.** Coupled with better serological tools from our team (**Section 2.2.d**), we will be able to identify the likely routes of exposure to known or novel coronaviruses, henipaviruses, and FVs in the study region, as well as build data on the illnesses they cause in people.

**2.2.d. Serological platform development:** Most emerging viruses produced a short-lived viremia in people so that large samples sizes are required to provide enough PCR-positive individuals to analyze infection patterns. For Aim 2, we will focus on serological sampling in the community, because antibodies are typically long-lived and can be used to assess prior virus exposure or infection with much smaller samples sizes (123). Most serological assays target a single protein, and for emerging viruses, it's often unclear which viral antigen will be immunodominant during human infection, and therefore which to target in developing serological assays. Co-Is Wang, Anderson (Duke-NUS) and Broder, Laing (USUS) have developed a series of approaches to deal with this problem, and which will be used in testing human biological samples in Aims 2 and 3. Henipaviruses, FV and CoVs express envelope receptor-binding proteins that are the target of protective antibody responses. Co-I Broder has led efforts to express and purify henipavirus native-like virus surface proteins for immunoassay application (166, 167), developing monoclonal antibodies (168, 169) and as subunit vaccines (170, 171), has developed a novel, multiplex microsphere immunoassay (MMIA) allowing serum samples to be simultaneously tested for antibodies reactive with henipaviruses, FVs and CoVs. This MMIA uses a Luminex-based multiplex platform and custom designed virus receptor-binding proteins expressed in a mammalian cell-culture system and purified as native-like oligomeric proteins. These oligomeric antigens retain post-translational modifications and quaternary structures, allowing capture of conformational-dependent antibodies raised during a natural infection, which represent the majority of the protective humoral response. The known diversity of henipaviruses includes five presently described viruses, NiV, HeV, CedV, GhV and MojV and this assay has been expanded to include all described species (**Fig. 11**). In the past, our collaborators have used NiV and HeV G protein antigens in a MMIA assay to identify a serological footprint of NiV-related African henipaviruses and exposure to virus(es) antigenically-related to NiV in livestock sampled in Bangladesh (78, 79). To strengthen serological data interpretation, the G protein from each virus is integrated

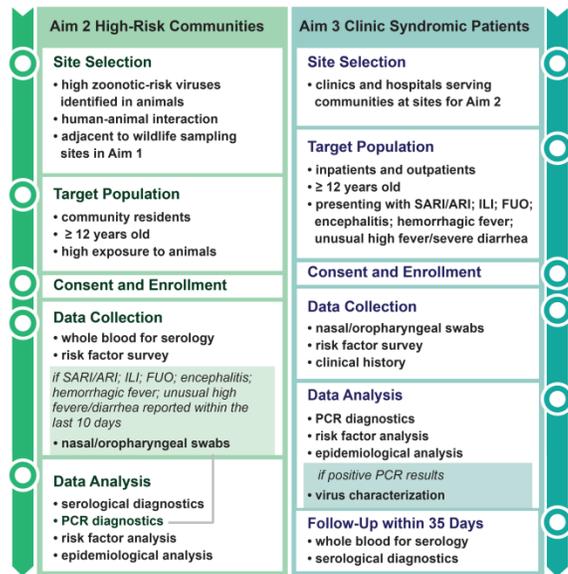

into the MMIA so that virus-specific vs. henipavirus cross-reactive antibodies can be detected and address specificity of past virus exposure. Extensive cross-reactivity exists among ebolaviruses and between ebolaviruses and marburgviruses (172-174). We are validating the MMIA pan-FV assay for specificity, and as part of this, in collaboration with Duke-NUS, we have found serological evidence of past exposure to a filovirus(es) most antigenically-related to ebolaviruses (e.g. Ebola virus, Bundibugyo virus), but unreactive with Reston virus GP in three under-sampled fruit bat species, suggesting that novel FVs circulate within bat hosts in SE Asia (43). **This platform has now been set up for use in Malaysia and Thailand and will be available for use in this proposed work.** Co-Is Hughes, Broder, Laing have conducted initial screening of human, wildlife and livestock samples at high-risk interfaces in Malaysia, finding serological evidence of past exposure to viruses antigenically-related to NiV and EBOV in humans, bats and non-human primates (NHPs).

**Fig. 11:** Validation of multiplex microsphere immunoassay (MMIA) specificity and identification of immunologically cross-reactive viruses for A) NiV B) EBOV.

Co-Is Wang and Anderson (Duke-NUS) have developed a phage-display method to screen antibodies for all known and related bat-borne viruses, including henipaviruses, FVs and CoVs and have set up a similar Luminex-based assay. Additionally the Duke-NUS team has demonstrated capacity for rapid and cost-effective development of LIPS serological assays against novel viral agents (**Sections 2.6.a, 3.2.a**). These will be used for verification and expanded surveillance. For molecular investigation (Aim 2 & 3), we will combine targeted PCR with a discovery-driven enrichment NGS strategy to not only survey currently known viruses, but also to discover potential novel viruses. Both the phage-display serological and enrichment platforms can be rapidly updated to include new viruses identified.

**2.3 General Approach/Innovation: Our human sampling approach uses two approaches in Aims 1 & 2 (Fig. 12). In Aim 2 we will conduct community-based surveillance using a brief, focused questionnaire to**

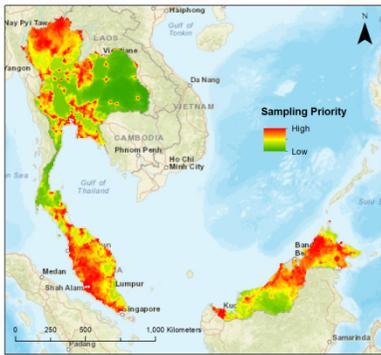

identify the prevalence and frequency of risk-factors for viral spillover in tandem with collection of high quality biological samples to determine the seroprevalence of spillover viruses in at-risk human populations. We will use generalized linear models to analyze correlation between biological results and risk-factors for viral spillover. **In Aim 3**, we will conduct clinic-based syndromic surveillance and biological sampling at clinics/hospitals that are the catchment healthcare facilities for the communities sampled in Aim 2. Both community-based and clinic-based syndromic surveillance programs are cross sectional case-control studies designed with the sample sizes necessary to statistically quantify (with a power of 80%) risk factors and health impacts for viral spillover, linked to serological status and PCR prevalence in symptomatic patients. All human sampling conducted under Aims 2 and 3 will adhere to strict criteria for inclusion and recruitment and protection of human subjects from research risk (**see Human Subjects and Clinical Trials Information**).

**Fig. 12:** Human sampling approach. Aim 2 (left) focuses on serology in high-risk communities to identify evidence of population exposure to novel zoonotic viruses. Aim 3 (right) sets up clinical cohorts at hospitals serving these high-risk communities to conduct syndromic surveillance and identify the etiology of new viral syndromes

**2.4 Target population & sample sizes:** We will target populations in the same geographic regions as those identified in Aim 1 that harbor wildlife with high potential zoonotic viral diversity, that are EID hotspots, and that are well-connected through regional travel and trade hubs to the global travel network (**Fig 13**). Within each geographic region we will identify populations at four sub-sites, building on our preliminary data (**Table 2**). We will target specific communities based on our analysis of previously collected behavioral questionnaire data, and other publicly available data (e.g. wildlife hunting licenses sold in a region, number of guano caves accessed for fertilizer etc.) to identify key at-risk populations and occupations with high exposure to wildlife. We will conduct concurrent sampling trips at visits to sub-sites during which members of the community will be enrolled and wildlife surveillance activities conducted. Individuals living or working around wildlife habitats (e.g. bat caves/roosts), who hunt wildlife, work with wildlife or livestock, or slaughtering wildlife will be considered for enrollment. Participants will complete a consent form and questionnaire in addition to having biological samples collected. During these community trips after data collection the field research staff will conduct community meetings to help inform the public health risk of zoonoses. **Target populations:** Thailand (Co-I Wacharapluesadee): 100 subjects of healthy high-risk community from 2 study sites, Chonburi (NiV, other PMVs and CoVs found by PCR in bats in our previous work), and Ratchaburi (bat guano harvester villages where we found a MERSr-CoV in bat guano (50, 175) and serological evidence of α-CoVs, HKU1-CoV in people (175)). Peninsular Malaysia (Co-I Hughes, CM Ltd.): We will expand our sampling of the Orang Asli indigenous communities to include sub-sites in communities in Districts we have already sampled and

additional Districts in the States of Kelantan Perak, Pahang, and Kelantan all close to bat caves. Samples will be stored and tested at NPHL. Sarawak (Co-I Tan, Fac. Med. Hlth. Sci. UNIMAS): We will expand our sampling of the Bidayuh and Iban indigenous people to include the Dayak and Orang Ulu (“people of the interior”) because this group has a more intimate connection to remote wildlife-rich areas than the other two, albeit all are hunters. Human sampling will be led by UniMAS in collaboration with CM Ltd / EHA. Sabah: We will conduct sampling at the Madai bat and bird cave that has 200 permanent residents who harvest bird’s nests for soup, and >1,000 during the harvesting season and at Gomantong cave – one of the largest bat and cave swiftlet nesting sites in the world. Sabah: (Co-I Hughes): We will conduct sampling at the Madai bat and bird cave that has 200 permanent residents who harvest bird’s nests for soup, and >1,000 during the harvesting season and at Gomantong cave – one of the largest bat and cave swiftlet nesting sites in the world. Protocols follow those for Peninsular Malaysia Singapore: (Co-I Wang, Duke-NUS): Active human surveillance will be not be conducted in Singapore, but archived human specimens e.g. from our Melaka virus serosurvey (8), will be made available to conduct retrospective serosurveys for specific pathogens that are identified as high interest to the EIDRC, NIH, and EID-CC.

**Fig. 13:** Targeting high-risk sites for human zoonotic disease surveillance in Thailand and Malaysia. This map plots areas with high numbers of expected viruses in wildlife (3), greater spillover probability based on EID risk factors (2), and higher levels of connectivity (measured by road density data) that may facilitate person-person spread.

**Sample sizes:** From our previous work we conservatively anticipate that 10-30% of the community population will have had exposure to wildlife allowing us to capture highly exposed and non-exposure individuals at each site. Individuals living or working around wildlife habitats (e.g. bat caves/roosts), who hunt wildlife, work with wildlife or livestock farming, transportation, selling, or slaughtering wildlife in the surveyed areas will be targeted so that they make

up  $\geq 30\%$  of the sampled population in each community. We will stratify sampling to ensure appropriate representation of sex, demographic, and socio-economic factors at each community site. In each of our regions, we will conduct sampling at four sub-sites in populations with high prevalence of high occupational and environmental risk of exposure to wildlife populations, sampling 175 persons at each sub-site. We will target populations with, on average, 30% or higher prevalence of occupational or environmental exposures to wildlife based on data from previous studies. This design will give us >80% power to detect 5 percentage point differences in seroprevalence against any of our viral groups between baseline and high-risk subgroups. We conservatively assume 5% base seroprevalence, as well as assuming high spatio-temporal variance amongst sub-sites, with baseline varying 0-25% amongst sub-sites and the fraction of the population at risk varying from 20-40%. (Power calculation conducted by 500 simulations of a generalized linear mixed model (GLMM)). For community-based surveillance, we will enroll 700 individuals per study region, allowing us to make county/province-level comparisons of differing effects; the total sample will be 3,500 participants over 5 years.

**2.5 Data & sample collection:** Following enrollment, biological specimens (5mL will be drawn for whole blood and serum collection, samples will be aliquoted, at least one max 500  $\mu$ L of whole blood and two 500  $\mu$ L serum samples) will be collected by locally certified healthcare professional proficient in phlebotomy techniques and a short questionnaire will be administered by trained project staff that speak appropriate local language to all participants. Through the serological findings and the survey we will investigate the details of five risk factors related to high risk wildlife exposure, to maximize the power of the analyses, based on continuing analysis of our previous work, and will focus on: 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, in/around house; 3) proximity of residence or work place to environments of increased risks, e.g. nearby bat roosts; 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms in the past 12mo and lifetime. For participants who report the symptoms relating to 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; or 5) hemorrhagic fever within the last 10 days, an additional sample type will be collected, nasal or oropharyngeal swab (2x). Blood of participants whose serum tests positive for emerging viral pathogens will be taken and Peripheral Blood Mononuclear Cells (PBMCs) frozen for future use.

These will be used for future harvesting of polyclonal and monoclonal antibodies as potential therapeutics/diagnostics (see Letter of Support NEIDL).

**2.6: Laboratory analysis: 2.6.a Serological testing:** We will screen all human specimens for henipaviruses, FVs and CoVs using our novel, multiplex microsphere immunoassay (MMIA) (Section 2.2.d). We will use ELISA and serum neutralization tests (SNT) as confirmatory, where feasible and appropriate for the biocontainment level given sensitivity and specificity variation, and the need for live virus for SNTs (See Select Agent Research). Serologic evidence of local spillover will be used to prioritize zoonotic strains for recombinant virus recovery from full length sequences. Preliminary data suggest ELISA will be effective for some viral groups. We previously developed a SARSr-CoV specific ELISA for serosurveillance using the purified NP of a bat SARSr-CoV (Rp3). The specificity of this assay was evaluated using polyclonal antibodies against HKU1, OC43, 229E, NL63, MERS-CoV and EBOV and no significant cross-activity detected (16). **This suggests that if we can expand our NP serology tests to cover other bat CoVs, and that doing so may identify many more seropositive individuals.** For CoVs, we will therefore use two serological testing approaches: 1) testing human sera collected from both community- and clinic- based sampling for a panel of bat CoVs that will include SARS-CoV, MERS-CoV, SADS-CoV and a range of bat SARSr-CoVs (16); 2) testing for antibodies to common human CoVs (HCoV NL63, OC43 – Section 2.8). We will test panels of NP and G recombinant proteins to assess if this approach will act as a comparison to MMIA for FVs and PMVs.

**2.6.b RT-PCR testing.** Specimens from individuals in the community who reported being symptomatic within the last 10 days (Section 2.5) will be screened using RT-PCR initially for CoVs, PMVs, and FVs following published protocols (Section 1.4.c). Positive samples will be subjected to full genome sequencing and RT-PCR amplification of the glycoprotein genes. Samples from the clinic-based syndromic surveillance will also be tested using RT-PCR for Influenza A & B, HCoV NL63, OC43, HKU1, SARS-CoV & 229E, NiV, HeV, Ebola (WHO PCR protocol) based on the symptom as rule-outs.

**2.6.c Biological characterization of viruses identified:** Novel viruses identified in humans will be recovered by cultivation or viruses re-derived from full length genome sequences using reverse genetic approaches. Viruses will be characterized for growth in primary human cell lines and in mouse models, including the Collaborative Cross Mice or humanized mice expressing human receptors from related strains. The approaches are discussed in more detail under Aim 1.

**2.7 Epidemiological analysis:** We will conduct a cross sectional case-control study to identify risk factors for Henipavirus, FVs, and CoVs spillover. “Cases” are defined as participants whose samples tested positive for Henipavirus, FVs, or CoVs by serological tests. “Controls” will be selected from the pool of participants admitted to the studies and whose samples tested negative for Henipavirus, FVs, or CoVs. We will use nearest neighbor matching to pair cases demographically (e.g. age, sex, location) with controls at a 1-to-3 ratio or greater. We will use generalized linear models and least absolute shrinkage and selection operator (LASSO) regression analyses (176) to analyze correlation between biological results, serological/PCR status, and risk factors related to high risk wildlife exposure including: 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, in/around house; 3) home or work proximity to environments of increased risks, e.g. nearby bat roosts; 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms lifetime and past 12mo. Additionally, we will use this procedure to determine how clinical presentation differs between Henipavirus, FVs, or CoVs in exposed and unexposed participants, as well as in the time course of illness, severity of symptoms, and type of symptoms.

**2.8 Potential problems/alternative approaches: Rarity of spillover events** means it may be difficult to identify sufficient seropositives to statistically analyze human risk profiles. First, we will be targeting our community-based surveillance to subpopulations with high-levels of wildlife exposure, at sites selected for diverse and prevalent viruses to increase likelihood of finding positive individuals. Second, our serology testing will include a multi-plex panel of assays for a large diversity of viruses, increasing likelihood of positives. For example, in previous work our overall bat CoV PCR prevalence in the community was, 11.8%;  $\beta$ -CoV, 3.4%;  $\alpha$ -CoV, 9.1%). Thus, using this broad serological panel to screen individuals prone to contact with species of higher zoonotic risk increases the potential for detecting spillover with enough power for statistical analyses,

and will shed light on behaviors that predispose to spillover. Third, we will include common human CoVs, PMVs, and influenza viruses in our panel, so that even if low prevalence of wildlife viruses is found, we will be able to conduct a valuable cross-sectional study of the seroprevalence of more common human viruses. Finally, we will be able to assess relative measures of human-wildlife contact from our survey work. We will analyze intensity of contact with high-risk taxa against other risk factors to provide useful proxy information for spillover risk. **Serological testing may be difficult to interpret in the presence of known and novel viruses.** We will use the three-tiered serological testing system outline in 2.6.a to try to identify exposure to these ‘novel’ viruses. However, we know exposure to a range of related viruses generates antisera that are cross-reactive with known, related virus antigens - a serious challenge to serological surveillance and diagnostics. Our collaborations have already demonstrated that SE Asia bat sera samples screened with our pan-filovirus MMIA have been exposed to an Ebola-like virus, that is antigenically-distinct from known Asiatic filoviruses, Reston virus and Měnglà virus (43). Using these three serological platforms we will address inherent challenges of indirect virus surveillance through antibody capture by testing multiple binding assay platforms and antigens, using positive control samples to establish serological profiles against known viruses that will aid in our interpretations of cross-reactive antisera responses likely representative of ‘novel’ viruses.

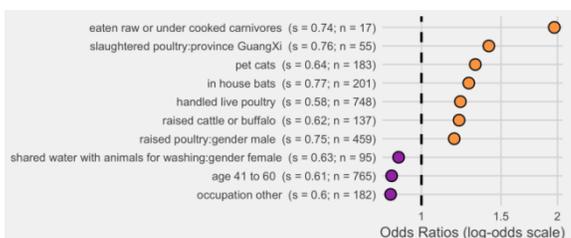

### **Aim 3: Identify and characterize viral etiology of ‘cryptic’ outbreaks in clinical cohorts.**

**3.1 Rationale/Innovation:** Our previous research (Table 1) and other data suggests that there are substantial numbers of outbreaks or clinical cases for which the etiologic agent is not diagnosed, e.g. (177, 178). To investigate this in SE. Asia, we have assembled a multi-disciplinary team that includes senior infectious disease doctors and clinicians and will work directly with local clinics and regional hospitals to identify the ‘cryptic’ outbreaks or cases that occur in the region. **In Aim 2, we will conduct serology in high zoonotic-risk communities to find evidence of prior exposure in people**, i.e. evidence of viral spillover into the community. In Aim 3 we identify members of these communities presenting at clinic with undiagnosed illness that may have high-impact zoonotic viral etiology. **Therefore, in Aim 3 we focus on PCR to identify the putative viruses that are replicating in these actively-infected patients (Fig. 12).** We will enroll, and collect high quality biological samples from patients who live in rural communities linked to Aim 2 and who present at regional clinics or hospitals with symptoms typical of high impact zoonotic viruses. We will collect detailed survey data to assess their contact type and frequency with wildlife and livestock and conduct molecular and serological diagnostic assays to test causal links between their syndromes and the known and novel viral agents identified in Aim 1. We will conduct molecular viral discovery assays on patients who present with symptoms indicative of a high-risk zoonotic virus. If novel pathogens are identified by PCR, we will attempt to isolate, obtain full genome sequence and/or biologically characterize the wildtype or molecularly re-derived pathogen, using the *in vitro* and *in vivo* strategy laid out in Aim 1.

**3.2 Preliminary data clinical surveillance: 3.2.a. Clinical surveys and outbreak investigations:** Our longterm collaboration in the region has included the following activities investigating clinical syndromes: *Peninsular Malaysia:* At the time of writing, an outbreak of suspected undiagnosed viral illness in the indigenous Batek Orang Asli (“people of the forest”) community living at Gua Musang (“civet cat cave”) district, in Kelantan, Malaysia, close to Taman Negara – a National Park containing the oldest known rainforest. This community is one where we have conducted prior routine surveillance and biological sampling, demonstrating proof-of-concept that our two-pronged high-risk community/clinic approach will work. Dozens of people are affected and the outbreak is currently being investigated by our group in collaboration with the Malaysian NPHL. The Orang Asli continue to practice traditional subsistence hunting of wild animals (bats, rodents, primates). These communities are remotely located, in heavily forested areas, with limited access to medical services. This outbreak, and others that will continue to emerge just like it, underscore the critical need for our EIDRC - to improve the technological tools, training, and human capacity for rapid EID surveillance, diagnosis, and response at the frontlines of disease emergence in SE Asia. **Investigating this outbreak is a key priority if EID-SEARCH is funded.** *Sabah:* Co-I Kamruddin (BMHRC) is leading an asymptomatic leptospirosis study on sanitation workers, an ILI study in a Kota Kinabalu clinic and diarrheal study in children under 5 yrs. Co-Is William, Tan and others have conducted clinical observational studies to determine the etiology of central nervous system infections and acute undifferentiated febrile illness in Sabah.

Co-Is William and consultant Yeo have collaborated with Co-I Wang to enroll 90 adult and over 100 pediatric participants with central nervous system infections, negative tests for malaria and dengue from 3 district hospitals in Sabah to determine the various etiologies. While a proportion tested positive for rickettsial agents, the majority had no clear diagnosis. Co-Is William, Rajahram, and Yeo have conducted clinical studies of over 200 inpatients with acute febrile illness with negative tests for malaria and dengue from 3 district hospitals in Sabah to determine the various etiologies. While a high proportion tested positive for rickettsial agents, the majority had no clear diagnosis. Sarawak: Co-I Siang (UNIMAS) is conducting a survey of high-risk female Kelabit indigenous people and has found 8% with HPV52 as the dominant strain. He is working on clinical cohorts of hand, foot and mouth disease and will recruit patients from that study in the current proposed work. Finally, Co-Is Siang, Kamruddin are conducting a long-term study of rotavirus and other viral etiologies of acute gastroenteritis in Kuching, Sarawak that will include swine herders and farmers. The Baric lab is a global leader in norovirus VLP diagnostic reagents to detect serologic evidence of norovirus gastroenteritis, as well as RT-PCR detection of novel noroviruses in humans, and has identified novel bat noroviruses, suggesting further opportunities for expansion of this work (142, 179-181). This work is particularly relevant in Malaysia because pig farms are shunned by the government and local villagers to they are placed far away from town centers, deep in the forest, and it is this scenario that led to the emergence of Nipah virus in 1998-9 (6, 22). Thailand: Co-Is Hemachudha, Wacharapluesdee (TRC-EID, Chulalongkorn Univ. Hosp.) work in coordination with the Thailand Ministry of Health to investigate outbreak etiology, including the first case of imported MERS-CoV in Thailand, **for which we produced sequence confirmation within 24 hours from acquiring the specimen**. Three imported MERS cases have been detected in Thailand since 2015, and all cases were confirmed at the TRC-EID. We worked during the Zika outbreak to identify > 500 PCR-positive Zika patients with sequence confirmation. We have also worked on returning and suspected Ebola travelers, syndromic surveillance for SARI, encephalitis, Hand Foot and Mouth disease in children and viral diarrhea. Consultant Hickey (US CDC, Thailand), screened specimens collected between 1998 and 2002 from a large cohort of children from Kamphaeng Phet Province to examine Dengue virus and JE epidemiology (182, 183). Among the 784/2,574 convalescent sera henipavirus-specific antibodies were detected in 13 serum samples (1.7% seroprevalence), suggesting prior exposure to endemic henipaviruses or a related PMV in rural Thailand. Singapore: Duke-NUS has worked with the Ministry of Health to investigate Zika cases (184), and other EIDs. With EHA and others, Duke-NUS has developed novel CoV assays for clinical surveillance, and for expedited analysis during outbreaks. Our pipeline of novel virus detection, reservoir host identification, serological assay development, and serological testing is as rapid as several months, with the development of novel serological assays from sequence data in 7 days (17). **For example, with the discovery of SADS-CoV, we identified and fully sequenced a new virus, screened archived wildlife specimens to identify the natural reservoir host species (*Rhinolophus* spp. bats), developed LIPS serological assays, and tested human and swine samples to assess seroprevalence in less than 3 months (17).**

**3.2.b Analysis of self-reported illness:** We have developed a standardized approach for analyzing data from study participants on self-reported symptoms related to target illnesses: fever with cough and shortness of breath or difficulty breathing (severe acute respiratory illness - SARI); fever with muscle aches (fevers of unknown origin (FUO)); and, cough or sore throat (influenza-like illness - ILI). For all of our prior human clinical surveillance in 20+ countries, including in Malaysia and Thailand, we used a least absolute shrinkage and selection operator (LASSO) regression to identify associations between participants who reported ILI and/or

SARI symptoms and demographics, occupation, and contact with animals in the last year. Results have clear biological relevance. For example, in Yunnan, China, factors strongly associated with prior disease involve animal hunting and consumption (Fig. 14). We will expand this approach for all clinical syndromes in Aim 3, and use targeted questions to assess patient's exposure to wildlife in terms that are relevant to each specific country.

**Fig. 14:** Factors associated with self-reported ILI & SARI in prior 12 months (s = bootstrap support; n = #+ve out of 1,585 respondents). **Orange circles** = odds ratios > 1 (+ve association); **purple** = odds ratios < 1 (-ve association).

**3.3 General Approach:** Our previous research suggests that there are substantial numbers of outbreak cases for which the etiologic agent has not been identified. To capture these, we will expand on our current syndromic surveillance to enroll, and collect high quality biological samples from patients who present at regional clinics and live in rural communities linked to Aim 2. Case definitions and enrollment criteria include: 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; 5) hemorrhagic fever; or 6) high fever/diarrhea with unusual presentation. We will collect survey data to assess contact with wildlife, and occupational and environmental exposures, conduct molecular and serological assays to test causal links between their syndromes and the known and novel viral agents identified in Aim 1. If novel pathogens are identified by PCR, we will attempt to isolate and biologically characterize the pathogen, using the collaborative cross to identify an appropriate animal model to conduct preliminary pathogenesis work. We will then use behavioral survey data, ecological and phylogeographic analyses to assess the likely reservoir hosts to inform intervention programs.

**3.4 Clinical cohorts. 3.4.a Cohort selection:** We will initiate active clinic-based syndromic surveillance at 2 town-level level clinics and 2 provincial-level hospitals in each Thailand, Peninsular Malaysia, Sabah and Sarawak. These serve as the catchment healthcare facilities for people in our community-based surveillance of Aim 2 and are inclusive of wildlife sampling sites in Aim 1. Patients  $\geq 12$  years old presenting at the health facility who meet the syndromic and clinical case definitions above will be recruited into the study after completing a consent form. We will aim to enroll 300 participants per hospital, with that we will have a 95% probability of detecting live virus in patients in each hospital assuming a population prevalence of 1%. This sampling effort will total of 4,800 individuals for clinical syndromic surveillance. We assume up to 40% loss from follow-up, therefore yielding 2880 participants that will be available for follow-up blood sampling (**Section 3.4.b**). While enrollment is limited by the number of patients that come to the healthcare facility presenting with relevant clinical symptoms, in our work in the PREDICT project we enrolled an average of 100 participants per year, so we are confident this is an achievable enrollment target. Study data will be pooled across country regions, as clinical patients are limited by the number of individuals presenting at hospitals. “Cases” will be determined as participants whose samples tested positive for either CoVs, henipavirus, or FVs, PCR tests. “Controls” will be selected from the pool of participants admitted to the studies and whose samples tested negative. We will use nearest neighbor matching to pair cases demographically (e.g. age, sex, location) with controls at a 1-to-3 ratio or greater. Sites: *Thailand:* We will work with two primary hospital, Phanat Nikhom Hosp., Chonburi district (Key Pers. Dr. P. Hemachudha) & Photharam Hosp., Ratchaburi Province, and a large tertiary hospital, King Chulalongkorn Memorial Hospital, Bangkok Thailand (Co-I Dr. T. Hemachudha). *Peninsular Malaysia:* **Focusing immediately on the current outbreak in Orang Asli, we will work closely with the Malaysian Ministry of Health to support their investigation, and with 6 Orang Asli clinics which focus solely on this indigenous community.** Co-I Sellaran (Lintang Clinic, Kuala Kangsar) refers patients to Sungai Siput Hospital and Gen. Hospital, Ipoh. Key Pers. I Lotfi (Pos Betau clinic, Kuala Lipis) will continue collaboration with Co-I Hughes in the communities at that site. *Sarawak:* Key Pers. Diyana (Director, Bario Clinic) refers patients to Miri Hospital (Co-I Utap) and serves people from the Kelabit, and nomadic tribes in the region, as well as populations within a number of large towns. *Sabah:* We will continue our collaboration with Queen Elizabeth Hospital, QEH (Key Pers. Lee, Rajahram) and Hospital University Malaysia Sabah, HUMS (Co-I Lasimbang, Director). Both clinics include our targeted sites for **Aim 2** in their catchment, and both have ongoing collaboration with the Borneo Medical Health Ctr (Co-I Kamruddin, Director). *Singapore:* Currently, there are no plans to conduct clinic surveillance based on budget constraints. However, in the event that that is an evolving need for clinic surveillance, enrollment, and sampling, we have close working relationships with all hospitals in the country, and the central infectious disease reference lab (key clinicians at which are aware of our proposal). This would allow us to rapidly on-board a hospital based site.

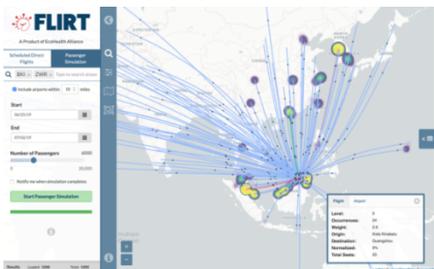

**3.4.b Clinic enrollment and follow-up:** We will recruit inpatients and outpatients to participate in the study after initial screening to determine if they meet our clinical case definitions. Once consented and enrolled, biological samples will be collected by trained and locally certified hospital staff and a questionnaire administered by trained hospital or research staff that speak appropriate local language. Every effort will be made to take samples concurrently when collecting samples for normative diagnostics. For both inpatients and outpatients, samples will be collected no more than 10 days of reported onset of illness to increase the chance

of PCR detection of viruses (185). Where possible, we will follow up 35 days after enrollment to collect an additional two 500  $\mu$ L serum samples conduct a standardized questionnaire supplement to collect additional data on the course of symptoms in the interim period. This gives adequate time for development of IgG, which occurs <28 days after onset of symptoms for SARS patients (186-188). Serum samples will be used to screen panels of high risk human and local zoonotic Filovirus, Henipavirus and Coronavirus strains as described in Aim 2. These samples may prove valuable to collaborators in that the PBMC could be used in production of therapeutic antibodies.

**3.4.c Sampling and clinical interview:** Biological specimens whole blood (5mL will be drawn for whole blood and serum collection, samples will be aliquoted, at least one max. 500  $\mu$ L whole blood; two 500  $\mu$ L serum samples) and two nasal or oropharyngeal swabs will be collected from all participants, and a questionnaire will be administered. We will investigate five risk factors, to maximize the power of the analyses, all related to high risk wildlife exposure, based on continuing analysis of our previous work, and will include: 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, in/around house; 3) proximity of residence or work place to environments of increased risks, e.g. nearby bat roosts; 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms in the past 12mo and lifetime. With additional consent considerations for participants enrolled from clinical settings, we will review clinical records to collect data on medical history, clinical syndromes, and patient etiology. Blood will be taken for future harvesting of Peripheral Blood Mononuclear Cells (PBMCs), as per **Section 2.5**.

**3.5 Sample testing:** The standard syndromic diagnostic PCR assays for common pathogens will be conducted and the results will be shared with the hospital with 48 hours. Specimens will be further tested for 3 viral families; CoV, PMV and filovirus by consensus PCR (**Section 1.4.c**). Necropsy samples from deceased patients will be further characterized by NGS if previous PCRs are negative and unable to identify the cause of infection. Co-Is Wang, Anderson will conduct a VirScan serological assay using paired serum samples at Duke-NUS that identifies antibodies with a four-fold rise in titer in the convalescent sample compared with the acute sample, thereby indicating a possible etiological agent. A PCR test with the specific primer from each virus antibody positive case will be further tested from acute specimens to confirm infection.

**3.6 Viral risk characterization and potential for pandemic spread:** We will use statistical models built from collated biological, ecological, and genetic data to assess the likelihood of pathogenicity for the range of diverse viruses we will characterize. The aim is to quickly identify and assess which viruses pose the most significant risk to human health and thus prioritize additional resources to more fully characterize, better understand pathogenicity, and invest in our animal model pipeline and ultimately therapeutic development for those pathogens. We will combine two independent but related statistical models to predict pathogen spillover risk and pathogenicity. First, we will expand a simple generalized additive modeling approach (3) to assess spillover risk probability to a new virus that is currently not known to infect people, when we have only limited genetic data from initial PCR screening and sequencing. Additional data from receptor binding protein homology and cell line infection experiments will be incorporated into the model framework as available. Second, given high likelihood to spillover and infect humans, or direct evidence of human infection from our clinical surveillance, we will then assess the likelihood of pathogenicity based on traits for phylogenetically related nearest neighbor viruses as a first approximation and incorporating more detailed data from genomic characterization and animal model experiments (Aim 1). Epidemiological trait data for ~300 viral species known to infect people (e.g. case fatality rate, global estimates of number of human cases per year or decade,  $R_0$ , infectious period, and primary symptoms) have been collated by recent studies and will be used as predictor variables (189). Thirdly, we will apply tools already developed, and being refined by EHA under DTRA and DHS supported research, to predict pandemic spread for viruses using global flight models, as well as additional datasets on human movement and connectivity across Southeast Asia (90, 91) (**Fig. 15**).

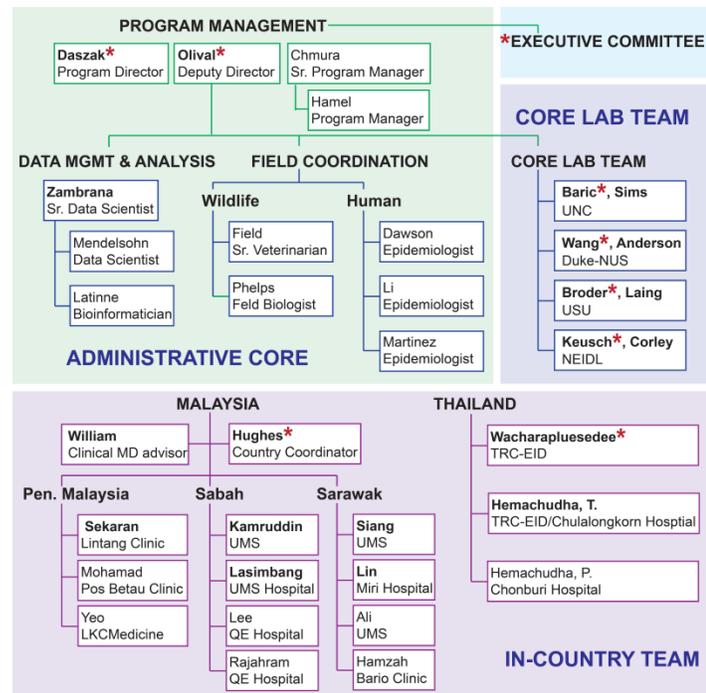

**Fig. 15:** Probability feed from EHA's Flight Risk Tracker tool (FLIRT). This image is of the likely pathways of spread and establishment for a Nipah-like virus emerging from Sabah, based on human movement and airline flight data (90, 91).

**3.7 Potential problems/alternative approaches: Patients visiting clinics may have cleared virus, but not yet developed IgG antibodies, reducing seropositive cases.** Our 35 day follow-up sampling should account for this because the maximum lag time between SARS infection and IgG development is ~28 days and Ebola virus infection and IgG approximately 20 days (185-188, 190). We also expect that patients in rural communities will only visit clinics when symptoms have progressed, likely coinciding with late illness and onset of IgG. We will also have data from our community study that can be analyzed in conjunction with, or in the absence of, clinical data from the hospital data to identify PCR- or seropositives. Finally, the risk of limited detection is outweighed by the potential public health importance of discovering active spillover of new henipaviruses, FVs or CoVs infection.

**4. Administrative Plan**

**4.1. Project management: 4.1.a. Administrative core:** The EID-SEARCH organizational partner roles are laid out by Specific Aim above (see Fig. 3). EcoHealth Alliance (EHA) will lead the administrative core of the EID-SEARCH, including: coordination and management of all human and animal research; communication with consortium partners, NIH, other EIDRCs, and the EIDRC-CC; data management and quality assurance; modeling and analysis; and compliance with all US, international, and institutional rules and regulations. The administration will be led by PI Daszak, who has >20 years' experience managing international research collaborations on emerging zoonoses, and has collaborated with all partners in the EIDRC consortium for 5-20 yrs on NIAID- and USAID-funded research (Fig. 16). He also has direct experience as one of two external reviewers of one of the CEIRS partners for NIAID (Program officer Diane Post). PI Daszak will be assisted by Deputy Lead, co-I Olival, who has overseen zoonotic disease research in Southeast Asia for >10 years and working directly with our partners in Thailand and Malaysia for 15 years. Senior program manager (Chmura) and full-time program assistant (Hamel) will provide administrative support. The EID-SEARCH data management, epidemiological analysis, and modeling activities will be led by co-Is Olival and Zambrana who have led all modeling and analytics on USAID USAID PREDICT for the last 10 years. They will oversee a programmer/data scientist (Mendelsohn), evolutionary biologist/bioinformatician (Latinne), and human epidemiologists (Dawson, Li, Martinez). Our human epidemiology team will work directly with country teams in Malaysia and Thailand to manage human surveillance, IRB applications and approvals, and ensure compliance with all human subjects work. EHA's senior veterinarian (Field) and wildlife field biologist (Phelps) have extensive experience working that bats, rodents, and primates in SE Asia and will coordinate all training and field research in Malaysia and Thailand and ensure compliance with IACUCs.

The EID-SEARCH data management, epidemiological analysis, and modeling activities will be led by co-Is Olival and Zambrana who have led all modeling and analytics on USAID USAID PREDICT for the last 10 years. They will oversee a programmer/data scientist (Mendelsohn), evolutionary biologist/bioinformatician (Latinne), and human epidemiologists (Dawson, Li, Martinez). Our human epidemiology team will work directly with country teams in Malaysia and Thailand to manage human surveillance, IRB applications and approvals, and ensure compliance with all human subjects work. EHA's senior veterinarian (Field) and wildlife field biologist (Phelps) have extensive experience working that bats, rodents, and primates in SE Asia and will coordinate all training and field research in Malaysia and Thailand and ensure compliance with IACUCs.

**Fig. 16: Administration and program management for the EID-SEARCH**

The EID-SEARCH core laboratory team includes global experts in virology, molecular pathogenesis, and the development of assays, reagents, and therapeutics for high consequence viral zoonoses (Co-Is Wang, Anderson at Duke-NUS; Baric, Sims at UNC; Broder, Laing at USU; Keusch, Corley at NEIDL). The core laboratory team will work with in-country diagnostic labs in Thailand (Wacharapluesedee, Hemachudha at the TRC-EID, Chulalongkorn University) and Malaysia (Hughes, Lee, CM Ltd.). Wacharapluesedee and Hughes will additionally serve as country coordinators for the EID-SEARCH, liaising directly with EHA on weekly conference calls, and working with in-country partners to ensure the smooth operation and coordination of clinical and community surveillance and wildlife research in Thailand and Malaysia, respectively. **A Core Executive Committee** comprising PI Daszak, Deputy Lead and Co-I Olival, and leads from each core partner and country: Co-Is Hughes, Wacharapluesedee, Baric, Wang, Broder, Keusch (or alternates), will conduct

regular conference calls and in-person meetings to facilitate rapid decision making within the EID-SEARCH. **This committee will also convene to manage EID-SEARCH response to outbreaks.**

**4.1.b Project Management in Thailand and Malaysia:** Wacharapluesedee and Hughes have collaborated directly with EHA for >15 years, including acting as country coordinators on the USAID PREDICT project for the last 10 years (project end date Sept. 2019). They maintain strong ties with Ministries of Health (MOH), Agriculture and Environment, multiple universities and research institutions, clinics, and hospitals, in their respective countries and across the region. The EID-SEARCH will use these connections to disseminate results, obtain permissions to conduct sampling, and also rapidly respond to and assist with outbreaks as they happen. Peninsular Malaysia, Sarawak, and Sabah are the three main Malaysian administrative regions, and effectively operate as three separate countries, with different regulations and government structures. We therefore provide specific details on the management of EID-SEARCH activities in each:

Coordination among Peninsular Malaysia, Sabah and Sarawak will be led by co-I Hughes (Conservation Medicine Ltd), and follow a successful model we implemented under USAID-PREDICT. **On Peninsular Malaysia** this project will be administered through the Zoonosis Technical Working Committee (ZTWC) established under the PREDICT project with a binding MOU among EHA, CM Ltd. and ZTWC, and including officers from MOH, Dept. of Veterinary Services, and PERHILITAN (the Govt. wildlife agency). EHA will communicate weekly with Co-I Hughes to coordinate and monitor implementation of research and reporting to ZTWC. Co-I Hughes will coordinate activities at all other Peninsular Malaysia institutions: NPHL, the National reference laboratory for diagnostic confirmation of pathogens, will manage molecular and serological screening (BioPlex) of Orang Asli samples, and serological screening of syndromic samples from Sabah and Sarawak; the PERHILITAN molecular zoonosis laboratory will store and conduct molecular and serological screening on wildlife samples; and Universiti Putra Malaysia (UPM) Faculty of Veterinary Medicine will conduct molecular and serological screening (BioPlex) of livestock samples, should these be required. **For Sabah & Sarawak**, work will be administered through the Sabah Zoonotic Diseases Committee (SZDC), a working technical committee comprising appointed and authorized officers from Sabah State Health Dept., Department of Veterinary Services, Sabah Wildlife Dept. (SWD), Universiti Malaysia Sabah (UMS) and EHA, all of which are also committed through a signed MOU. Co-I Hughes will oversee work at all other partners in Sabah, including: the Kota Kinabalu Public Health Lab (KKPHL) for molecular screening of syndromic samples from Sabah and Sarawak; the SWD Wildlife Health and Genetic and Forensics Lab for molecular screening of Sabah wildlife samples; The Borneo Medical Health Research Center (BMHRC) for screening some Sabah wildlife and livestock samples, if required, and human syndromic samples from Sabah and Sarawak. **In Thailand** all human community and wildlife research and testing will be coordinated by co-I Wacharapluesedee from the TRC-EID center. Clinical surveillance will be overseen by senior clinical physician and co-I T. Hemachudha.

**4.1.c. Approval and release of results:** In our experience, it is critical when working in resource-poor countries, on potentially important pathogens, to strictly adhere to protocols for release of results. EID-SEARCH will liaise with existing points of contact in the Ministries of Health, Environment, and Agriculture in each our administrative areas to approve and release project findings publicly. Results from human screening will be shared with participants when they become available, as per our IRB agreements ensuring no violations to anonymize data requirements (**see Protection of Human Subjects**).

**4.2. Flexibility to extend the EID-SEARCH to new sites as needed:** The EID-SEARCH consortium partners maintain extensive working relationships with leaders in EID outbreak control, clinical investigations and research at over 50 clinics, research institutes and public health laboratories across Southeast Asia. Due to space constraints, we haven't listed each of these, nor have we solicited >50 Letters of Support for this project. However, each core EID-SEARCH partner has contacted their networks and obtained permission for inclusion in the broader goals of the EIDRC. As examples of these contacts, our core partner, the Thai Red Cross Emerging Infectious Disease Health Science Centre (TRC-EID) at Chulalongkorn University, also serves as the WHO Collaborating Centre for Research and Training on Viral Zoonoses and has ongoing research collaborations across WHO SEARO countries including Bangladesh, Bhutan, Democratic People's Republic of Korea, India, Indonesia, Maldives, Myanmar, Nepal, Sri Lanka, (Thailand), Timor-Leste; and has recently served as a training hub for scientists from Malaysia, Myanmar, Laos, the Philippines, and China to learn methods of wildlife sampling and diagnostic screening. Our Thai clinicians (Co-I T. Hemachudha and KP P.

Hemachudha) provide regular case consultations and clinical trainings for doctors across SEARO countries, including with Yangon General Hospital and the National Health Lab in Myanmar, 2018. To maximize leverage of this broad network, EHA has budgeted for annual meetings in SE Asia, in addition to regular smaller network meetings, with our core team and key public health experts from network labs in each of the 10 SE Asian countries. Additionally, we will set up a listserv and an internal communication network to facilitate collaboration and information exchange, including on the first reports of new disease outbreaks. Our annual and smaller network meetings will critically allow face-to-face meetings of the EID-SEARCH that will foster greater sharing of information on novel research and diagnostic approaches, pathogens that are of key pandemic potential, regions or populations at high risk of spillover, and information from the greater network on likely outbreaks of novel disease. This platform will coordinate sample sharing and diagnostic platforms and help build a rapid response to outbreaks in the region, guided by the PI, Deputy and the Executive Committee.

**4.3. Outbreak response:** EHA collaboration with expert networks around the world allows us to mobilize and enhance effective One Health response to disease emergencies (191), ranging from real-time situation updates and risk analyses to on-the-ground investigations (192-194). We will adopt management tools from Emergency Operating Center (EOCs) (195) and Incident Management Systems (IMS) (196), to shift resources where necessary to help respond to novel zoonotic outbreak events and other public health emergencies. EHA has extensive experience working with governments in low and middle income countries (LMIC) applying these principles of epidemic preparedness during outbreak responses we've been involved with under the USAID-PREDICT project. For example, at the request of the government of Bangladesh, we provided technical field and laboratory support for Nipah virus and avian influenza outbreak investigations, assisting with wildlife sampling as part of the outbreak response alongside human and domestic animal sampling. In India, we provided technical assistance in response to the Nipah virus outbreak in Kerala in 2018. Last month in Indonesia we assisted the Ministry of Health's Center for Health Laboratory in Makassar to provide technical assistance in a mysterious outbreak in a small village in South Sulawesi that killed 4 villagers and infected 72. Our network partners include the key government and govt. approved laboratories that would be directly involved in public health emergency response in their respective countries. The serological and PCR platforms that EID-SEARCH develops will be made available to the main government outbreak investigation teams for clinical work and research during the outbreak. EID-SEARCH will also offer assistance training and conducting animal sampling during an outbreak, epidemiological analysis and modeling to help identify likely reservoirs or likely pathways to spread. Technical and material support for lab, field and analytical activities during an outbreak will be provided by EHA, UNC, USU, Duke-NUS, and NEIDL, as well as in-country partners. Any clinical samples, viral isolates and sequence data will be shared among partners to promote the rapid development of new diagnostic assays, reagents, and therapeutics that can be deployed to the region or other regions as part of the larger NIH EIDRC network.

Finally, while the initial pathogen focus of our group is on CoVs, PMVs and FVs, our broad collaborative group has multidisciplinary expertise on a number of virus-host systems. For example: PI Daszak was PI on a subaward from PI Laura Kramer's U01 on Poxviruses and Flaviviruses, managing a multidisciplinary research project on West Nile virus ecology. He was also co-I on a 5-year NSF-funded project to understand West Nile virus dynamics and risk in the USA (197-201); Co-I Baric is a global leader in Norovirus research leading to the development of vaccines and therapeutics (202-205); Co-I Wang has conducted significant work on bat immunology, therapeutic, and reagent development, as well as being involved in a range of outbreak investigations, viral discovery programs and other research on a wide diversity of viral groups (206-215). Additionally, the serological and PCR-based diagnostic platforms being developed by Co-Is Wang and Broder are adaptable to other viral targets. The modeling tools developed by Co-Is Olival and Zambrana-Torrel can be used to predict the emergence and spread of diverse viral targets, including influenza, antimicrobial resistance, and vector-borne diseases (216-221). Our clinicians working in Thailand and Malaysia have a wide range of infectious disease investigations to adapt to any outbreak situation.

**4.4. Communications:** EHA will coordinate communication among all co-Is and key personnel, including:

- Multiple meetings per week with PI, Deputy Lead, Senior Program Manager (on project and task status)
- Weekly web/phone meetings between Program Manager and subawardee admin. staff
- Monthly web/phone conferences between EHA PIs and all subawardee PIs.

- Monthly web conferences between key personnel (research presentations/coordination)
- In-person Annual meetings with partner leads, key personnel at EHA and two in-person partner meetings annually between subawardees.
- Annual in-person meeting among all key personnel

**4.5. Problem identification and resolution:** Regular planning, monitoring, and evaluation meetings will be the primary mechanisms for problem identification. Minor problems (e.g. delays in sample availability or test results) will be dealt with internally through appropriate action and resolution monitored by PI Daszak and co-PI Olival, and our Senior Program Manager. In the event of significant problems, such as prolonged poor productivity, inadequate scientific collaboration, or major disputes regarding research direction or resource allocation, EHA will assist with resolving the problem through negotiation with relevant co-PIs and consultation with the Executive Committee. Should a resolution not be forthcoming, consultation with the EIDRC-CC, additional external technical advisors, and NIH staff may be warranted.

**4.6. Adaptive management and risk mitigation:** Maintaining a timeline and meeting milestones will require strict and continuous oversight of all project phases, frequent and regularly scheduled communication, and the ability to make decisions and implement strategies. To maintain our timeline on all projects, including the EID-SEARCH, we use an adaptive management approach to continually evaluate these trade-offs, to make decisions about when iteration is appropriate and when it is necessary to move forward with current information. Our ethos is that regular, scheduled communication among all staff, partners and collaborators will go a long way towards mitigating risks, especially if the process is collaborative and transparent.

## 5. Data Management Plan

EHA will house the Data Management and Analysis (DMA) team for EID-SEARCH, led by Co-PIs Olival and Zambrana-Torreilo and include Key Personnel Latinne and Mendelsohn. EHA has served as the data and analysis hub for numerous multi-institutional, multi-sectoral, international disease research groups, including acting as Modeling and Analytics lead for the PREDICT project (122), the Western Asia Bat Research Network (222) and EHA's Rift Valley Fever Consortium. We will leverage our experience and infrastructure from those projects to benefit the EID-SEARCH. **5.1. Project Database:** We will create a dedicated, centralized EID-SEARCH database to ingest, store, link, and provide for analysis all data associated with the proposed study and other expanded projects associated with the research network. The database will be SQL-based and use encrypted, secure cloud hosting services and enable export to archival and platform-independent formats. It will ensure data and metadata compatibility between project components, track data versioning and annotations. The system will be designed to work with both with both paper- and tablet-based field data entry and with the Lockbox laboratory information management systems (**Section 5.2**) in place in individual partner labs. The database will use existing metadata standards, including NCBI standards for genetic and molecular data and Ecological Metadata Language (EML) for field and wildlife data, as well as other standards and formats designated by the EIDRC CC. This will enable rapid publication and deposition of data. Granular security and privacy controls will be applied so that specific expansion projects undertaken in the network may be managed while maintaining data confidentiality as needed.

**5.2. Biological Specimen Management:** Project laboratories will use the Lockbox Laboratory Information Management System (LIMS), to manage the security, traceability, and quality of biological specimens. The LIMS will support sample barcoding at creation, tracking through transport, storage/inventory, and use via portable scanners. Lockbox supports CLIA and ISO 17025 as well as direct export to NCBI formats such as Sequence Read Archive. We will use the Lockbox LIMS application programming interface (API) to link to the central project database and associated samples with field and ecological data. We note that the project focuses on highly pathogenic viruses, including select agents; Lockbox LIMS supports sample tracking and movement compliant with US Select Agent Regulations and US Department of Commerce Pathogen Import and Export Control Regulations, and includes all necessary encryption, security, and backup protocols.

**5.3. Training:** Members of the DMA team will team will develop documentation and provide training for field and laboratory teams at all partner institutions in data management, metadata standards and data hygiene best practices. The DMA team will act as trainers and consultants for partner institutions in experimental

design, power analysis, data analysis, and computational and reproducibility issues, and visit each partner institution and/or field team base for training workshops and analysis consultations.

**5.4. Data Identification and Privacy:** For human clinical data and questionnaires, data will be identified by a unique identification code assigned to each individual and only this, de-identified code will be accessible in the project database, and destroyed at the end of the project - as per details provided in the Clinical Management Plan and Protection of Human Subjects forms.

**5.5. Computing Resources:** EHA operates a cluster of high-performance servers for data analysis activities, as well as infrastructure to launch cloud-based computing environments (**see EHA Facilities**). Our servers host all necessary software for statistical and bioinformatics work that is available to the DMA and partners anywhere in the world. We use a mixture of cloud services (AWS, Azure, Backblaze, GitHub) to provide redundancy, backup, version control, and rapid post-disaster recovery, and will be available to all project partners for analysis and training.

**5.6. Data and Code Sharing:** See details provided in the **Resource Sharing Plan**.

## **6. Clinical Management Plan**

**6.1. Clinical site selection:** Our consortium partners have been conducting lab and human surveillance research, including during outbreaks, for >20 years and have developed strong relationships with local clinical facilities and processes in SE Asia and in LMIC globally. The plan for selection of clinical sites will begin in the same geographic regions as those identified in Aim 1 with high zoonotic viral diversity. Clinical sites will additionally serve as the catchment healthcare facilities for people in our community-based surveillance of Aim 2. We have already developed successful working relationships with the major healthcare facilities in Thailand and Malaysia and will use these established partners to rapidly gain appropriate permits and begin data collection quickly. Focusing on these EID hotspots in select biogeographic areas (see **Fig 13**) also reduces the number of additional sites needed to meet our goals within our geographic range. The capacity and capability requirements for clinical sites are fairly minimal, and include ability to enroll patients that meet the clinical case definitions of interest, collect and temporarily store biological samples, and follow standards for data management and subject protection with locked filing cabinets to store all paper records and an encrypted computer. We will be enrolling inpatient and outpatient participants within 10 days of the presentation of symptoms to increase the chance of PCR detection of viruses so we will not wait for advanced normative diagnostic tests, that are likely unavailable in the more remote sites, to be completed. We will work with clinical sites to determine the best process for project staff, in most cases supporting the time of currently hired staff at each site. We will recruit and train hospital staff in project-specific procedures including enrollment of patients, sample types to be collected, storage of samples, administration of the questionnaire, and data management plans. During the development and onboarding of new clinical sites we will assess the physical needs of the site and what supplies will be required for collection of data.

**6.2. Standardized approach, oversight, and implementation:** Management and oversight for all study sites will be undertaken by the local country coordinator with support from our Core Administrative team at EHA. Our research team has over 10 years of experience building capacity on human subjects' research and has developed training resources and materials for standardized implementation of community and clinical research and SOPs for screening, enrollment, and retention of participants. The country coordinator will conduct regular site visits to the clinical sites and annual visits to observe, monitor and evaluate the research process, and conduct follow-up training if required. Through our work with clinical sites under the USAID-PREDICT project we have developed culturally appropriate screening measures for clinical sites that do not disrupt the flow or quality of medical treatment received by the patient. This was done by working collectively with clinical staff to evaluate current procedures and patient flow at the site to determine the most efficient while minimal invasive inclusion of our study into the daily working of the clinical site. Most efficiently this was done by adding minimal basic screening questions to the current clinical intake forms, which allows the clinical research officer to quickly scan charts or logs for potential patients to enroll avoiding potential enrollees from being overlooked if staff are too busy or not on duty. Patients will be enrolled following established clinical criteria (**see Section 6.3**), samples collected and brief surveys conducted to assess the participants contact with wildlife through: 1) occupational exposures; 2) animal contact; and 3) the environment. With permission

from each clinic, and consent from participants, we will review clinical records to collect data on medical history, clinical syndromes, and patient etiology. Additionally, we will be following up with clinical participants to determine how clinical presentation differs between CoV, henipavirus, or FV in exposed and unexposed participants, as well as in the time course of illness, severity of symptoms, and type of symptoms. The country coordinator will be continually monitoring the project database to ensure we hit target sample sizes. While patient's enrollment is limited by the number of individuals presenting at hospitals, in previous research we enrolled an average of 105 patients per year, ranging from 77-244.

**6.3. Clinical cohort setup, recruitment, enrollment:** We will recruit inpatients and outpatients from clinical sites to participate in the study after initial screening to determine if they meet the clinical case definitions for 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; 5) hemorrhagic fever, of unknown etiology or severe diarrhea with unusual presentation for symptoms to increase the chance of PCR detection of viruses. Once enrolled, biological samples will be collected by trained hospital staff. When possible, samples will be taken concurrently with samples being collected for normative diagnostics. We will collect 5mL of blood for whole blood and serum collection, samples will be aliquoted, at least one max. 500  $\mu$ L whole blood; two 500  $\mu$ L serum samples and two nasal or oropharyngeal swabs will be collected. Controls who test positive for CoVs, FVs, or Henipaviruses will be selected from the pool of participants admitted to the studies and whose samples tested negative for coronaviruses, henipavirus, or filoviruses. We will follow up 35 days after enrollment to collect an additional 5mL blood draw for collection of two 500  $\mu$ L serum samples and a standardized questionnaire supplement to collect additional data on the course of symptoms in the interim period. Following up 35 days post initial collection gives adequate time for 1) development of IgG and IgM, which occurs <28 days after onset of symptoms to evaluate the immunological progression of disease and 2) further the risk assessment of the participants to monitor contact with wildlife, people, and to assess the likely reservoir hosts to collect information to inform potential intervention programs.

**6.4. Utilization of collected data:** Sampling of wildlife and the enrollment of community surveillance participants and a clinical cohort of participants give us the ability to assess the viruses that are circulating in each of the three populations in a similar geographic region. We will use phylogenetic analysis to compare the relationship between wildlife viruses found and viruses found in human participants. Additionally, the questionnaire data will allow us to assess relative measures of human-wildlife contact that we will analyze the intensity of contact with species known to be at a higher risk for spillover against other risk to provide useful proxy information for spillover risk. The clinical cohort will be split into cases and controls. "Cases" are defined as participants whose samples tested positive for either CoV, henipavirus, or FV via PCR tests. "Controls" will be selected from the pool of participants admitted to the studies and whose samples tested negative. We will use nearest neighbor matching to pair cases demographically (e.g. age, sex, location) with controls at a 1-to-3 ratio or greater. In clinical study, we will use this procedure to determine how clinical presentation differs between virus-exposed and -unexposed participants, as well as in the time course of illness, severity of symptoms, and type of symptoms. We will model the outcomes to analyze correlation between biological results and risk factors related to high risk wildlife exposure. With this collective data set we aim to quantify and detect novel viruses likely to spillover regularly to people, are often unreported or misdiagnosed as their clinical manifestations, and are unknown to detect cryptic outbreaks causing previously 'hidden' clinical syndromes in people. Our strategy for targeted surveillance and detection of spillover and illness in at-risk human populations can be used as an 'early warning system' to conduct public health interventions and disrupt disease emergence.

**6.5. Development of reagents of value to the community.** Members of the EID-SEARCH consortium have substantial experience producing reagents, assays, and other products that are used widely by the clinical and research community, and some of which are on a pathway to commercialization. These include: PIs Daszak and Co-I Olival have produced software for analyzing the spread of novel viral agents through air travel networks; Co-I Baric has collaborated with a Norovirus surveillance collaboration with surveillance cohort at CDC and has developed therapeutics that have reached phase 2 and 3 clinical trials, He is currently working with Takeda Sanofi Pasteur on a Dengue therapeutic and with NIH on a tetravalent vaccine; Co-I Broder

developed a Hendra virus subunit vaccine that was commercially produced by Zoetis for horses and is labeled for human use under compassionate circumstances during outbreak situations.

**6.6. Potential expansion:** Expansion of the research project to other clinical sites or research areas could happen as new information is gathered, either through our research, the EID-SEARCH information network, or an outbreak being identified in the region by other organizations. If expansion is required we would rapidly shift research activities towards the clinical or community sites where the outbreak is active, using the same process we used to set up initial research locations. First, by working with local stakeholders to create a working relationship and on-boarding new clinical research staff through advanced trainings of project aims, SOPs on data collection and storage, and ethical guidelines. The network of infectious disease researchers in the community and hospital settings would allow for an accelerated response to any potential infectious disease outbreaks as staff are well trained on ethical guidelines for working with human subjects, data and specimen collection, storage, and transpiration, project staff would be on the front lines ready for the call to action. Ideally, our testing for viruses in priority viral families may lead to the discovery cryptic outbreaks before it spreads in the general public. Biological results coupled with survey data on key risk factors will provide necessary information for granular understanding of disease spread.

## **7. Statistical Analysis Plan:**

**7.1. Framework:** Statistical analyses across the project will be conducted under a common Bayesian framework. These models provide a unified, probabilistic approach best-suited for estimating effect sizes in heterogeneous populations of human clinical and wildlife subjects in observational studies. Within this Bayesian framework, we will use generalized linear mixed models to estimate population prevalences and seroprevalences, and estimate the effects of demographic, occupational and environmental factors affecting these. We will use occupancy models (223) to estimate total viral species and strain diversity and completeness of sampling within the human and wildlife sub-populations, and discrete phylogeographic models to identify taxonomic and geographic centers of viral diversification. All statistical analyses will be performed reproducibly using scripted, programmatic workflows (e.g., the R and Stan languages) and maintained under source code version control (git). As with data management, the DMA team will act as trainers and consultants for exploratory data analysis, power analysis, and study design with project partners, and the EHA computing cluster will be available for partners undertaking additional or expansion studies. Power analyses, current and expansion, are performed via simulation approaches allowing planning for complex, hierarchical variation in study populations. Power analyses and specific analytical components of this study are detailed under each Specific Aim.

**7.2. Data Quality Control and Data Harmonization:** All data will be examined at entry by field and lab teams upon data entry, followed by examination by DMA team members at upload and integration, for complete de-identification, completeness, accuracy, and logical consistency. The DMA will provide field and lab teams with reports, produced automatically, of data summaries, including aggregates, distribution, detected outliers and possible mis-entries. On a regular basis (quarterly or as-needed during data collection), DMA team members will review reports with field and lab teams to identify errors and update collection and entry procedures as necessary.

**7.3. Statistical Considerations for Behavioral Questionnaires and Clinical Metadata:** The data collected from the questionnaire will be analyzed to assess the reported measures of contact for each risk group under study, related to 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, rodents, and primates in/around house and other livestock animals (e.g. farming, butchering, slaughtering); 3) proximity of residence or workplace to environments of increased risks (e.g. nearby bat roosts); 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms in the past 12 months and lifetime. Specific measures we are interested in are the proportion of respondents indicating they consume wildlife, where wildlife is obtained for consumption, have hunted wildlife, butchered or slaughtered live animals, seen wildlife in their homes, been bitten or scratched by animals, etc. Comparisons of measures of exposure contacts and types between men and women, children and adults, different study regions will be conducted in order to explore the occupational, environmental, and demographic factors (gender, age, socioeconomic status (SES)) that influence contact with animals and to determine who is

most at-risk. Statistical analysis will be employed to identify differences between groups with a 95% probability of detecting a difference. Measures of contact related to different activities within specific groups will be compared to determine the activities that put groups at most risk. As appropriate multivariate analysis (e.g. ordinary linear regression, logistic regression, non-normal distributions of outcome, least absolute shrinkage and selection operator (LASSO) regression, etc.) will be utilized to evaluate the relationship between the outcome variables, positive biological results (PCR or serology) key measures of contact and the factors that influence frequency and types of human-animal contact.

## 8. Project Milestones and Timelines

**8.1 Milestones: End of Year 1: Aim 1:** Sample targeting locations, species (for wildlife), sample size justifications completed for whole project and reported to in-country teams; Sample testing, viral isolation, NGS, glycoprotein sequencing begun for all archival and some newly-collected samples; *in vitro* work begun; host-pathogen dynamic analyses; animal model work begun. **Aim 2:** Target human community populations identified and sample sizes calculated for some sites in each country; Community data collection, serological testing and RT-PCR testing begun; first epidemiological analyses of data begin in last quarter. **Aim 3:** Clinical cohort selection underway; clinical enrollment, data collection and sample analysis begun. First Annual meeting in last quarter. First publications submitted by end of year, summary overview papers or reviews.

**End of Year 2: Aim 1:** No sample targeting or sample size justification analyses needed. All other aspects underway **Aim 2:** All aspects underway **Aim 3:** All sub-aims underway. Second Annual meeting in last quarter. Further 2 publications submitted by end of year, including first data papers.

**End of Year 3: Aim 1:** No sample targeting or sample size justification analyses needed. All other aspects underway **Aim 2:** All aspects underway **Aim 3:** All sub-aims underway. Third Annual meeting in last quarter. Further 3 publications submitted by end of year, largely data papers.

**End of Year 4: Aim 1:** No sample targeting or sample size justification analyses needed. All other aspects underway **Aim 2:** All aspects underway. Receptor binding work completed. **Aim 3:** No further cohort selection required; all other sub-aims underway. Fourth Annual meeting in last quarter. 3 further publications submitted, including first papers analyzing risk factors, pathogenic potential of novel viruses submitted.

**End of Year 5: Aim 1:** No sample targeting or sample size justification analyses needed. No receptor binding assays continuing. Serological and PCR testing completed end of 2<sup>nd</sup> quarter. Glycoprotein, *in vitro* and *in vivo* analyses, analysis of viral risk continue to end of project. **Aim 2:** No further community targeting or sample size work. Community data collection completed at end of 2<sup>nd</sup> quarter. All other aspects continue to end of project **Aim 3:** All sub-aims underway. Final Annual meeting in last quarter. Further 3 publications submitted.

### 8.2. Timeline:

ACTIVITIES	YEAR 1				YEAR 2				YEAR 3				YEAR 4				YEAR 5			
	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4
AIM 1	1.4.a. sampling targets

CREID Network Governance  
 Appointments to Steering Committee  
 and Working Groups  
 15-Jul-20

Research Center Steering Committee	Research Center Appointment
Representatives	
Primary Representative	
Secondary Representative	

Working Groups	CC Facilitator(s)	DMID Facilitator(s)	Draft Goals of WG	Date Established	Research Center Appointment
Data Capture and Harmonization	Nathan Vandergrift, Sean Hanlon	Primary: Amber Linde, Secondary Sara Woodson	(1) Develop data standards and best practices for data collection for different assays types as well as clinical data that comply with FAIR Data Principles (Wilkinson et al. 2016) (2) Develop data templates that will facilitate data sharing and dissemination to data repositories.	August/ September 2020	
Biorepository Oversight and Quality	Tony Moody	Primary: Sara Woodson, Secondary: Julie Dyall	(1) Harmonize specimen collection and processing procedures.	August/ September 2020	
Laboratory Assays Oversight and Quality	Greg Sempowski	Primary: Julie Dyall, Secondary: Sara Woodson	(1) Develop, implement, and facilitate use of harmonized SOPs for quality laboratory assays.	August/ September 2020	
Rapid Research Response	Pia MacDonald	Primary: Jean Patterson, Secondary: Sara Woodson, Candice Beaubien	(1) Identify and document roles and responsibilities for the CREID CC, the RCs and sites during an outbreak research response; (2) Review the information collected in the Inventory and Site Capacity Management system to identify gaps, potential stressors, and existing challenges; (3) Document lessons learned and best practices for rapid research response.	August/ September 2020	
Capacity Building and Country Ownership	Gretchen Van Vliet	Primary: Candice Beaubien, Secondary: Sara Woodson	(1) Define requirements for Pilot Study program, which will be implemented in Years 2-5 of the CREID Network; (2) Identify strategies for sustainability and country ownership.	December 2020/January 2021	

## Direct COVID projects

- Serology of underserved, disenfranchised communities (e.g. Orang Asli, illegal immigrant communities in Borneo, migrant workers Singapore-Thailand-Malaysia)
- Thailand – first responders, people with high exposure (customs)
- Linfa – strain ID (cf. his work on SARS-like deletion)
- Serological testing across Thailand/Malaysia of archived human sample prior to COVID outbreak to see if COVID-like exposure prior to known outbreak
- Linfa's neutralization assay to see how effective vaccines are in trials.
- Ralph/Chris ideas -

## COVID-related

- Linfa pseudovirus neuts to other bat-CoVs
- Tom – undiagnosed Disease X (COVID –ve)
- Tom – archived bat/intermediate host sample testing for SARS-CoV-2

---

Dear Members of EID-SEARCH (Emerging Infectious Diseases - South East Asia Research Collaboration Hub) Center,

It was very nice to speak to you on Friday. Sorry, we have missed some of you on the call. (please feel free to add your team members who will work on this project into this email chain)

Attached please find the project summary and proposal in PDF if some of you haven't got a chance to read the details before.

Now we would like to ask everyone's input on two items:

**1) COVID-19 related side projects: please send paragraphs about any ideas you might be able to rapidly working on through the CREID collaborations re. COVID-19 for potential extra fundings from NIAID (by Monday, July 21).** NIAID asked about this, and Peter is talking to the program officers on Tuesday morning, so the goal is to get ~10 ideas to propose to them, to find out what they are interested to fund. Attached in the Word document are some ideas we captured from previous calls with Linfa, Tom, and Supaporn, please feel free to add on and/or flash out any of the bullet points.

**2) Working Groups: please volunteer or recommend one person from your team on the Working Groups in the attached Excel sheet (by Wednesday, July 23).** These Working Groups have been identified by DMID and the Coordinating Center as the initial Groups to establish as the Network gets up and running. The Working Groups are expected to meet monthly, and 4 of them will be convened initially if possible, in August, and will meet again in September during the NIAID-facilitated Network kickoff meeting. Each center will appoint one person for each Working Group, but we are considering a second appointment as well in case of the schedule conflicts.

Apologies for this short notice. Please let me know if you have any questions or any further information I can provide. Look forward to hearing from you.

Best regards,  
Hongying

Dear All,

During the call today, we would like to talk about the CREID Working Groups.

Please see below a brief description of the functions for each to help inform your appointments. The attached Excel file provides additional information on the Working Groups.

**Working Groups:** These Working Groups have been identified by DMID and the Coordinating Center as the initial Groups to establish as the Network gets up and running. The Working Groups are expected to meet monthly, and 4 of them will be convened initially if possible, in August, and will meet again in September during the NIAID-facilitated Network kickoff meeting. Research Centers can appoint one person for each Working Group but can choose not to make appointments for all Working Groups.

Look forward to speaking with you soon.

Kind regards,  
Hongying

24 **Abstract**

25 Nipah virus (NiV) is an emerging bat-borne zoonotic virus with pandemic potential that causes near-  
26 annual outbreaks of fatal encephalitis in South Asia – one of the most populous regions on Earth. In  
27 Bangladesh, infection occurs when people drink date palm sap contaminated with bat excreta, but a  
28 recent outbreak in India involved a different, but yet unknown, route of spillover. Outbreaks are  
29 sporadic and the influence of viral dynamics in bats over their temporal and spatial distribution poorly  
30 understood. We analyzed data on host ecology, molecular epidemiology, serological dynamics, and viral  
31 genetics to characterize spatio-temporal patterns of NiV dynamics in its wildlife reservoir, *Pteropus*  
32 *medius* bats, in Bangladesh. We found that NiV transmission occurred throughout the country and  
33 throughout the year. Model results indicated that local transmission dynamics were driven by density-  
34 dependent transmission, acquired immunity which is lost over time, and recrudescence. Increased  
35 transmission followed multi-year periods of declining seroprevalence likely due to bat population  
36 turnover and individual loss of humoral immunity. Individual bats had smaller host ranges than other  
37 *Pteropus* spp., although movement data and the discovery of a Malaysia-clade NiV strain in eastern  
38 Bangladesh suggest connectivity with bats east of Bangladesh. We conclude that discrete multi-annual  
39 local epidemics in bat populations contribute to the sporadic nature of Nipah virus outbreaks in South  
40 Asia. At the same time, the broad spatial and temporal extent of NiV transmission, including the recent  
41 outbreak in Kerala, India, highlights the continued risk of spillover to humans wherever they may  
42 interact with pteropid bats, and the importance of improving Nipah virus surveillance throughout  
43 *Pteropus*'s range.

44

45 **Keywords:** bats, henipavirus, Nipah virus, *Pteropus medius*, *Pteropus giganteus*, satellite telemetry,  
46 viral phylogeny, disease dynamics, modeling

47

48 **Introduction.**

49 Outbreaks of zoonotic diseases are often sporadic, rare events that are inherently difficult to predict,  
50 but can have devastating consequences (1). Several emerging viral zoonoses with wildlife reservoirs  
51 have become pandemics, including HIV/AIDS, SARS coronavirus, and 1918 Pandemic Influenza H1N1 (2-  
52 4). Bats are important hosts for many zoonotic viruses (5) including Ebola virus, SARS-CoV, and Nipah  
53 virus, but the ecological drivers and transmission dynamics of these viruses in their reservoir hosts are  
54 poorly understood (6-10). A better understanding of the transmission dynamics of zoonotic pathogens in  
55 their natural reservoirs may help anticipate and prevent outbreaks (9, 11).

56 Nipah virus (NiV) is an emerging zoonotic paramyxovirus (genus *Henipavirus*) that has  
57 repeatedly spilled over from bats to cause outbreaks in people and livestock with high case fatality rates  
58 across a broad geographic range, making it a significant threat to global health. It has caused repeated  
59 outbreaks in Bangladesh and India, with a mean case fatality rate greater than 70% (12-14). A single  
60 genus of frugivorous bats (*Pteropus*) appears to be the main reservoir for henipaviruses throughout Asia  
61 and Australia (15-19), including *Pteropus medius* (formerly *Pteropus giganteus* (20)) in Bangladesh and  
62 India (21-24). Nipah virus has several characteristics that make it a significant threat to human and  
63 animal health (25-27): 1) its bat reservoir hosts are widely distributed throughout Asia, overlapping  
64 dense human and livestock populations, providing broad opportunity to cause outbreaks; 2) it can be  
65 transmitted directly to humans by bats or via domestic animals; 3) it can be transmitted from person to  
66 person; 4) spillover has repeatedly occurred in highly populous and internationally connected regions,  
67 giving it pandemic potential; 5) it is associated with high mortality rates in people; and 6) there are  
68 currently no commercially available vaccines or therapeutics. As a result, the World Health Organization  
69 has listed Nipah virus among the ten most significant threats to global health (28). To date, human  
70 Nipah virus infections have been identified in India, Bangladesh, Malaysia, Singapore, and the  
71 Philippines (12, 22, 29-31). In May 2018, an outbreak of Nipah virus encephalitis associated with a 91%  
72 mortality rate, occurred in a new location - Kerala, India - more than 1,200 km southwest of previous  
73 Indian and Bangladeshi outbreaks (32). A single case was subsequently reported in Kerala in 2019, and  
74 while local *P. medius* populations have been implicated as the local source of infection, the route of  
75 spillover in both instances remains unknown (32, 33).

76 In Malaysia and Bangladesh, consumption of cultivated food resources contaminated with bat  
77 excreta such as mangoes in Malaysia and date palm sap in Bangladesh and northeastern India have been  
78 identified as the predominant cause of spillover to pigs and people respectively (34). Human outbreaks

79 occur almost annually in Bangladesh and the seasonal timing (November-April) and spatial distribution  
80 of outbreaks coincide with patterns of raw date palm sap consumption in a region termed the “Nipah  
81 belt” (35). However, there is variability in the number of spillover events and magnitude of the  
82 outbreaks that occur each year (36), and spillover has occasionally occurred outside the predominant  
83 season and region of date-palm sap consumption (37). Further, date palm sap harvesting and  
84 consumption also occurs in eastern Bangladesh, yet no human outbreaks have been reported, while  
85 date palm sap is not cultivated in Kerala at all, suggesting an alternate route of spillover (35). While the  
86 full range of mechanisms for zoonotic transmission remain unknown, so too are the underlying viral  
87 infection dynamics in bats and the extent of genetic diversity within the virus – each of which may  
88 influence the timing, location and epidemiology of human outbreaks (35).

89           Previous research on the transmission dynamics of Nipah and Hendra viruses in *Pteropus* spp.  
90 bats have produced mixed and sometimes contradictory findings. Nipah virus, like Ebola, Marburg,  
91 Hendra and some bat coronaviruses, might be hypothesized to have seasonal spikes in infection that  
92 coincide with annual or semi-annual synchronous birth pulses (15, 38-44). Seasonal periods of Nipah  
93 virus shedding were observed in *P. lylei* in Thailand and seasonal spikes in NiV (or a related henipavirus)  
94 seroprevalence coinciding with pregnancy periods were observed in *Eidolon dupreanum* in Madagascar  
95 (45, 46), but not in *P. vampyrus* or *P. hypomelanus* in Peninsular Malaysia (19). Hendra virus prevalence  
96 in Australian pteropid bats has shown multi-year inter-epidemic periods where very little virus can be  
97 detected, followed by periods of increased viral shedding, suggesting that viral dynamics are not annual  
98 (47-49). It has been hypothesized that multi-year periodicity in infection henipavirus dynamics could  
99 arise from a build-up and waning of herd immunity in the reservoir host, with re-introduction of virus via  
100 immigration or recrudescence or viral persistence (10, 50-52). Some pteropid bat species are migratory  
101 and interconnected colonies form a metapopulation which could allow for viral re-introductions (9, 19,  
102 53, 54). In addition, NiV recrudescence has been observed in wild-caught *P. vampyrus* and *Eidolon*  
103 *helvum* and either of these phenomena could allow it to persist regionally during periods of high local  
104 immunity (55). However, no study has yet shown evidence in open, free-ranging bat populations that  
105 favors one or the other hypothesis in driving NiV transmission dynamics.

106           The goal of the current study was to understand the distribution and drivers of NiV infection  
107 dynamics and NiV diversity in *Pteropus medius* in Bangladesh to provide new insight into human  
108 outbreak patterns. We examined spatial, temporal and demographic variation in serological dynamics  
109 and viral shedding in bats over a six-year period to determine the spatio-temporal drivers and dynamics

110 of virus transmission. We also studied movement patterns of individual bats and analyzed NiV  
111 phylogenetics to understand patterns of spatial mixing and virus strain diversity.

112

## 113 **Results**

114 *Comparative Nipah virus prevalence study in bats inside and outside the Nipah Belt and concurrent*  
115 *longitudinal bat study inside the Nipah Belt (2006-2012)*

116 We caught and tested 883 *P. medius* (~100 per district) from eight different districts across  
117 Bangladesh. We detected anti-Nipah IgG antibodies in all colonies (**Figure 1**). Seroprevalence varied by  
118 location ( $\chi^2 = 55.61$ ,  $p < .001$ ), but there was no statistical difference between seroprevalence in bats  
119 inside the Nipah Belt and outside. In all locations except Tangail, adult seroprevalence exceeded  
120 juvenile. Viral detection in individuals was rare. Overall, we detected NiV RNA in 11 individuals as well as  
121 3 pooled oropharyngeal samples (representing 5 bats, but which could not be resolved to an individual)  
122 and 21 pooled urine samples ("roost urine") collected from tarps underneath the roost (**Table 1**). We  
123 detected viral RNA in individual bats in Faridpur and Rajbari and from pooled samples from Thakurgaon  
124 and roost urine samples from Comilla. Of the 10 PCR positive individuals, three had detectable IgG  
125 antibodies (**Table S1**). We also detected virus in pooled urine collected from tarps placed below bats at  
126 roosts associated with human outbreaks in Bhanga and Joypurhat. The viral prevalence in Rajbari in  
127 January 2006 was 3.8% (95% CI: 0% -11%; n=78). In Faridpur, where we also conducted an intensive  
128 longitudinal study (see below), viral prevalence estimates ranged from 0% to 3% (95% CI: 0%-10%;  
129 n=100 at each of 18 sampling times) (**Table 1**). Nipah virus RNA was detected in individual bats from  
130 inside (Rajbari, Thakurgaon, and Faridpur) and outside (Comilla) the Nipah Belt. We detected viral RNA  
131 in bats both with and without detectable IgG antibodies (**Table S1**). Urine samples provided the highest  
132 NiV detection rate. Detection rates in individual bats by sample type were: urine/urogenital swab = 4%  
133 (n=2,126); oropharyngeal swab 3% (n=2,088); and rectal swab = 1.3% (n=79). The estimated detection  
134 rate from pooled urine samples across the entire study was 2.7% (+/- 1.6%; n=829).

135

136 *Factors associated with NiV IgG serostatus in P. medius*

137 Among adult and juvenile bats sampled in the aforementioned the cross-sectional study from  
138 which we got blood samples (844 of 883), seropositivity was 2.4 times more likely among adults than  
139 juveniles, and 1.6 times more likely among males than females (**Figure 2**). Among females, seropositivity  
140 was higher in pup-carrying (4 times) and pregnant (1.5 times) individuals. Weight or forearm length did  
141 not consistently correlate with seropositivity, however, body condition (an assessment of pectoral

142 muscle mass by palpation) was significantly negatively correlated (Poor/Fair body condition OR = 0.69)  
143 with serostatus. Finally, serostatus was strongly correlated in mother-pup pairs, with 71/80 pairs (89%)  
144 having matching status.

145

#### 146 *NiV serodynamics over time in a population of P. medius, Faridpur district (2006-2012)*

147 We conducted an intensive longitudinal study of NiV serology in a population of bats in the  
148 Faridpur district and used flexible generalized additive models (GAMs) to characterize changes over  
149 time. There were significant fluctuations in adult (>24 mo.) and juvenile (6 – 24 mo.) seroprevalence  
150 over the six-year study period (**Figure 3A**). Juvenile seroprevalence ranged from 0% to 44% (95%CI 37%-  
151 51%), and decreased over the first year of life for bats born in each year (“yearlings”), consistent with  
152 loss of maternal antibodies in juveniles. A more pronounced decrease occurred from mid-October to  
153 mid-December. However, the GAM indicating this had only marginal better fit ( $\Delta AIC < 1$ ), than one with  
154 a linear decrease over the whole year (**Figure 3B**). The effect of birth cohort was significant on overall  
155 seroprevalence.

156 Adult seroprevalence ranged from 31% (95% CI: 20%-46%) to 82% (95% CI: 77%-87%) and went  
157 through three periods of significant decrease then increase over the course of the study (**Figure 3A**). We  
158 found no evidence of regular seasonal fluctuations; a GAM with annual cyclic terms fit worse than one  
159 without ( $\Delta AIC > 10$ ). Viral RNA detections occurred in periods of increasing, decreasing, and stable  
160 seroprevalence.

161 We fitted a series of age-stratified mechanistic models to examine different biological processes  
162 influencing serodynamics, including density- vs. frequency-dependent transmission, recrudescence,  
163 immigration of infected individuals, and seroreversion (loss of antibodies) in both juveniles and adults  
164 (**Figure 4**). We included annual, synchronous birthing, which we observed occurs between March and  
165 April. We assumed that pups weaned from their dams at 3 months, becoming independent flyers, but  
166 that maternal antibodies waned after 6 months at which point we had pups transition into the  
167 “juvenile” class (56, 57). We assumed that juveniles became sexually mature at 24 mo., and entered the  
168 “adult” class based on other pteropid species(43, 56, 58). Density-dependent models were a far better  
169 fit to the data than frequency-dependent models (difference in log-likelihood 10.0;  $\Delta AIC = 20.0$ ),  
170 suggesting that movements of bats and fluctuations in colony size alter spatio-temporal variation in the  
171 risk of NiV epidemic spillover to humans. In this colony (Domrakhandi/Khaderdi) during the period of  
172 sampling, the roost population declined from approximately 300 bats to 185, which decreased  
173 transmission. In the six-year study period, the number of infected bats increased when the

174 seroprevalence of adults fell below 72% (when bat counts were highest - in 2006) and 52% (when bat  
175 counts were lowest).  $R_0$  in adult bats was estimated to decrease from 3.5 to 2.1 as the number of bats in  
176 the colony decreased. Serodynamics in juveniles were strongly driven by inheritance and loss of  
177 maternal antibodies. The rate of loss of maternal antibodies was 17.6 weeks (95% CI: 13.7-25.0), which  
178 was much quicker than the loss of antibodies in adults (290.8 weeks, 95% CI: 245.0-476.4) (**Table S2**).  
179 Finally, models with recrudescence fit the data better than models without recrudescence (**Table S2**;  
180 difference in log-likelihood 32.6;  $\Delta$ AIC = 30.6), and models with recrudescence fit the data better than  
181 models with immigration ( $\Delta$ AIC = 3.76).

182

### 183 *Mark-recapture and seroconversion/seroreversion*

184 A total of 2,345 bats from the Faridpur/Rajbari region were sampled and microchipped between  
185 2007 and 2012. There were 56 recapture events (**Table S3**). Thirty-one bats were recaptured at a roost  
186 other than the original capture location. This network of roosts or “roost complex” formed a polygon  
187 covering approximately 80 Km<sup>2</sup> and included 15 roosts sampled during the longitudinal study (**Figure**  
188 **S2A and S2B**). Ten instances of seroconversion (change from IgG negative to IgG positive) and nine  
189 instances of seroreversion (positive to negative) were observed (**Table S3**). The mean time between  
190 positive and negative tests in *adults* (excluding juveniles with maternal antibodies) was 588 days (n=6)  
191 (range: 124-1,082 days).

192

### 193 *Homerange and inter-colony connectivity analysis*

194 Home range analysis of satellite telemetry data from 14 bats (**Table S4**) showed that the  
195 majority of bats roosted within 10 km of where the bats were originally collared, in the Faridpur (Nipah  
196 belt) colony, and within 7 km from where the bats in the Cox’s Bazaar colony were originally collared  
197 (315km east of Faridpur). The average foraging radius was 18.7 km (s.d. 21.5 km) for the Faridpur bats  
198 and 10.8 km (s.d. 11.9 km) for the Cox’s Bazaar bats (**Figure S2**). Homerange analysis suggests that bats  
199 in Faridpur and Cox’s Bazar would have a <5% probability of intermingling (**Figure 5**). Homerange size  
200 was significantly larger during the wet season than the dry season (2,746 km<sup>2</sup> vs. 618 km<sup>2</sup>) (**Figures S3 &**  
201 **S4**).

202

### 203 *NiV phylogenetic analysis.*

204 Phylogenetic analysis of NiV sequences from a 224nt section of the N gene (nt position 1290-  
205 1509 [position ref [gb|FJ513078.1](#) India]) suggests that strains from both India and Malaysia clades are

206 present in Bangladesh bats (**Figure 6**). This finding is supported by an analysis of near-whole N gene  
207 sequences (~1720 nt) from bats, pigs, and humans, including those from a subset of *P. medius* from this  
208 and a more recent study by our group (**Figure S5**) (59). Eleven 224nt N gene sequences obtained from  
209 bats between 2006 and 2012 (all from the Faridpur population) were identical. Overall, the N gene  
210 sequences identified from the Faridpur, Rajbari and Bhanga colonies between 2006 and 2011 had  
211 98.21%-100% shared nucleotide identity. Sequences from Rajbari district obtained five years apart  
212 (January 2006 and January 2011) had only a single nucleotide difference resulting in a synonymous  
213 substitution (G to A) at position 1304, which was found in four other bat NiV sequences from this study,  
214 as well as in the NiV isolate from *P. vampyrus* in Malaysia. Five Human NiV N gene sequences from  
215 various locations within the Nipah belt over the same time period as our bat study show more  
216 nucleotide diversity than those from the Faridpur *P. medius* population. Human sequences throughout  
217 Bangladesh and from Kerala, India, all nested within the diversity found in *P. medius* (**Figure 6**). By  
218 contrast, the sequences found in *P. medius* from Comilla, a location 150Km to the east of Faridpur,  
219 showed 80.8%-82.59% shared nucleotide identity with sequences from *P. medius* in Faridpur and  
220 clustered within the Malaysia group of NiV sequences. The two Comilla sequences were identical to  
221 each other, and had up to 87.95% shared nucleotide identity to sequences from *P. lylei* in Thailand.  
222 *Pteropus lylei* bats in Thailand were also found to carry NiV strains from both Malaysia and Bangladesh  
223 groups.

224

## 225 **Discussion**

226 Our study provides new insights into Nipah virus transmission dynamics, genetics and host ecology.  
227 Previous studies from Bangladesh suggested that human NiV outbreaks occur only within a defined  
228 region in western Bangladesh, termed the “Nipah belt,” and during a defined season (Nov-Apr), which  
229 generated the question of whether that observation was entirely due to date palm sap consumption, or  
230 whether ecological factors such as the distribution and timing of bat viral infection also influenced the  
231 timing and location of human cases (13, 35, 60). We undertook the most geographically extensive survey  
232 of *Pteropus medius* in Bangladesh to date. This study was designed to better understand Nipah virus  
233 infection patterns in its putative reservoir, *Pteropus medius*, which is common in Bangladesh and  
234 throughout the Indian subcontinent (21, 22, 56).

235 Overall, our findings suggest viral circulation is not limited to the Nipah belt, but that NiV  
236 transmission occurs in bat populations throughout the country. We observed that virus can be shed at  
237 any time of year, and that viral dynamics are not annual or seasonal, but driven by demographic and

238 immunological factors. Analysis of serological data from our longitudinal study suggests that the  
239 underlying mechanism driving the timing of NiV transmission in bats is the waning of herd immunity in  
240 discrete bat populations allowing heightened viral transmission.

241           A number of mechanisms have been proposed for the maintenance of acute viral infections in  
242 bat metapopulations, including synchronous birthing and subsequent loss of maternal antibodies (10,  
243 39, 41), lowered immunity within pregnant females due to stress, nutritional stress and other factors  
244 (43) immigration of infected individuals from other colonies (53, 61, 62), and recrudescence within  
245 previously-infected individuals (10, 55, 63). Our modeling indicates that NiV is primarily driven by  
246 density-dependent transmission dynamics among adult bats, with cycles of higher seroprevalence that  
247 would dampen intra-colony transmission followed by waning of antibody titers within individuals and at  
248 a population level. Waning humoral immunity against Nipah virus is a consistent feature of henipavirus  
249 studies in African pteropodid bats (52, 64). Our recapture data has provided the first reported evidence  
250 of the loss of detectable NiV IgG antibodies in recaptured individual free-ranging bats, which supports  
251 our observation of population level waning immunity. The consistently lower and decreasing  
252 seroprevalence that we observed in juveniles suggests that they lose maternal antibodies over their first  
253 year, and likely in the first 6-7 months, consistent with other studies of maternal antibodies against  
254 henipaviruses in pteropodid bats (43, 52, 57, 65). However, our analysis refutes the hypothesis that  
255 seasonal pulses of these new seronegative individuals are the primary driver of new outbreaks in adults  
256 (41).

257           Our model outputs suggest that spikes in viral transmission occur after virus is reintroduced into  
258 the colony – most likely via recrudescence, though immigration is another possible factor in  
259 maintenance. Recrudescence would presumably occur in individuals with antibody titers that have  
260 waned below a neutralizing titer, if loss of humoral immunity following a primary infection is sufficient  
261 to allow a second infection. Recrudescence of henipavirus infection has been observed for NiV in captive  
262 *P. vampyrus* (55), for henipavirus in captive *E. helvum* (52, 66), and has also been observed in humans  
263 infected by NiV (67) and Hendra virus (68). It is difficult to know from serology alone whether wild-  
264 caught seronegative bats had been previously infected. Experimental infection of naïve and previously  
265 infected *Pteropus medius* that have sero-reverted would provide a better understanding of how  
266 humoral immunity influences individual susceptibility to infection, and inform dynamics models  
267 attempting to explain viral maintenance within bat populations (64).

268           Our longitudinal study is limited in that it may not necessarily reflect temporal infection  
269 dynamics in all bat populations across Bangladesh. Our roost count data and recapture data from

270 microchipped bats showed how roost sizes can fluctuate, and local roost shifting can occur. The  
271 observation of individual bats using multiple roost sites suggests that changes in roost count, which our  
272 models suggest impacts transmission dynamics, could reflect local shifting rather than true fluctuations  
273 in population due to wider dispersal – a limitation in our model parameterization where the latter  
274 interpretation was used.

275           Understanding how bat populations connect across landscapes is also important for  
276 understanding viral maintenance, and studying local and migratory bat movements can provide  
277 important ecological information related to viral transmission, including how bats move between  
278 different colonies (53). Our satellite telemetry data suggest that *P. medius* exists as a metapopulation,  
279 like other pteropid species (10, 62), though *Pteropus medius* appear to travel shorter distances and  
280 remain within a smaller home range (321.46km<sup>2</sup> and 2,865.27km<sup>2</sup> for two groups) compared to *P.*  
281 *vampyrus* in Malaysia (64,000 km<sup>2</sup> and 128,000 km<sup>2</sup>) and *Acerodon jubatus* in the Philippines which are  
282 similarly sized fruit bats (53, 69). Pteropodid bat migration is primarily driven by seasonal food resource  
283 availability (54, 70-72). In Bangladesh, *P. medius* prefer to roost in human-dominated environments in  
284 highly fragmented forests (73). The anthropogenic colonization and conversion of land over recent  
285 human history has likely led to increased food availability for *P. medius* and reduced necessity for long-  
286 distance migration (34). This may reflect a similar adaptation to anthropogenic food resources as  
287 observed over the last few decades in Australian *Pteropus* species (62). Genetic analysis of *P. medius*  
288 across Bangladesh has shown that the population is panmictic – that historically, there has been  
289 interbreeding among populations across Bangladesh(74). If movements are generally more localized, as  
290 suggested by telemetry, then less connectivity among flying fox populations may influence Nipah  
291 transmission by creating longer inter-epidemic periods and larger amplitude fluctuations in population  
292 level immunity compared to more migratory species (62).

293           Bat movement and population connectivity may also influence the genetic diversity of Nipah  
294 virus found in different locations, and genotypic variation has been associated with different clinical  
295 outcomes in people. While the overall strain diversity among Nipah virus has not been well  
296 characterized due to a dearth of isolates, two distinct NiV clades have been described: A Bangladesh  
297 clade, which includes sequences identified in India and Bangladesh; and a Malaysian clade, which  
298 comprises sequences from Malaysia, Cambodia, The Philippines and Thailand (31, 59, 75). Strains of NiV  
299 from these two clades are associated with differences in pathogenesis, epidemiological and clinical  
300 profiles in humans and animal models and observed shedding patterns in bats (45, 76-80). Phenotypic  
301 variation in Nipah virus could influence observed human outbreak patterns by altering transmission to,

302 or pathogenesis in, humans, and the likelihood of smaller outbreaks being identified or reported (81).  
303 Human-to-human NiV transmission via contact with respiratory and other secretions has been regularly  
304 observed in Bangladesh and India, including the recent 2018 outbreak in Kerala (12, 82, 83), whereas  
305 transmission among people was not a common feature of the Malaysia outbreak, despite close contact  
306 between cases and health care providers (84, 85). Nipah virus cases in Bangladesh have shown more  
307 strain diversity than in the Malaysia outbreak (86).

308         Until now, there have been very few Nipah sequences obtained from *P. medius*. We found that  
309 Nipah N-gene sequence from bats from the Faridpur population were nearly identical over time,  
310 compared to variation in N-gene sequences from bats and humans from other locations observed over  
311 the same time period (2006-2010). This suggests that there may be locally prevalent and stable NiV  
312 genotypes that persist within bat colonies. Human NiV genotype diversity is likely a reflection of the  
313 relative diversity of the NiV strains in the local bats that seed outbreaks (9). This is also supported by  
314 viral sequences obtained from human and bats associated with the 2018 NiV outbreak in Kerala, India,  
315 where human NiV sequences were most closely related to local *P. medius* sequences (87). We found a  
316 significantly divergent NiV strain in Comilla, which clustered within the Malaysia NiV clade, suggesting  
317 that strains from both clades are circulating in bats in Bangladesh.

318         Connectivity of pteropid bats in Bangladesh with those in Southeast Asia could explain the  
319 observed strain diversity in our study. Historical interbreeding of *P. medius* with pteropid species found  
320 in Myanmar, Thailand, and Malaysia and our telemetry findings showing bats are capable of flying  
321 hundreds of kilometers, could explain our discovery of a Malaysia clade NiV sequence in bats from  
322 Comilla (74). NiV Bangladesh strains have also been found in *P. lylei* in Thailand (88). The N gene of the  
323 Comilla NiV strain differs from those reported from bats in the Nipah belt by 20%, whereas NiV Malaysia  
324 and NiV Bangladesh differ by only 6-9% and are associated with different clinical profiles. Whole  
325 genome sequence (which could not be obtained) would have allowed for better characterization of the  
326 Comilla strain, but the N gene is generally conserved relative to other genes, and suggests the rest of the  
327 genome may also be highly divergent. It is therefore plausible that the clinical profile of a 20% divergent  
328 NiV strain differs significantly from known strains. Further studies linking viral genotype to clinical  
329 phenotype would provide insight into the implications of strain diversity in bats for human outbreaks.

330         Finally, our study sheds light on the sporadic nature of NiV outbreaks with multi-year inter-  
331 epidemic periods in South Asia. Firstly, PCR results show that overall NiV incidence in *P. medius* is low,  
332 consistent with previous studies of Hendra and Nipah virus (43, 48, 89, 90). The data and our modeling  
333 suggests that PCR-positive samples are only likely to be identified during viral transmission spikes after

334 periodic reintroduction into populations that have become susceptible through waning population-level  
335 immunity (10). Vial detection in bats has also coincided with human outbreaks (59, 87). This is likely a  
336 rare or at least sporadic event. In the current study, observed seroprevalence patterns and the fitted  
337 model suggest that three periods of transmission occurred over the 6 years of sampling, each of which  
338 followed periods of low adult seroprevalence, though not all measurements of low seroprevalence were  
339 followed by outbreaks. We detected NiV RNA during periods of both increasing and decreasing  
340 seroprevalence, supporting the fitted model which suggested that shedding can occur at low levels in  
341 bats even in periods without sustained transmission. Our observation that not every instance of rising  
342 seroprevalence resulted in detectable viral shedding suggests that not all episodes of viral circulation in  
343 bats are of equal magnitude, and that other factors (e.g. variation in human-bat contact and exposure)  
344 may affect likelihood of spillover. Together, this evidence suggests that outbreaks can occur in bats  
345 when the population falls below a protective threshold of immunity in any season, but variability in how  
346 many bats become infected may impact the likelihood of spillover to humans, assuming a route of  
347 transmission is available. This could explain variation in the number of human outbreaks (e.g. spillover  
348 events) from year-to year in Bangladesh. Thus, the timing of multiple factors involved in driving  
349 transmission dynamics needs to align for intra-colony NiV transmission events and further align with  
350 human behavior and availability of a route of spillover for human outbreaks to occur, as previously  
351 hypothesized (91). This, and the seasonality and specific geography of date palm sap consumption in  
352 Bangladesh likely explains the somewhat sporadic nature of human outbreaks in the region, albeit that  
353 when spillover occurs, it is within the well-defined date palm sap collection season and geographic zone  
354 (35).

355         These findings suggest that Nipah virus outbreaks in other regions of Bangladesh where  
356 *Pteropus* spp. bats occur, are also likely to be sporadic and rare, leading to under-reporting or a lack of  
357 reporting, particularly given that human neurologic symptoms are similar to other common infections,  
358 e.g. Japanese encephalitis, malaria, measles (92). Understanding whether some NiV strains are capable  
359 of causing mild or asymptomatic cases will provide important insights about why outbreaks may not  
360 have been detected in areas such as eastern Bangladesh (or other parts of Asia), where host, virus, and  
361 potential routes of spillover exist. Mild or asymptomatic cases would be unlikely to be detected by  
362 current surveillance systems and it's possible that cryptic spillovers have occurred in Bangladesh, where  
363 about half of all outbreaks between 2007 and 2014 were unreported (93). Our work and other reports  
364 suggest that Nipah virus transmission is possible wherever *Pteropus* spp. bats and humans live in close  
365 association and at any time of year, provided there is an available route of transmission. The 2018 and

366 2019 spillover events in Kerala, India, which were linked to local *P. medius* colonies and which occurred  
367 in an area that does not cultivate date palm sap, further emphasize this point.

368 Identifying areas where high risk interfaces exist between pteropid bats and people, throughout  
369 their range, will be important for monitoring Nipah spillover events and quickly responding to  
370 outbreaks, as well as establishing interventions to prevent spillover. Raising awareness of the potential  
371 for contaminated food to be a route of Nipah virus transmission and in protecting food resources to  
372 limit human or livestock exposure, may be effective in reducing the risk of a more transmissible strain of  
373 Nipah virus from emerging and causing an epidemic with significant human and animal mortality.

374

## 375 **Methods**

376 The study period was between January 2006 and November 2012. The study was conducted under Tufts  
377 University IACUC protocol #G929-07. Locations were selected based on whether the district had any  
378 previously recorded human NiV encephalitis clusters at the time of this study and was therefore inside  
379 the Nipah Belt (e.g. Rajbari, Tangail, Thakurgaon, and Kushtia) or whether they had not and were  
380 outside the Nipah Belt (e.g. Comilla, Khulna, Sylhet, and Chittagong). The Thakurgaon study was  
381 conducted as part of an NiV outbreak investigation, and coincided with ongoing human transmission  
382 (94). Between 2006-2012, three different studies of *Pteropus medius*, with similar bat sampling  
383 protocols were performed: 1) a cross-sectional spatial study with a single sampling event in each of the  
384 eight locations listed above; 2) a longitudinal study of a Faripur bat colony with repeated sampling  
385 approximately every 3 months from July 2007 to November 2012; and 3) a longitudinal study of the  
386 Rajbari colony with repeated sampling at a monthly interval between 12 month period between April  
387 2010 and May 2011. Opportunistic sampling of *Pteropus medius* was also performed during this time  
388 period during NiV outbreak investigations [Bangha, Faridpur (Feb 2010), Joypurhat (Jan 2012), Rajbari  
389 (Dec 2009), West Algi, Faridpur (Jan 2010)]. These data are included here because NiV testing of bat  
390 samples during these investigations supported the aims of the study. Bats were captured using mist nets  
391 at locations within eight different districts across Bangladesh between January 2006 and December  
392 2012 (**Figure 1**).

393

### 394 *Capture and sample collection*

395 For the country-wide cross-sectional and Faridpur longitudinal study, on average, 100 bats were  
396 sampled at each sampling event, which lasted 7-10 days. This sample size allowed us to detect at least  
397 one exposed bat (IgG antibody-positive) given a seroprevalence of 10% with 95% confidence. Bats were  
398 captured using a custom made mist net of approximately 10 m x 15 m suspended between bamboo  
399 poles which were mounted atop trees close to the target bat roost. Catching occurred between 11 pm  
400 and 5 am as bats returned from foraging. To minimize bat stress and chance of injury, nets were  
401 continuously monitored and each bat was extracted from the net immediately after entanglement.  
402 Personal protective equipment was worn during capture and sampling, which included dedicated long-  
403 sleeve outerwear or Tyvek suits, P100 respirators (3M, USA), safety glasses, nitrile gloves, and leather  
404 welding gloves for bat restraint. Bats were placed into cotton pillow cases and held for a maximum of 6  
405 hours before being released at the site of capture. Bats were sampled at the site of capture using a field  
406 lab setup. Bats were anesthetized using isoflurane gas (95) and blood, urine, oropharyngeal swabs, and

407 wing membrane biopsies (for genetic studies) were collected. For some sampling periods, rectal swabs  
408 were collected but due to resource constraints, these samples were deemed to likely be lower yield than  
409 saliva and urine for NiV, and were discontinued during the study. For each bat sampled we recorded  
410 age, weight, sex, physiologic and reproductive status, and morphometric measurements as described  
411 previously (21). Bats were classified as either juveniles (approximately four to six months - the age by  
412 which most pups are weaned) to two years old (the age when most *Pteropus* species reach sexual  
413 maturity) or adults (sexually mature) based on body size and the presence of secondary sexual  
414 characteristics, pregnancy, or lactation - indicating reproductive maturity (21, 96).

415 Up to 3.0 mL of blood were collected from the brachial vein and placed into serum tubes with  
416 serum clot activator (Vacutainer, USA). Blood tubes were stored vertically on ice packs in a cold box  
417 and serum was allowed to separate overnight. Serum was drawn from the tube after 24 hours and  
418 placed in a screw-top cryovial (Corning, USA) and stored in a liquid nitrogen dewar (Princeton  
419 Cryogenics, NJ, USA). Sterile pediatric swabs with polyester tips and aluminum shafts were used to  
420 collect urogenital and rectal samples, and larger polyester swabs with plastic shafts (Fisher, USA) were  
421 used to collect oropharyngeal samples. All swabs were collected in duplicate, with one set being placed  
422 individually in cryotubes containing lysis buffer (either tri-reagent or NucliSENS Lysis buffer,  
423 BIOMERIEUX, France) and the second set in viral transport medium. All tubes were stored in liquid  
424 nitrogen in the field then transferred to a -80C freezer.

425 During each sampling event, pooled urine samples were collected beneath bat roosts using  
426 polyethylene sheets (2' x 3') distributed evenly under the colony between 3 am and 6 am. Urine was  
427 collected from each sheet either using a sterile swab to soak up droplets, or a sterile disposable pipette.  
428 Swabs or syringed urine from a single sheet were combined to represent a pooled sample. Each urine  
429 sample was divided in half and aliquoted into lysis buffer or VTM at an approximate ratio of one part  
430 sample to two parts preservative.

431

#### 432 *Serological and molecular assays*

433 Sera from the cross-sectional survey were heat inactivated at 56°C for 30 minutes, as described  
434 (97) prior to shipment to the Center for Infection and Immunity at Columbia University (New York, USA)  
435 for analysis. Samples were screened for anti-NiV IgG antibodies using an enzyme linked immunosorbent  
436 assay (ELISA) as described in (21). Sera from the longitudinal studies were sent to the Australian Animal  
437 Health Laboratory and were gamma irradiated upon receipt. Because of the large sample size and  
438 development of a high throughput multiplex assay of comparable specificity and sensitivity, for these

439 samples we used a Luminex-based assay to detect anti-Nipah G IgG antibodies reactive to a purified NiV  
440 soluble G protein reagent (98, 99).

441 Total nucleic acids from swabs and urine samples were extracted and cDNA synthesized using  
442 Superscript III (Invitrogen) according to manufacturer's instructions. A nested RT-PCR and a real-time  
443 assay targeting the N gene were used to detect NiV RNA in samples (100). A RT-qPCR designed to detect  
444 the nucleocapsid gene of all known NiV isolates was also utilized (101). Oligonucleotide primers and  
445 probe were as described (101). Assays were performed using AgPath-ID One-StepRT-PCR Reagents  
446 (Thermofisher) with 250 nM probe, 50 nM forward and 900 nM reverse primers. Thermal cycling was  
447 45°C for 10 min, followed by 45 cycles of 95°C for 15 s and 60°C for 45 s. Cut-off values were cycle  
448 threshold ( $C_T$ )  $\leq 40$  for positive and  $CT \geq 45$  for negative. Results with  $C_T$  values between 40 and 45 were  
449 deemed indeterminate, i.e. not conclusively positive or negative. Samples with NiV RNA detected by real  
450 time PCR were confirmed by gel electrophoresis and product sequencing.

451 A subset of NiV-positive samples was processed by high-throughput sequencing (HTS) on the Ion  
452 Torrent PGM platform in order to obtain additional NiV genomic sequence. Libraries were prepared  
453 according to the manufacturer's instructions, and 1 million reads allocated per sample. HTS reads were  
454 aligned against host reference databases to remove host background using bowtie2 mapper, and host-  
455 subtracted reads primer trimmed and filtered based on quality, GC content and sequence complexity.  
456 The remaining reads were de novo assembled using Newbler (v2.6) and mapped to the full length NiV  
457 genome. Contigs and unique singletons were also subjected to homology search using MegaBlast  
458 against the GenBank nucleotide database, in case variance in parts of the genome precluded efficient  
459 mapping. From these data, N gene consensus sequences were constructed using Geneious v 7.1, and  
460 used for phylogenetic analyses.

461

#### 462 *Phylogenetic analysis*

463 All *P. medius* NiV sequences have been submitted to Genbank and accession numbers are  
464 included in **Figure 6**. Sequence alignments were constructed using ClustalW in Geneious Prime software  
465 (102). Phylogenetic trees of NiV N-gene sequences were constructed using Neighbor-Joining, Maximum-  
466 Likelihood algorithms and figures constructed in FigTree 1.4.2.

467

#### 468 *Satellite telemetry and homerange analysis*

469 We developed a collar system to attach 12g solar-powered Platform Terminal Transmitters (PTT)  
470 (Microwave Telemetry, Columbia, MD, USA) to adult bats using commercial nylon feline collars with the

471 buckle removed and 0-gauge nylon suture to attach the PTT to the collar and to fasten the collar around  
472 the bat's neck. Collars were fitted to the bat such that there was enough space to allow for normal neck  
473 movement and swallowing, but so that the collar would not slip over the head of the animal (**Figure S6**).  
474 PTTs were programmed with a duty cycle of 10 hours on and 48 hours off. Data was accessed via the  
475 Argos online data service (argos-system.org; France). A total of 14 collars were deployed as follows: Feb  
476 2009: 3 males, 3 females from a colony in Shuvarampur, Faridpur district; Feb 2011: 3 males, 2 females  
477 from the same colony; and April 2011 Cox's Bazaar, 3 bats from a colony in Cox's Bazaar, Chittagong  
478 district. Bats were selected based on size such that the total weight of the collar (~21g) was less than 3%  
479 of the bat's body mass (Table S3).

480 The individual telemetry dataset was combined for each region and its aggregate utilization  
481 distributions (UD) computed in R using package 'adehabitatHR' (103). Population-specific home range is  
482 represented by the \*95% area enclosure of its UD's volume. The volume of intersection between the  
483 colonies quantifies the extent of home range overlap. To evaluate the potential for contact with the  
484 Sylhet colony, we calculated the most likely distance moved ('mldm') for each sampled bat at Faridpur  
485 where the population was more intensively monitored. Movement distance was measured in kilometers  
486 with respect to a centroid location ( $\omega$ ) shared by the whole colony; assuming random spatial distribution  
487 in tracking rate, we estimated its kernel density function per individual and defined mldm as the mode.

488

#### 489 *Statistical approach – cross-sectional study*

490 We fit a full Bayesian generalized linear model with a logit link and a Bernoulli distribution to  
491 identify potential predictors which influenced a bat's serostatus. We included age, sex, age- and sex-  
492 normalized mass and forearm length, mass:forearm ratio, body condition, and whether the bat was  
493 pregnant, lactating, or carrying a pup. We included location of sampling a random effect nested within  
494 Nipah Belt or non-Nipah Belt regions. We fit the models and performed posterior predictive checks in R  
495 3.4.3 , using the **brms** and **rstan** packages.

496

#### 497 *Statistical approach – longitudinal study*

498 We fit binomial general additive models (GAMs) (104) to the time series of adult and juvenile  
499 seroprevalence in the longitudinal study. For juveniles, we modeled the birth cohort of bats as separate  
500 random effects in a pooled model of juveniles' dynamics starting from June of their birth year, June  
501 being the earliest month we sampled free-flying juveniles in any cohort. We determined the cohort year  
502 of juveniles by using cluster analysis to group individuals by weight, assuming those in the smallest

503 group were born in the year prior to sampling and those in the larger group were born the previous  
 504 year. 92% of juveniles captured were yearlings. For adults, we modeled dynamics of adults as a single  
 505 pool over the entire course of the study. We tested models with and without annual cyclic effects.

506 Where time series had significant temporal autocorrelation (adults only), we aggregated data by  
 507 week. We determined periods of significant increase in decrease as those where the 95% confidence  
 508 interval of the GAM prediction's derivative did not overlap zero. We fit the models and performed  
 509 checks in R 3.4.3, using the **mgcv** package.

510 We fit an age-structured (adult and juvenile) maternally immune (M)-susceptible (S)-infected (I)-  
 511 recovered (R) model with recrudescence (R to I) and loss of immunity (R to S) to the seroprevalence  
 512 data on a weekly timescale:

513

$$\frac{dS_J}{dt} = -S_J(\beta_{JJ}I_J + \beta_{AJ}I_A) - \mu_J S_J + bN_A(t-5)\frac{S_A}{N_A} - bN_A(t-52)\frac{S_J}{N_J}(1-\mu_J)^{52} + \lambda M_J$$

$$\frac{dI_J}{dt} = S_J(\beta_{JJ}I_J + \beta_{AJ}I_A) - \gamma I_J - bN_A(t-52)\frac{I_J}{N_J}(1-\mu_J)^{52}$$

$$\frac{dR_J}{dt} = \gamma I_J - \mu_J S_J - \mu_J R_J - bN_A(t-52)\frac{R_J}{N_J}(1-\mu_J)^{52}$$

514 
$$\frac{dM_J}{dt} = bA(t-5)\frac{R_A}{N_A} - \lambda M_J - \mu_J M_J - bN_A(t-52)\frac{R_A}{N_A}(1-\mu_J)^{52} \lambda^{52}$$

$$\frac{dS_A}{dt} = -S_A(\beta_{AA}I_A + \beta_{JA}I_J) - \mu_A S_A + \tau R_A + bN_A(t-52)\frac{S_J}{N_J}(1-\mu_J)^{52}$$

$$\frac{dI_A}{dt} = S_A(\beta_{AA}I_A + \beta_{JA}I_J) - \gamma I_A - \mu_A I_A + bN_A(t-52)\frac{I_J}{N_J}(1-\mu_J)^{52} + \Delta R_A$$

$$\frac{dR_A}{dt} = \gamma I_A - \mu_A R_A + bN_A(t-52)\frac{R_J}{N_J}(1-\mu_J)^{52} - \tau R_A - \Delta R_A$$

515 We included a class M for the density of juvenile bats with maternal antibodies to allow for the biological  
 516 possibility that maternal antibodies are lost at a much higher rate than antibodies acquired following  
 517 infection. The subscripts J refer to juveniles and A to adults,  $\beta$  is the transmission rate,  $\gamma$  is the recovery  
 518 rate,  $\mu$  is the mortality rate,  $\tau$  is the rate of loss of adult immunity,  $\lambda$  is the rate of loss of maternal  
 519 antibodies(57),  $\Delta$  is the adult recrudescence rate (R to I),  $b$  is the birth rate (pups join the juvenile  
 520 population after 5 weeks). Juveniles transition to adults after 52 weeks. We included terms for loss of  
 521 antibody in adults ( $\tau$ , S to R), and viral recrudescence ( $\Delta$ , R to I) based on previous studies on captive bats  
 522 that demonstrated the existence of these processes without providing enough data to characterize them  
 523 precisely (55, 65). We fit this deterministic model to the seroprevalence data by maximum likelihood,

524 which assumes that deviations from the model are due to observation error. We estimated the confidence  
525 intervals around maximum likelihood parameter estimates using likelihood profiles using the *profile*  
526 function in package *bbmle* in R v3.2.2.

527 We used model fitting and model comparison to examine the need for several of the biological  
528 processes in the model above that could influence NiV dynamics. First, we examined both density and  
529 frequency-dependent transmission by comparing the fit of the model above to one with transmission  
530 terms that have population size ( $N_A$  or  $N_j$ ) in the denominator. Second, we examined the confidence  
531 intervals of the parameters describing viral recrudescence, loss of antibodies in adult bats, and loss of  
532 antibodies in juvenile bats. If the confidence bounds for these parameters included zero, then these  
533 biological processes are not needed to explain the serological dynamics. Finally, we examined the  
534 confidence bounds for parameters describing the loss of maternal and non-maternal antibodies ( $\tau$  and  
535  $\lambda$ ), to determine if the rate of loss of these two types of immunity were different. We note that this  
536 model structure has similarities to a susceptible-infected-latently infected(L)-infected (SILI) model (if  
537 latently infected individuals are seropositive), but the model above differs in allowing for the possibility  
538 of individuals to transition from the R class back to the S class.

#### 539 *Code availability*

540 SIR model code written in R is available upon request.

541

#### 542 *Data availability*

543 All molecular sequences are available via Genbank. The datasets generated during and/or analyzed  
544 during the current study are available from the corresponding author on reasonable request.

545

546 **Acknowledgements:** We thank Pitu Biswas, Md. Sheikh Gofur, Abdul Hai, and Craig Smith for assistance  
547 in the field, Christopher Allen, and Parvize Hosseini for technical input, Eliza Choi; Yan-Ru Feng and  
548 Lianying Yan for preparing recombinant viral glycoproteins; Jennifer Barr, Vishal Kapoor, Neil Renwick,  
549 and Mohammad Ziadur for laboratory diagnostic and technical support, anonymous reviewers for their  
550 useful comments, and the Government of Bangladesh for permits and logistical support that made this  
551 work possible. This study was funded by an NIH NIAID awards to JHE (AI067549) and CCB (AI054715), an  
552 NIH Fogarty International Center Ecology and Evolution of Infectious Diseases (EEID) award to PD (R01  
553 TW005869) a NSF-NIH EEID award to AMK (EF-0914866), a NIH NIAID award to Lipkin (U19 AI109761), a  
554 US Agency for International Development PEER award to MSK (Award 226), and the US Agency for

555 International Development Emerging Pandemic Threats: PREDICT program (PD, JHE, AI, SA, NR, CZT,  
556 KJO). icddr,b is also grateful to the Governments of Bangladesh, Canada, Sweden and the UK for  
557 providing core/unrestricted support. Study development (JHE, SJA, AI, AMK, SUK, EG, MJH, HEF, GC, MR,

783

784  
 785 **Figure 1.** Map showing age-stratified seroprevalence in *Pteropus medius* colonies, Bangladesh. Bats from eight  
 786 colonies were sampled and tested for anti-NiV IgG antibodies: four within the “Nipah Belt” (orange shaded) and  
 787 four outside. Seroprevalence of adults (blue, purple), juveniles (red, orange) and total seroprevalence (green, light  
 788 blue) are shown. Number (n) of Adult, Juvenile, and Total bats sampled (clockwise): Tangail [53,41,94], Sylhet [63,  
 789 37, 100], Comilla 2008 [73,27,100], Comilla 2011 [30,20,50], Chittagong [72,24,96], Khulna[85,15,100], Rajbari  
 790 [65,15, 80], Kushtia [64,36,100], Thakurgaon [89,29,118]. The shaded region represents the “Nipah Belt” where  
 791 previous human NiV outbreaks have been reported.  
 792

### GLM Estimates: Factors Affecting Nipah Serostatus

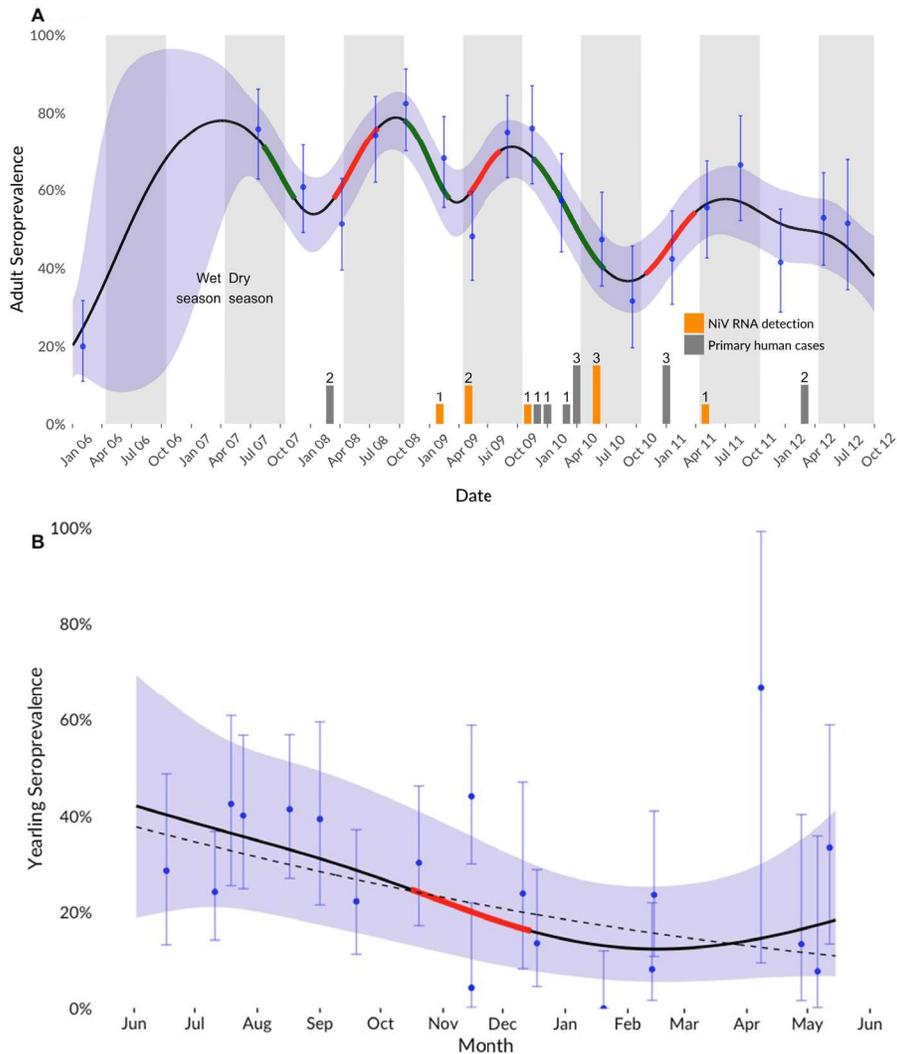

793

794 **Figure 2.** Results of Bayesian GLM of factors affecting Nipah serostatus in bats in cross-sectional study. Bars  
 795 indicate odds ratios and 50% (inner) and 95% (outer) credible intervals for model parameters. Factors with  
 796 asterisks (\*) have 95% CIs that do not overlap 1. Model intercept (predicted probability of seropositivity for a  
 797 juvenile, female, bat outside the Nipah belt of mean size and good body condition) was 0.26, (95% CI 0.12-0.56).  
 798 Random effect of location (not shown) had an estimated SD of 0.63 (95% CI 0.29-1.27)

799

Nipah virus IgG antibody serodynamics in adult and juvenile *Pteropus medius*, Faridpur, Bangladesh 2006-2012

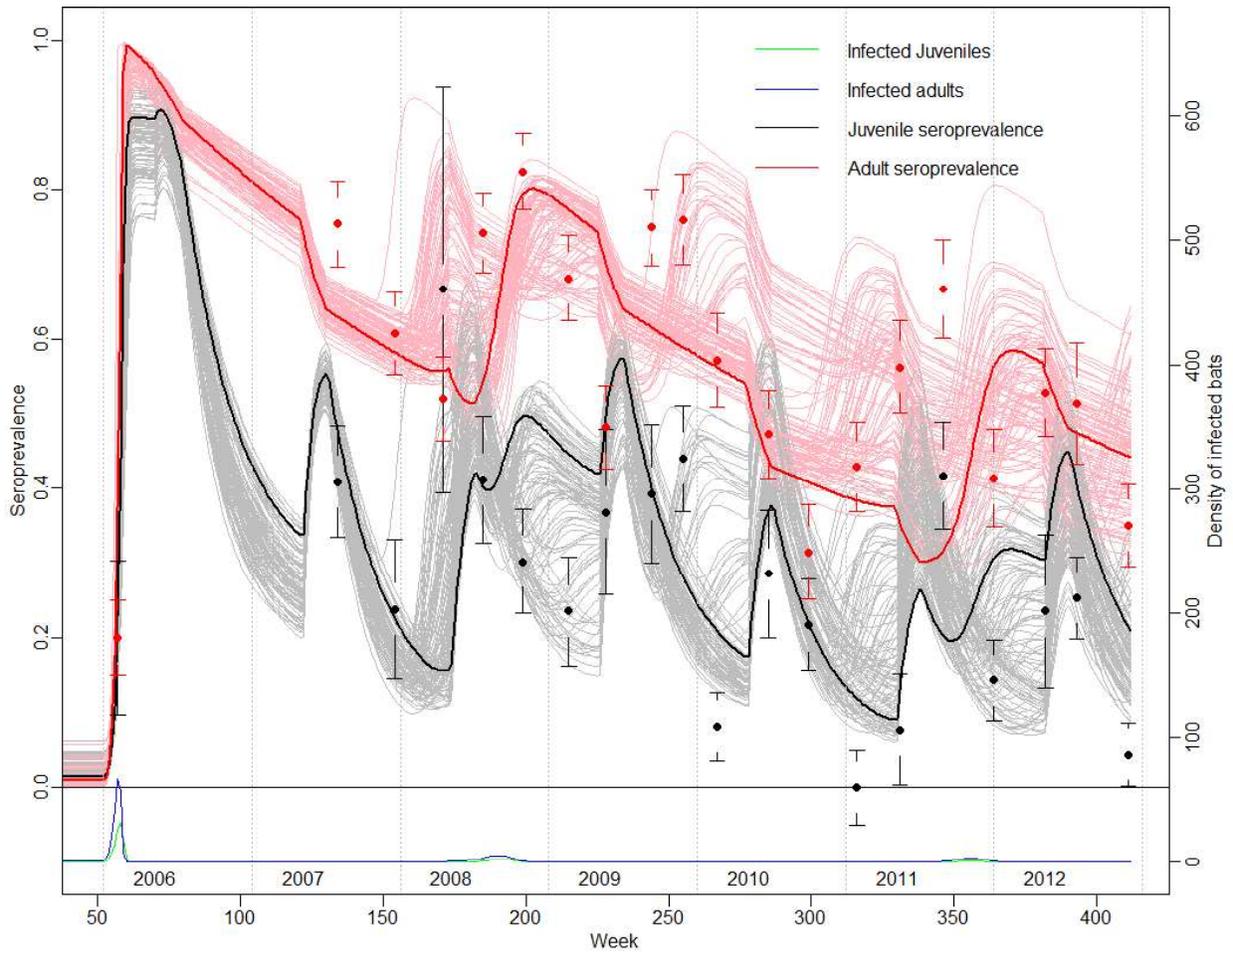

800

801 **Figure 3 A & B.** Serodynamics of the Faridpur bat population. (A) Adult serodynamics, with measured values and  
 802 95% CI in blue, and mean GAM prediction and 95% shown with line and surrounding shaded areas. Periods of  
 803 significant increase (red) and decrease (green) shown where the GAM derivative's 95% CI does not overlap zero.  
 804 Counts of primary human cases from local district (orange, and bat viral detections (dark grey, see Table 1), shown  
 805 on bottom. (B) Juvenile serodynamics during the first year of life ("yearlings"), with all years' measurements  
 806 overlay to show cohort-level dynamics across all study years. Measured values and 95% CI in blue, and mean and  
 807 95% CI for the GAM model pooled across cohorts shown with line and surrounded shaded areas. The period of  
 808 significant decline in the GAM is shown in red. Also shown is the mean prediction of a model with only a linear  
 809 mean term, with similar fit ( $\Delta AIC < 1$ ) as the GAM (dotted line).

810

811

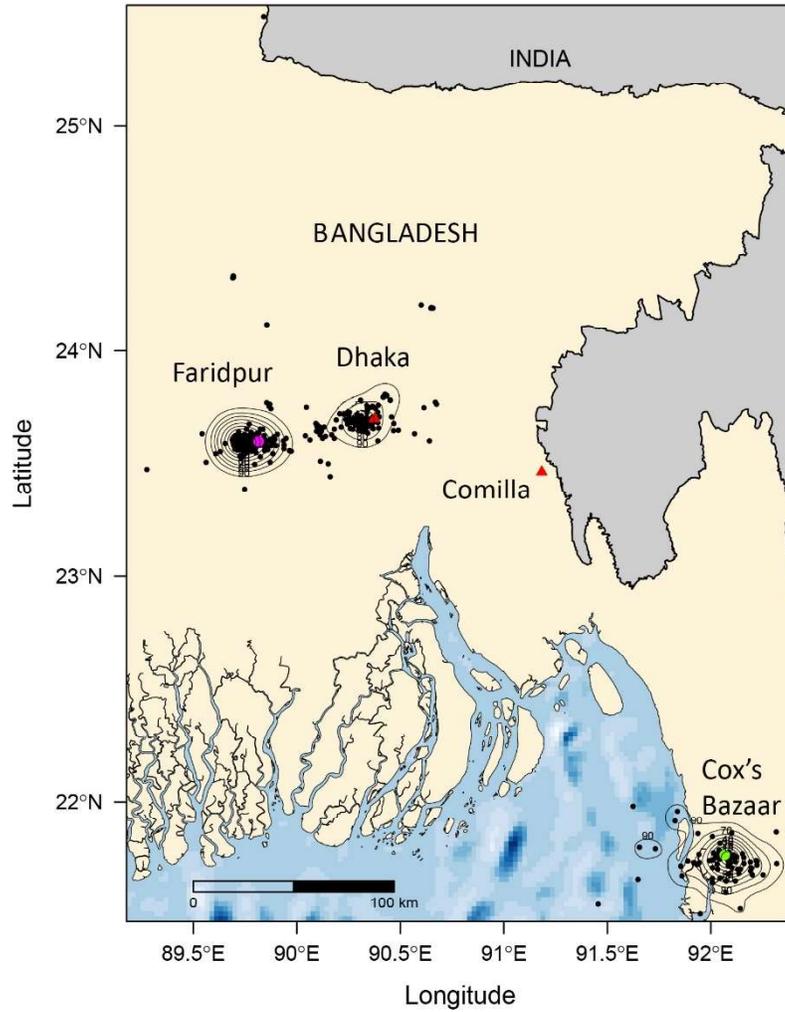

812

813 **Figure 4. NiV serological dynamics in adult and juvenile bats.** The observed data (red and black points  $\pm 1$  SE) and  
814 model fit (solid lines) for the fraction of adults and juveniles seropositive for NiV (left axis), and the model  
815 estimated density of infected adult and juvenile bats (bottom panel and right axis). See Methods for details of  
816 model structure.

**Figure 5.** Satellite telemetry and homerange analysis. Location data from satellite collars (n=14) placed on 11 bats from Faridpur and 3 bats from Cox's Bazaar, Chittagong collected between 2009 and 2011, were used to calculate local and long-range movement patterns and home range for these two groups.

866 **Figure 6. Nipah Virus N gene phylogenetic tree (224nt):** Tree created in Geneious Prime 2019 using a Neighbor-  
 867 joining Tamura-Nei model with 1,000 replicates (105). The percentage of trees in which the associated taxa clustered  
 868 together is shown next to the branches. The tree is drawn to scale, with branch lengths measured in the number of  
 869 substitutions per site. Hendra virus was used as an outgroup. Sample collection date, location and Genbank accession  
 870 numbers are included in the label for each sequence except *P. medius* sequences which are accession Nos MK995284  
 871 – MK995302. Blue labels indicate bat sequences from Faridpur and Bhanga (an outbreak response in Faridpur).  
 872 Purple sequences are from *P. medius* from other roosts sampled during the longitudinal study. Red sequences are  
 873 from *P. medius* in Comilla. Green sequences are human NiV sequences from Bangladesh and India.

874

1 Supplemental Data

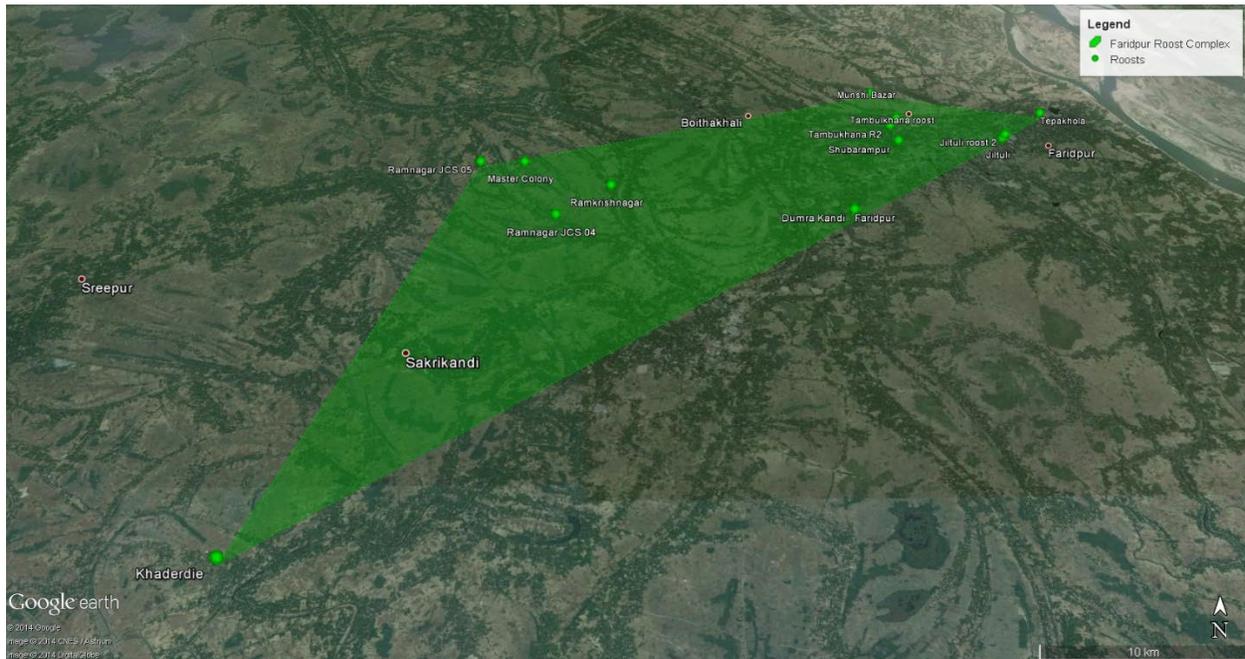

2

3 **Figure S1.** *Pteropus medius* counts from selected roosting sites within the Faridpur Roost Complex: 2008-2012.

4 Sites were included if repeated counts were conducted. Domrakandi and Kaderdi were the two primary roost sites  
5 sampled for the longitudinal study and counts were used for the model parameter.

6

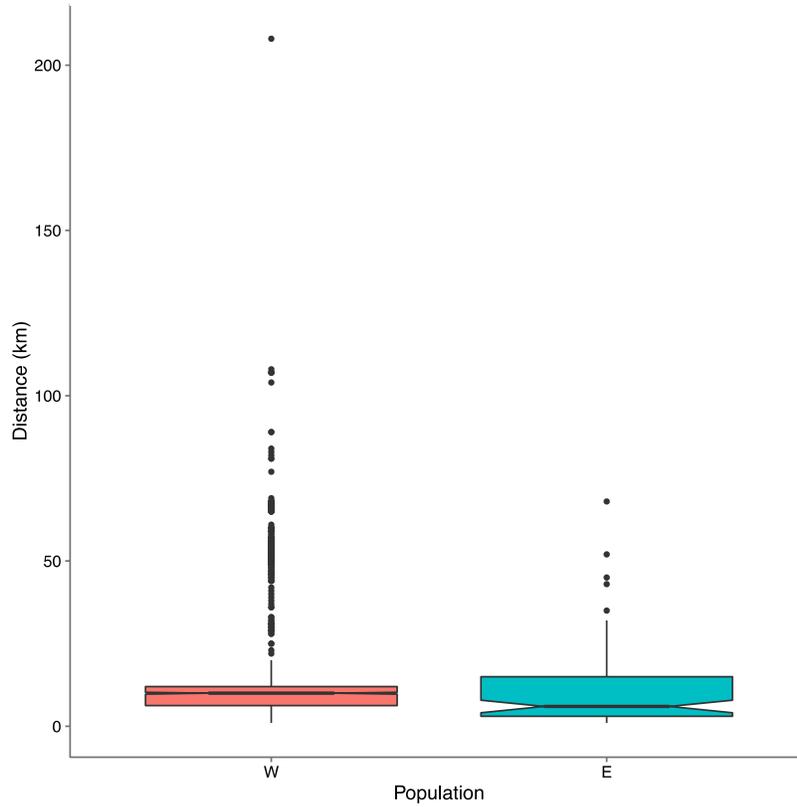

8

9 **Figure S2.** Faridpur Roost Complex. 51 Individual bats were recaptured during the longitudinal study at various  
 10 locations. 33 bats were recaptured at a different site from where they were originally sampled. 15 unique roosts  
 11 within an 80km<sup>2</sup> area were identified.

Mean foraging distance from roost in western and eastern colonies, based on satellite telemetry

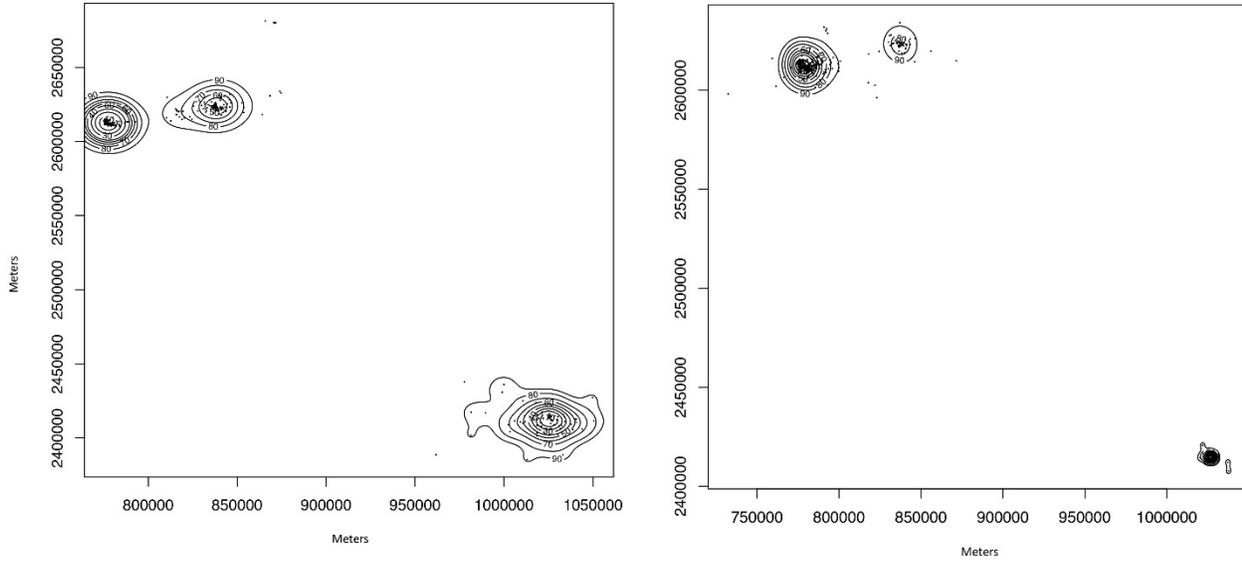

**Figure S3.** Mean foraging distance of western (W) and eastern (E) bat populations, based on satellite telemetry locations obtained between 1800h and 0600h, when *P. medius* typically forages.

54

55

Home range of *Pteropus medius* in wet and dry seasons.

56 **Figure S4.** a) Homerange of *Pteropus medius* during the wet season (left) and dry season (right). Maps are  
57 projected in UTM (Universal Transverse Mercator) Zone 45 where units are represented in meters. The mean wet  
58 season homerange size was 2,746 km<sup>2</sup>. Homerange size in the dry season is contracted and represents less than a  
59 quarter (618 km<sup>2</sup>) of the homerange in the wet season.

**Figure S5. Nipah Virus phylogenetic tree, N gene:** Clustal W alignment using nearly whole N gene consensus sequence from *P. medius* (1,592 nt) using Geneious Prime 2019 (1). The evolutionary history was inferred by using the Maximum Likelihood method and Hasegawa-Kishino-Yano model (2). The percentage of trees in which the associated taxa clustered together is shown next to the branches. The tree is drawn to scale, with branch lengths measured in the number of substitutions per site. Evolutionary analyses were conducted in MEGA X (3). Genbank accession numbers for sequences (from top to bottom): *P. medius* Maniganj & Sylhet pending (63); JN808864, AY988601, MH396625, FJ513078, JN808863, JN808857, AY858110, FN869553, AJ627196, AJ564623, AY029767, AF376747, AY029768, JN255803.

**Subject:** Re: Nipah dynamics in P medius draft for PNAS

- External Email -

Dear co-authors,

Our paper has been submitted to PNAS! Thank you all for your thoughtful and helpful comments.

I think you've each received a link to the submission from PNAS, but if not, here's the version that was submitted.

I'll be in touch when I hear anything.

Cheers,  
Jon

On Wed, Dec 18, 2019 at 3:00 PM Jon Epstein <[epstein@ecohealthalliance.org](mailto:epstein@ecohealthalliance.org)> wrote:

All,

I hope this email finds you well. Attached is a draft of our manuscript entitled Nipah virus dynamics in bats and implications for spillover to humans. After multiple protracted periods of review in Science Advances, and ultimately a rejection, I've prepared this draft for submission to PNAS. I've revised the manuscript and updated figures and supplemental data in response to the last round of review (comments below, if you're interested).

I have an editor at PNAS willing to send this for review, so please send me any input you may have by December 28th so that I can submit by the 31st. Unless I hear otherwise, I will assume you still consent to co-authorship.

Thank you for your patience, and happy holidays!

Cheers,  
Jon

Reviewer: 1

Epstein et al aim to better understand the distribution and drivers of Nipah virus infection dynamics in *Pteropus medius* in Bangladesh by analysing a large set of serological, virological and movement data over a commendable spatial and temporal scale. Overall, this is a highly exciting study with valuable results that are well-deserving of publication. I have a number of minor comments regarding the addition of detail for clarity (and to ensure transparency in the interpretation of results). I think that the conclusions are mostly justified, however, my major criticism is that the integration and interpretation of the results (particularly those presented in the first paragraph of the discussion) requires a little further thought and explanation. The assumptions surrounding the serological implications of within-host persistence and recrudescence needs to be clearly stated. This is likely to become a 'classic' paper, and there are so few studies in this area supported by data that it is important to ensure that the results are not over-interpreted.

Specific comments:

Abstract:

Line 32- 33: The wording here is too strong regarding recrudescence. Suggest inserting "model results indicated that" prior to "local transmission dynamics.

Line 33-34: Similarly - this is too strong. Suggest "likely due to "

Results:

Figure 1 - presumably the first three bats in the Comilla represent 2008 and the second three represent 2011, but this is not clear. This should be annotated on the plot

Figure 1 - "Adult bats had equal or greater seroprevalence than juveniles in each location."  
- except Tangail?

Line 129: "detected NiV RNA in 11 individuals, 3 pooled" - insert 'from' before 3

Line 131: - describe "pooled samples" - pooled under-roost urine samples?

Line 132 and 137: This 'figure 2' seems to be missing? Figure 2 refers to serological analyses

Line 145: I suggest that the reference to Figure 2 in line 146 should go in the sentence ending on line 145

Line 149: the significant negative association with body condition warrants mentioning in these results.

Line 154-155 and Figure 3: Additional clarity here regarding juvenile vs. yearling terms. Suggest saying "Juveniles in their first year of life (yearlings)" at first mentioning in the text, as well in the figure legend.

Line 159 - incomplete sentence

Lines 160-164: Fascinating results!

Lines 170-171: This information would be helpful to include earlier, with the serological results

Figure 3 and Figure S1 - It would be helpful to have a "total population" size from this roost complex included on Figures 3 and 4. Understanding more about the bat ecology and the size and stability of these populations over time would be a tremendous help to aid interpretation of these results by researchers working in other systems.

Lines 175-176: "Serodynamics in juveniles were strongly driven by inheritance and loss of maternal antibodies". Supported by what result? This should be explained further, and/or it would be helpful to include the serology (fig 3), model output (fig 4) and population size (Figure s1) together as a series of vertical panels in the one figure to aid interpretation

Lines 178-180: I can't see this information in the supplementary information

Line 182 - this paragraph (and ideally also table S2) should provide information on the duration of tracking for each bat. This would be very helpful in assessing the home range information

Line 195 - should the 'of' be 'if'?

Figure 6 - the utility of this figure would be greatly improved with some annotation and colouring to help identify the new sequences from this study, and their source location, and the 'groups' that are referred to in the text

Lines 238 - 240 - So, your data has found cyclical serodynamics, but no clear links between those dynamics and detection of NiV in bats or in people. Based on experimental studies, it is still a bit unclear exactly what seropositivity in flying foxes represents. If there is within-host persistence of infection, a cycle of infection > seroconversion (in the absence of clearance) > seroreversion > then recrudescence with seroconversion may occur in the

absence of ongoing transmission. Additionally, this does not take into account drivers of recrudescence - if this is stress related, then transmission at the population level will also be affected by these broader drivers. Given all the uncertainty around this topic, I think that the wording here needs to be precise. e.g the first sentence should first state the assumption "Assuming that seroconversion results only from new infections, then ...". This could be followed up with a sentence along the lines of "If however, seroconversion can result from recrudescence in the absence of transmission, then broader drivers of recrudescence would also need to be assessed". More clarity here would also help to assess the claims being made in the paragraph beginning 315.

Lines 240 onwards - consider restructuring this paragraph to more clearly step through each stage of the viral dynamics that you are proposing and your assumptions and evidence along the way. For example, you assume infection results in seroconversion, and that antibodies then wane after ~4 years. Are you assuming that all individuals are persistently infected, and it is only when Ab wane that recrudescence can occur? And following that, the individual seroconverts again?

Lines 243 - 245: Not correct - See Brooks et al 2019 JAE Figure S5. That study also involved modelling and has implications for this study more broadly

Lines 245-247: "via recrudescence FROM bats that have previously been infected"? It's also not clear how this links to lines 238-240

Lines 257-259: Consider also cite Peel et al (2018). Scientific Reports, 8(1), e0004796. This study examines waning maternal immunity and waning acquired immunity against henipaviruses in African fruit bats, finding a similar duration of immunity for both  
Line 267 - insert "in our study area" after 'Pteropus medius' as you cannot infer whether these patterns hold true for the species across its range. It may be highly dependent on available food resources - as you go on to discuss

Line 277 - replace 'be' with 'result in'

Lines 295-296 - this links with the SILI hypotheses in Plowright et al (2016) PLoS NTD (see Figure 3)

Line 321- suggest "three periods of transmission (significant at the population level) occurred"

Line 315 See my comments re: paragraph beginning Line 238. The sporadic nature of detections is challenging to draw conclusions and much of the paragraph here (starting line 315) seems over-stated. However, that may become clearer if the comments for the earlier paragraph are addressed.

Methods:

Line 364: I can't see reference to the Faripur colony in the list of colonies in lines 358-359. What are its characteristics? Also, I presume it should be "Faridpur"? Also, it would be helpful if the "Faridpur roost complex:" could be described in more detail in the methods as to the structure of this population and what this term means.

Line 366: Delete the first 'between'

Lines 388-390 - check the placement of parentheses here

Line 417: what cutoff was used for the Luminex assay and how was it determined?

Line 425 - fix formatting of second Ct

Line 493- 504: More information on the underlying population dynamic model is required e.g. Were births seasonal or continuous in your model? I can't see where this is stated. If not seasonal, then the effect of this on model output should be addressed. How was the death rate modelled? Was the total population size kept stable inter annually? The latter, in particular, may have implications for interpretation of the density-dependent vs frequency dependent results. The population size is touched on in the discussion in lines 288-291 but never really explained.

Table S1 - there is extra text below Table S1 that looks like it's not supposed to be there

Table S2 - Include what serostatus 0/1 refers to in the table caption

Reviewer: 2

Dear editor, I have reviewed the manuscript entitled "Nipah virus dynamics in bats and implications for zoonotic spillover to humans". The manuscript describes a longitudinal surveillance in Pteropid spp. Bats from 2006 until 2012. Biometric data was collected, sera and swabs/urine were analyzed, and inferences were made largely based on serological data. The manuscript is a compendium of relatively loosely compiled data, ranging from seroprevalence in a variety of different sampling sites, but the majority of the samples stem from Faridpur. The problem is that most of the claims by the authors within the paper are not directly supported by the data. The direct problem of the data is the limited amount of detected virus shedding, out of 2789 animals sampled only 11 were found to be shedding the virus. From this only 8 were from the larger study cohort from Faridpur. This directly hampers some of the conclusion of potential spillover dynamics as this cannot be directly inferred from serological data alone. In addition, it does not provide any answers on the occurrence of Nipah spillover in the Nipah belt vs the other regions. Moreover, the significant spillover events in Kerala, India from the last two years, are not discussed. Most emphasis has been put on analyzing the serological results from the *Pteropus medius* bats. The authors show variation in the seroprevalence within the population based on timing and age status of the animal. The results have been reported before in other natural reservoir-pathogen systems like avian influenza, however even within these systems inferences on spillover can rarely be made. It is interesting that the authors did not correlate the positive individual bats in Faridpur and Rajbari with their respective serostatus? Is this data not available? It is unclear to me why the authors have not put more effort in trying to perform full genome analyses on the positive samples obtained throughout this study. Currently there are only 27 full genomes available from Nipah virus and relatively limited amount are from the natural reservoir. Performing phylogenetic analyses on a 224 nucleotide fragment of a 19kb virus is really not up to standard. Where it might be suitable for identification of the lineage no additional data can be inferred from this. Interestingly, there appears to be full genome sequencing performed but only N is shown in the supplemental data.

Although I do understand the logistics involved with this kind of work, unfortunately some of the claims, especially regarding spillover, need to be supported by more additional data rather than just serology.

Minor points:

Line 65: pandemic potential, given the limited amount of h-to-h transmission the pandemic potential of this particular virus appears to relatively limited.

Line 143: n=844 or n=883? Why do the numbers not match-up?

Line 410, include level of biosecurity involved in sample analyses. In addition, heatinactivation

is typically to inactivate complement and not inactivation of the pathogen.

From the current wording it is unclear what the authors mean by this? Complement inactivation or pathogen inactivation?

Line 428, is this data missing? Where is the NSG data? Why not data on the full genomes? I only was able to find the full N gene data in the supplemental figures.

Line 509, given that actual recrudescence in the context of virus shedding in the natural reservoir has never been shown it would be good to treat this a little bit more carefully.

**Subject:** Re: Nipah dynamics in P medius draft for PNAS

Dear co-authors,

Our paper has been submitted to PNAS! Thank you all for your thoughtful and helpful comments.

I think you've each received a link to the submission from PNAS, but if not, here's the version that was submitted.

I'll be in touch when I hear anything.

Cheers,  
Jon

On Wed, Dec 18, 2019 at 3:00 PM Jon Epstein <[epstein@ecohealthalliance.org](mailto:epstein@ecohealthalliance.org)> wrote:

All,

I hope this email finds you well. Attached is a draft of our manuscript entitled Nipah virus dynamics in bats and implications for spillover to humans. After multiple protracted periods of review in Science Advances, and ultimately a rejection, I've prepared this draft for submission to PNAS. I've revised the manuscript and updated figures and supplemental data in response to the last round of review (comments below, if you're interested).

I have an editor at PNAS willing to send this for review, so please send me any input you may have by December 28th so that I can submit by the 31st. Unless I hear otherwise, I will assume you still consent to co-authorship.

Thank you for your patience, and happy holidays!

Cheers,  
Jon

Epstein et al aim to better understand the distribution and drivers of Nipah virus infection dynamics in *Pteropus medius* in Bangladesh by analysing a large set of serological, virological and movement data over a commendable spatial and temporal scale. Overall, this is a highly exciting study with valuable results that are well-deserving of publication. I have a number of minor comments regarding the addition of detail for clarity (and to ensure transparency in the interpretation of results). I think that the conclusions are mostly justified, however, my major criticism is that the integration and interpretation of the results (particularly those presented in the first paragraph of the discussion) requires a little further thought and explanation. The assumptions surrounding the serological implications of within-host persistence and recrudescence needs to be clearly stated. This is likely to become a 'classic' paper, and there are so few studies in this area supported by data that it is important to ensure that the results are not over-interpreted.

Specific comments:

Abstract:

Line 32- 33: The wording here is too strong regarding recrudescence. Suggest inserting "model results indicated that" prior to "local transmission dynamics."

Line 33-34: Similarly - this is too strong. Suggest "likely due to "

Results:

Figure 1 - presumably the first three bats in the Comilla represent 2008 and the second three represent 2011, but this is not clear. This should be annotated on the plot

Figure 1 - "Adult bats had equal or greater seroprevalence than juveniles in each location." - except Tangail?

Line 129: "detected NiV RNA in 11 individuals, 3 pooled" - insert 'from' before 3

Line 131: - describe "pooled samples" - pooled under-roost urine samples?

Line 132 and 137: This 'figure 2' seems to be missing? Figure 2 refers to serological analyses

Line 145: I suggest that the reference to Figure 2 in line 146 should go in the sentence ending on line 145

Line 149: the significant negative association with body condition warrants mentioning in these results.

Line 154-155 and Figure 3: Additional clarity here regarding juvenile vs. yearling terms. Suggest saying "Juveniles in their first year of life (yearlings)" at first mentioning in the text, as well in the figure legend.

Line 159 - incomplete sentence

Lines 160-164: Fascinating results!

Lines 170-171: This information would be helpful to include earlier, with the serological results

Figure 3 and Figure S1 - It would be helpful to have a "total population" size from this roost complex included on Figures 3 and 4. Understanding more about the bat ecology and the size and stability of these populations over time would be a tremendous help to aid interpretation of these results by researchers working in other systems.

Lines 175-176: "Serodynamics in juveniles were strongly driven by inheritance and loss of maternal antibodies". Supported by what result? This should be explained further, and/or it would be helpful to include the serology (fig 3), model output (fig 4) and population size (Figure s1) together as a series of vertical panels in the one figure to aid interpretation

Lines 178-180: I can't see this information in the supplementary information

Line 182 - this paragraph (and ideally also table S2) should provide information on the duration of tracking for each bat. This would be very helpful in assessing the home range information

Line 195 - should the 'of' be 'if'?

Figure 6 - the utility of this figure would be greatly improved with some annotation and colouring to help identify the new sequences from this study, and their source location, and the 'groups' that are referred to in the text

Lines 238 - 240 - So, your data has found cyclical serodynamics, but no clear links between those dynamics and detection of NiV in bats or in people. Based on experimental studies, it is still a bit unclear exactly what seropositivity in flying foxes represents. If there is within-host persistence of infection, a cycle of infection > seroconversion (in the absence of clearance) > seroreversion > then recrudescence with seroconversion may occur in the absence of ongoing transmission. Additionally, this does not take into account drivers of recrudescence - if this is stress related, then transmission at the population level will also be affected by these broader drivers. Given all the uncertainty around this topic, I think that the wording here needs to be precise. e.g the first sentence should first state the assumption "Assuming that seroconversion results only from new infections, then ...". Dear co-authors,

Our paper has been submitted to PNAS! Thank you all for your thoughtful and helpful comments.

I think you've each received a link to the submission from PNAS, but if not, here's the version that was submitted.

I'll be in touch when I hear anything.

Cheers,

Jon

All,

I hope this email finds you well. Attached is a draft of our manuscript entitled Nipah virus dynamics in bats and implications for spillover to humans. After multiple protracted periods of review in Science Advances, and ultimately a rejection, I've prepared this draft for submission to PNAS. I've revised the manuscript and updated figures and supplemental data in response to the last round of review (comments below, if you're interested).

I have an editor at PNAS willing to send this for review, so please send me any input you may have by December 28th so that I can submit by the 31st. Unless I hear otherwise, I will assume you still consent to co-authorship.

Thank you for your patience, and happy holidays!

Cheers,

Jon

Epstein et al aim to better understand the distribution and drivers of Nipah virus infection dynamics in *Pteropus medius* in Bangladesh by analysing a large set of serological, virological and movement data over a commendable spatial and temporal scale. Overall, this is a highly exciting study with valuable results that are well-deserving of publication. I have a number of minor comments regarding the addition of detail for clarity (and to ensure transparency in the interpretation of results). I think that the conclusions are mostly justified, however, my major criticism is that the integration and interpretation of the results (particularly those presented in the first paragraph of the discussion) requires a little further thought and explanation. The assumptions surrounding the serological implications of within-host persistence and recrudescence needs to be clearly stated. This is likely to become a 'classic' paper, and there are so few studies in this area supported by data that it is important to ensure that the results are not over-interpreted.

Specific comments:

Abstract:

Line 32- 33: The wording here is too strong regarding recrudescence. Suggest inserting "model results indicated that" prior to "local transmission dynamics.

Line 33-34: Similarly - this is too strong. Suggest "likely due to "

Results:

Figure 1 - presumably the first three bats in the Comilla represent 2008 and the second three represent 2011, but this is not clear. This should be annotated on the plot

Figure 1 - "Adult bats had equal or greater seroprevalence than juveniles in each location." - except Tangail?

Line 129: "detected NiV RNA in 11 individuals, 3 pooled" - insert 'from' before 3

Line 131: - describe "pooled samples" - pooled under-roost urine samples?

Line 132 and 137: This 'figure 2' seems to be missing? Figure 2 refers to serological analyses

Line 145: I suggest that the reference to Figure 2 in line 146 should go in the sentence ending on line 145

Line 149: the significant negative association with body condition warrants mentioning in these results.

Line 154-155 and Figure 3: Additional clarity here regarding juvenile vs. yearling terms. Suggest saying "Juveniles in their first year of life (yearlings)" at first mentioning in the text, as well in the figure legend.

Line 159 - incomplete sentence

Lines 160-164: Fascinating results!

Lines 170-171: This information would be helpful to include earlier, with the serological results

Figure 3 and Figure S1 - It would be helpful to have a "total population" size from this roost complex included on Figures 3 and 4. Understanding more about the bat ecology and the size and stability of these populations over time would be a tremendous help to aid interpretation of these results by researchers working in other systems.

Lines 175-176: "Serodynamics in juveniles were strongly driven by inheritance and loss of maternal antibodies". Supported by what result? This should be explained further, and/or it would be helpful to include the serology (fig 3), model output (fig 4) and population size (Figure s1) together as a series of vertical panels in the one figure to aid interpretation

Lines 178-180: I can't see this information in the supplementary information

Line 182 - this paragraph (and ideally also table S2) should provide information on the duration of tracking for each bat. This would be very helpful in assessing the home range information

Line 195 - should the 'of' be 'if'?

Figure 6 - the utility of this figure would be greatly improved with some annotation and colouring to help identify the new sequences from this study, and their source location, and the 'groups' that are referred to in the text

Lines 238 - 240 - So, your data has found cyclical serodynamics, but no clear links between those dynamics and detection of NiV in bats or in people. Based on experimental studies, it is still a bit unclear exactly what seropositivity in flying foxes represents. If there is within-host persistence of infection, a cycle of infection > seroconversion (in the absence of clearance) > seroreversion > then recrudescence with seroconversion may occur in the absence of ongoing transmission. Additionally, this does not take into account drivers of recrudescence - if this is stress related, then transmission at the population level will also be affected by these broader drivers. Given all the uncertainty around this topic, I think that the wording here needs to be precise. e.g the first sentence should first state the assumption "Assuming that seroconversion results only from new infections, then ...". This could be followed up with a sentence along the lines of "If however, seroconversion can result from recrudescence in the absence of transmission, then broader drivers of recrudescence would also need to be assessed". More clarity here would also help to assess the claims being made in the paragraph beginning 315.

Lines 240 onwards - consider restructuring this paragraph to more clearly step through each stage of the viral dynamics that you are proposing and your assumptions and evidence along the way. For example, you assume infection results in seroconversion, and that antibodies then wane after ~4 years. Are you assuming that all individuals are persistently infected, and it is only when Ab wane that recrudescence can occur? And following that, the individual seroconverts again?

Lines 243 - 245: Not correct - See Brooks et al 2019 JAE Figure S5. That study also involved modelling and has implications for this study more broadly

Lines 245-247: "via recrudescence FROM bats that have previously been infected"? It's also not clear how this links to lines 238-240

Lines 257-259: Consider also cite Peel et al (2018). Scientific Reports, 8(1), e0004796. This study examines waning maternal immunity and waning acquired immunity against henipaviruses in African fruit bats, finding a similar duration of immunity for both

Line 267 - insert "in our study area" after 'Pteropus medius' as you cannot infer whether these patterns hold true for the species across its range. It may be highly dependent on available food resources - as you go on to discuss

Line 277 - replace 'be' with 'result in'

Lines 295-296 - this links with the SILI hypotheses in Plowright et al (2016) PLoS NTD (see Figure 3)

Line 321- suggest "three periods of transmission (significant at the population level) occurred"

Line 315 See my comments re: paragraph beginning Line 238. The sporadic nature of detections is challenging to draw conclusions and much of the paragraph here (starting line 315) seems over-stated. However, that may become clearer if the comments for the earlier paragraph are addressed.

Methods:

Line 364: I can't see reference to the Faripur colony in the list of colonies in lines 358-359.

What are its characteristics? Also, I presume it should be "Faridpur"? Also, it would be helpful if the "Faridpur roost complex:" could be described in more detail in the methods as to the structure of this population and what this term means.

Line 366: Delete the first 'between'

Lines 388-390 - check the placement of parentheses here

Line 417: what cutoff was used for the Luminex assay and how was it determined?

Line 425 - fix formatting of second Ct

Line 493- 504: More information on the underlying population dynamic model is required e.g. Were births seasonal or continuous in your model? I can't see where this is stated.

If not seasonal, then the effect of this on model output should be addressed. How was the death rate modelled? Was the total population size kept stable inter annually? The latter, in particular, may have implications for interpretation of the density-dependent vs frequency dependent results. The population size is touched on in the discussion in lines 288-291 but never really explained.

Table S1 - there is extra text below Table S1 that looks like it's not supposed to be there

Table S2 - Include what serostatus 0/1 refers to in the table caption

Reviewer: 2

Dear editor, I have reviewed the manuscript entitled "Nipah virus dynamics in bats and implications for zoonotic spillover to humans". The manuscript describes a longitudinal surveillance in Pteropid spp. Bats from 2006 until 2012. Biometric data was collected, sera and swabs/urine were analyzed, and inferences were made largely based on serological data. The manuscript is a compendium of relatively loosely compiled data, ranging from seroprevalence in a variety of different sampling sites, but the majority of the samples stem from Faridpur. The problem is that most of the claims by the authors within the paper are not directly supported by the data. The direct problem of the data is the limited amount of detected virus shedding, out of 2789 animals sampled only 11 were found to be shedding the virus. From this only 8 were from the larger study cohort from Faridpur. This directly hampers some of the conclusion of potential spillover dynamics as this cannot be directly inferred from serological data alone. In addition, it does not provide any answers on the occurrence of Nipah spillover in the Nipah belt vs the other regions. Moreover, the significant spillover events in Kerala, India from the last two years, are not discussed. Most emphasis has been put on analyzing the serological results from the Pteropus medius bats. The authors show variation in the seroprevalence within the population based on timing and age status of the animal. The results have been reported before in other natural reservoir-pathogen systems like avian influenza, however even within these systems inferences on spillover can rarely be made. It is interesting that the authors did not correlate the positive individual bats in Faridpur and Rajbari with their respective serostatus? Is this data not available? It is unclear to me why the authors have not put more effort in trying to perform full genome analyses on the positive samples obtained throughout this study. Currently there are only 27 full genomes available from Nipah virus and relatively limited amount are from the natural reservoir. Performing phylogenetic analyses on a 224 nucleotide fragment of a 19kb virus is really not up to standard. Where it might be suitable for identification of the lineage no additional data can be inferred from this. Interestingly, there appears to be full genome sequencing performed but only N is shown in the supplemental data.

Although I do understand the logistics involved with this kind of work, unfortunately some of the claims, especially regarding spillover, need to be supported by more additional data rather than just serology.

Minor points:

Line 65: pandemic potential, given the limited amount of h-to-h transmission the pandemic potential of this particular virus appears to relatively limited.

Line 143: n=844 or n=883? Why do the numbers not match-up?

Line 410, include level of biosecurity involved in sample analyses. In addition, heatinactivation is typically to inactivate complement and not inactivation of the pathogen.

>From the current wording it is unclear what the authors mean by this? Complement inactivation or pathogen inactivation?

Line 428, is this data missing? Where is the NSG data? Why not data on the full genomes? I only was able to find the full N gene data in the supplemental figures.

Line 509, given that actual recrudescence in the context of virus shedding in the natural reservoir has never been shown it would be good to treat this a little bit more carefully.

41 **Abstract**

42 Nipah virus (NiV) is an emerging bat-borne zoonotic virus with pandemic potential that causes near-  
43 annual outbreaks of fatal encephalitis in South Asia – one of the most populous regions on Earth. In  
44 Bangladesh, infection occurs when people drink date palm sap contaminated with bat excreta.  
45 Outbreaks are sporadic and the influence of viral dynamics in bats on their temporal and spatial  
46 distribution is poorly understood. We analyzed data on host ecology, molecular epidemiology,  
47 serological dynamics, and viral genetics to characterize spatio-temporal patterns of NiV dynamics in its  
48 wildlife reservoir, *Pteropus medius* bats, in Bangladesh. We found that NiV transmission occurred  
49 throughout the country and throughout the year. Model results indicated that local transmission  
50 dynamics were modulated by density-dependent transmission, acquired immunity that is lost over time,  
51 and recrudescence. Increased transmission followed multi-year periods of declining seroprevalence due  
52 to bat population turnover and individual loss of humoral immunity. Individual bats had smaller host  
53 ranges than other *Pteropus* spp., although movement data and the discovery of a Malaysia-clade NiV  
54 strain in eastern Bangladesh suggest connectivity with bats east of Bangladesh. These data suggest that  
55 discrete multi-annual local epidemics in bat populations contribute to the sporadic nature of Nipah virus  
56 outbreaks in South Asia. At the same time, the broad spatial and temporal extent of NiV transmission,  
57 including the recent outbreak in Kerala, India, highlights the continued risk of spillover to humans  
58 wherever they may interact with pteropid bats, and the importance of improving Nipah virus  
59 surveillance throughout *Pteropus*'s range.

60

61

62 **Significance**

63 Nipah virus (NiV) is a zoonotic virus and WHO priority pathogen that causes near-annual outbreaks in  
64 Bangladesh and India associated with >75% mortality. This work advances our understanding of the  
65 circulation of NiV in its natural bat reservoir by analyzing data from a 6-year multidisciplinary study of  
66 serology, viral phylogenetics, bat ecology and immunology. We show for the first time that outbreaks in  
67 *Pteropus* bats are driven by population density, loss of immunity over time and viral recrudescence,  
68 resulting in multi-year inter-epidemic periods. Incidence is low, but bats carry NiV across Bangladesh  
69 and can shed virus at any time of year, highlighting the importance of routes of transmission to the  
70 timing and location of human Nipah virus outbreaks.

71

72 **Introduction.**

73 Outbreaks of zoonotic diseases are often sporadic, rare events that are difficult to predict, but can have  
74 devastating consequences (1). Emerging viral zoonoses of wildlife that have become pandemic include  
75 HIV/AIDS, SARS coronavirus, and the 1918 H1N1 influenza virus (2-4). Bats are important hosts for many  
76 zoonotic viruses including ebola virus, SARS-CoV, and Nipah virus; the ecological drivers and  
77 transmission dynamics of these viruses in their reservoir hosts are poorly understood (5-10). A better  
78 understanding of the transmission dynamics of zoonotic pathogens in their natural reservoirs may help  
79 anticipate and prevent outbreaks (9, 11).

80 Nipah virus (NiV) is an emerging zoonotic paramyxovirus (genus *Henipavirus*) that has  
81 repeatedly spilled over from bats to cause outbreaks in people and livestock with high case fatality rates  
82 across a broad geographic range. To date, human Nipah virus infections have been identified in India,  
83 Bangladesh, Malaysia, Singapore, and the Philippines (12-16). It has caused repeated outbreaks in  
84 Bangladesh and India, with a mean case fatality rate greater than 70% (12, 17, 18). A single genus of  
85 frugivorous bats (*Pteropus*) appears to be the main reservoir for henipaviruses throughout Asia and  
86 Australia (19-23), including *Pteropus medius* (formerly *Pteropus giganteus* (24)) in Bangladesh and India  
87 (14, 25-27). Nipah virus has several characteristics that make it a significant threat to human and animal  
88 health: 1) its bat reservoir hosts are widely distributed throughout Asia, overlapping dense human and  
89 livestock populations, providing broad opportunity to cause outbreaks; 2) it can be transmitted directly  
90 to humans by bats or via domestic animals; 3) it can be transmitted from person to person; 4) spillover  
91 has repeatedly occurred in highly populous and internationally connected regions, giving it pandemic  
92 potential; 5) it is associated with high mortality rates in people; and 6) there are currently no  
93 commercially available vaccines to prevent infection or drugs to mitigate disease (28-30). As a result, the  
94 World Health Organization has listed Nipah virus among the ten most significant threats to global health  
95 (31). In May 2018, an outbreak of Nipah virus encephalitis associated with a 91% mortality rate occurred  
96 in a new location - Kerala, India - more than 1,200 km southwest of previous Indian and Bangladeshi  
97 outbreaks (32). A single case was subsequently reported in Kerala in 2019, and while local *P. medius*  
98 populations have been implicated as the local source of infection, the route of spillover in both instances  
99 remains unknown (32, 33).

100 In Malaysia and Bangladesh, consumption of cultivated food resources contaminated with bat  
101 excreta such as mangoes in Malaysia and date palm sap in Bangladesh and northeastern India have been  
102 identified as the predominant cause of spillover to pigs and people, respectively (34). Human outbreaks  
103 occur almost annually in Bangladesh and the seasonal timing (November-April) and spatial distribution  
104 of outbreaks coincide with patterns of raw date palm sap consumption in a region termed the "Nipah  
105 belt" (35). However, there is variability in the geographic locations and number of spillover events, as  
106 well as the number and magnitude of human outbreaks that occur each year (36). Spillover has also  
107 occurred outside the predominant season and region of date-palm sap consumption (37). Whereas no  
108 human outbreaks have been reported in eastern Bangladesh despite date palm sap harvesting and  
109 consumption, human outbreaks have been reported in Kerala, India where date palm sap is not  
110 cultivated (35). These observations suggest an alternate route of spillover in certain locations, and a  
111 critical need to understand the mechanisms of underlying viral infection dynamics in bats and the extent

112 of genetic diversity within the virus – each of which may influence the timing, location and epidemiology  
113 of human outbreaks (35).

114 Previous research on the transmission dynamics of Nipah and Hendra viruses in *Pteropus* spp.  
115 bats has produced mixed and sometimes contradictory findings. Nipah virus, like Ebola, Marburg,  
116 Hendra and some bat coronaviruses, are associated with seasonal spikes in infection that coincide with  
117 annual or semi-annual synchronous birth pulses (19, 38-44). Seasonal periods of Nipah virus shedding  
118 were observed in *P. lylei* in Thailand and seasonal spikes in NiV (or a related henipavirus) seroprevalence  
119 coinciding with pregnancy periods were observed in *Eidolon dupreanum* in Madagascar (45, 46), but not  
120 in *P. vampyrus* or *P. hypomelanus* in Peninsular Malaysia (23). Hendra virus prevalence in Australian  
121 pteropid bats has shown multi-year inter-epidemic periods during which little virus can be detected,  
122 followed by periods of markedly increased viral shedding (47-49). It has been hypothesized that multi-  
123 year periodicity in the incidence of henipavirus infections could arise from a build-up and waning of herd  
124 immunity in the reservoir host, with re-introduction of virus via immigration or recrudescence or viral  
125 persistence (10, 50-52). Some pteropid bat species are migratory and interconnected colonies form a  
126 metapopulation which could allow for viral re-introductions (9, 23, 53, 54). In addition, NiV  
127 recrudescence has been observed in wild-caught *P. vampyrus* and possibly also in *Eidolon helvum* (55-  
128 57). Either of these phenomena could allow it to persist regionally during periods of high local immunity.  
129 However, no study has yet shown evidence in open, free-ranging bat populations that favors one or the  
130 other hypothesis in driving NiV transmission dynamics.

131 Here we examine the distribution, dynamics, genetic diversity, and underlying drivers of NiV  
132 infection in *Pteropus medius* in Bangladesh to improve our understanding of human outbreak patterns.  
133 Specifically, we analyze the spatial, temporal and demographic variation in serological dynamics and  
134 viral shedding in bats over a six-year period to determine the spatio-temporal drivers and dynamics of  
135 virus transmission. We also analyze the movement patterns of individual bats and analyze NiV  
136 phylogenetics to understand patterns of spatial mixing and virus strain diversity.

137

## 138 **Results**

139 *Comparative Nipah virus prevalence study in bats inside and outside the Nipah Belt and concurrent*  
140 *longitudinal bat study inside the Nipah Belt.*

141 In a cross-sectional spatial study conducted between January 2006 and July 2012, we caught and  
142 tested 883 *P. medius* (~100 per district) from eight colonies in different districts across Bangladesh. We  
143 detected anti-Nipah IgG antibodies in all colonies (**Figure 1**). Seroprevalence varied by location ( $\chi^2 =$   
144 55.61,  $p < .001$ ). In all locations except Tangail, adult seroprevalence exceeded juvenile seroprevalence.  
145 Viral detection in individuals was rare; overall, we detected NiV RNA in 11/2088 individuals as well as  
146 three pooled oropharyngeal samples (representing five bats, but which could not be resolved to an  
147 individual) (**Table 1**). We detected viral RNA in individual bats in Faridpur and Rajbari and from pooled  
148 samples from Thakurgaon and roost urine samples from Comilla. Of the 11 PCR positive individuals,  
149 three had IgG antibodies (**Table S1**). We also detected virus in pooled urine collected from tarps placed  
150 below bats at roosts associated with human outbreaks in Bhanga and Joypurhat. The viral prevalence in  
151 Rajbari in January 2006 was 3.8% (95% CI: 0% -11%;  $n=78$ ). In Faridpur, where we also conducted an  
152 intensive longitudinal study of (see below), viral prevalence estimates ranged from 0% to 3% (95% CI:

153 0%-10%; n=100 at each of 18 sampling times) (**Table 1**). Nipah virus RNA was detected in individual bats  
154 from inside (Rajbari, Thakurgaon, and Faridpur) and outside (Comilla) the Nipah Belt. There was no  
155 significant difference between NiV detection rates from individual bats by the two main sample types:  
156 urine/urogenital swabs, 0.37% (n=2,126) and oropharyngeal swabs, 0.15% (n=1973) ( $\chi^2 = 1.92$  p=0.17).  
157 The estimated detection rate from pooled urine samples, collected from tarps placed underneath  
158 roosts) across the entire study was 2.5% (n=829), which was significantly higher than either sample type  
159 collected from individual bats ( $\chi^2 = 55.6$ ,  $p < 0.001$ ).

160

#### 161 *Factors associated with NiV IgG serostatus in P. medius*

162 There was no statistical difference between seroprevalence in bats inside the Nipah Belt and  
163 outside (odds ratio 90% high density interval of 0.55-2.5). Adults had higher seropositivity than juveniles  
164 (OR 2.4, 1.7-3.4 HDI), and males greater than females (OR 1.6, 1.1-2.2 HDI) (**Figure 2**). Among females,  
165 odds ratios were weakly higher in pup-carrying (4 times, HDI 0.7-21) and pregnant (1.5 times, HDI 0.89-  
166 2.5) individuals. Weight, forearm length nor the W:FA ratio ( a proxy for age ) did not consistently  
167 correlate with seropositivity, however, body condition (an assessment of pectoral muscle mass by  
168 palpation) was significantly negatively correlated (Poor/Fair body condition OR = 0.69, HDI 0.52-0.90)  
169 with serostatus. Finally, serostatus was strongly correlated in mother-pup pairs, with 71/80 pairs (89%)  
170 having matching status.

171

#### 172 *Longitudinal NiV serodynamics in P. medius, Faridpur district (2006-2012)*

173 We sampled bats quarterly from the same population in the Faridpur district, collecting  
174 biological samples, as described above, and microchipping a total of 2,345 bats between 2007 and 2012.  
175 We used generalized additive models (GAMs) to characterize changes in NiV seroprevalence over time.  
176 There were significant fluctuations in adult (>24 mo.) and juvenile (6 – 24 mo.) seroprevalence over the  
177 six-year study period (**Figure 3A**). Juvenile seroprevalence ranged from 0% to 44% (95%CI 37%-51%),  
178 and decreased over the first year of life for bats born in each year (“yearlings”), consistent with loss of  
179 maternal antibodies in juveniles. A more pronounced decrease occurred from mid-October to mid-  
180 December. However, the GAM indicating this had only marginal better fit ( $\Delta AIC < 1$ ), than one with a  
181 linear decrease over the whole year (**Figure 3B**). The effect of introducing annual cohorts of pups via  
182 synchronized birthing pulses was significant on overall seroprevalence.

183 Adult seroprevalence ranged from 31% (95% CI: 20%-46%) to 82% (95% CI: 77%-87%) with three  
184 cycles of clear variability over the course of the study (**Figure 3A**). We found no evidence of regular  
185 seasonal fluctuations; a GAM with annual cyclic terms fit worse than one without ( $\Delta AIC > 10$ ). Viral RNA  
186 was detected during periods of increasing, decreasing, and stable seroprevalence.

187 We fitted a series of age-stratified mechanistic models to examine different biological processes  
188 influencing serodynamics, including density- vs. frequency-dependent transmission, recrudescence vs.  
189 immigration of infected individuals, and seroreversion (loss of antibodies) in both juveniles and adults  
190 (see Methods and (**Figure 4**)). Density-dependent models were a far better fit to the data than  
191 frequency-dependent models (difference in log-likelihood 10.0;  $\Delta AIC = 20.0$ ), suggesting that  
192 movements of bats and fluctuations in colony size alter spatio-temporal variation in the risk of NiV  
193 infection in bats. In Faridpur (see “Domrakhandi/Khaderdi” in **Figure S1** ) during the period of sampling,

194 the roost population declined from approximately 300 bats to 185, which decreased transmission  
195 potential in the fitted model:  $R_0$  in adult bats was estimated to decrease from 3.5 to 2.1 as the number  
196 of bats in the colony decreased. As a result, over the six-year study period, the fitted model predicted  
197 that the number of infected bats increased when the seroprevalence of adults fell below 72% (when bat  
198 counts were highest - in 2006) and 52% (when bat counts were lowest).

199 The fitted model suggests that serodynamics in juveniles were strongly driven by inheritance  
200 and loss of maternal antibodies. The rate of loss of maternal antibodies was 17.6 weeks (95% CI: 13.7-  
201 25.0), which was much quicker than the loss of antibodies in adults (290.8 weeks, 95% CI: 245.0-476.4)  
202 (**Table S2**). Finally, models with recrudescence fit the data better than models without recrudescence  
203 (**Table S2**; difference in log-likelihood 32.6;  $\Delta$ AIC = 65.1), and models with recrudescence fit the data  
204 better than models with immigration ( $\Delta$ AIC = 3.76).

205

#### 206 *Mark-recapture and seroconversion/seroreversion*

207 There were 56 recapture events over the study period (**Table S3**). Thirty-one bats were  
208 recaptured at a roost other than the original capture location. This network of roosts or “roost complex”  
209 formed a polygon covering approximately 80 Km<sup>2</sup> and included 15 roosts sampled during the  
210 longitudinal study (**Figure S2A and S2B**). Ten instances of seroconversion (change from IgG negative to  
211 IgG positive) and nine instances of seroreversion (positive to negative) were observed (**Table S3**). The  
212 mean time between positive and negative tests in *adults* (excluding juveniles with maternal antibodies)  
213 was 588 days (n=6) (range: 124-1,082 days).

214

#### 215 *Home range and inter-colony connectivity analysis*

216 Home range analysis of satellite telemetry data from 14 bats (mean duration of collar data  
217 transmission = 6.25mo; range = 1-25mo; **Table S4**) showed that the majority of bats roosted within 10  
218 km of where the bats were originally collared, in the Faridpur (Nipah belt) colony, and within 7 km from  
219 where the bats in the Cox’s Bazaar colony were originally collared (315km east of Faridpur). The average  
220 foraging radius was 18.7 km (s.d. 21.5 km) for the Faridpur bats and 10.8 km (s.d. 11.9 km) for the Cox’s  
221 Bazaar bats (**Figure S2**). Home range analysis suggests that bats in Faridpur and Cox’s Bazaar would have  
222 a <5% probability of intermingling (**Figure 5**). Home-range size was larger during the wet season than the  
223 dry season (2,746 km<sup>2</sup> vs. 618 km<sup>2</sup>) (**Figures S3 & S4**).

224

#### 225 *NiV phylogenetic analysis.*

226 Phylogenetic analysis of NiV sequences from a 224nt section of the N gene (nt position 1290-  
227 1509 [position ref [gb|FJ513078.1](#) India]) suggests that strains from both India and Malaysia clades are  
228 present in bats in Bangladesh (**Figure 6**). This finding is supported by an additional analysis of near-  
229 whole N gene sequences (~1720 nt) from bats, pigs, and humans, including those from a subset of *P.*  
230 *medius* from this and a more recent study by our group (**Figure S5**) (58). Eleven 224nt N gene sequences  
231 obtained from bats between 2006 and 2012 (all from the Faridpur population) were identical. Overall,  
232 the N gene sequences identified from the Faridpur, Rajbari and Bhanga colonies between 2006 and 2011  
233 had 98.21%-100% shared nucleotide identity. Sequences from Rajbari district obtained five years apart  
234 (January 2006 and January 2011) had only a single nucleotide difference resulting in a synonymous  
235 substitution (G to A) at position 1304, which was found in four other bat NiV sequences from this study,

236 as well as in the NiV isolate from *P. vampyrus* in Malaysia. Five human NiV N gene sequences from  
237 various locations within the Nipah belt over the same time period as our bat study show more  
238 nucleotide diversity than those from the Faridpur *P. medius* population. Human sequences throughout  
239 Bangladesh and from Kerala, India, all nested within the diversity found in *P. medius* (**Figure 6**). By  
240 contrast, the sequences found in *P. medius* from Comilla, a location 150Km to the east of Faridpur,  
241 showed 80.8%-82.59% shared nucleotide identity with sequences from *P. medius* in Faridpur and  
242 clustered within the Malaysia group of NiV sequences. The two Comilla sequences were identical to  
243 each other, and had up to 87.95% shared nucleotide identity to sequences from *P. lylei* in Thailand.  
244

## 245 **Discussion**

246 Our study provides new insights into Nipah virus transmission dynamics, genetics and host  
247 ecology. Previous studies from Bangladesh suggested that human NiV outbreaks occur primarily (though  
248 not exclusively) within a defined region in western Bangladesh, termed the “Nipah belt,” during a  
249 defined season (Nov-Apr)(37, 59). These observations raised the question of whether human infections  
250 were due solely to the frequency of date palm sap consumption, or whether ecological factors such as  
251 the distribution and timing of bat viral infection also influenced the timing and location of human cases  
252 (17, 35, 60). We undertook an extensive survey of *Pteropus medius* in Bangladesh to understand Nipah  
253 virus infection patterns in its putative reservoir, which is common in Bangladesh and throughout the  
254 Indian subcontinent (14, 25, 61).

255 Overall, our findings suggest viral circulation in bats is not limited to the Nipah belt, but that NiV  
256 transmission occurs in bat populations throughout the country. We observed that virus can be shed by  
257 bats at any time of year, and that viral dynamics are cyclical but not annual or seasonal. Our models fit  
258 to serological data suggest that these cycles may be driven by demographic and immunological factors;  
259 the waning of herd immunity through turnover or individual waning in bat populations allows  
260 heightened viral transmission when seroprevalence passes below a critical threshold.

261 A number of mechanisms have been proposed for the maintenance of acute viral infections in  
262 bat meta-populations, including synchronous birthing and subsequent loss of maternal antibodies (10,  
263 39, 41), lowered immunity within pregnant females due to stress, nutritional stress and other factors  
264 (43) immigration of infected individuals from other colonies (53, 62, 63), and recrudescence within  
265 previously-infected individuals (10, 55, 64). Our modeling indicates that NiV is primarily driven by  
266 density-dependent transmission dynamics among adult bats, with cycles of higher seroprevalence that  
267 would dampen intra-colony transmission followed by waning of antibody titers within individuals and at  
268 a population level. Waning humoral immunity against Nipah virus is a consistent feature of henipavirus  
269 studies in African pteropodid bats (52, 65). Our recapture data provided the first reported evidence of  
270 the loss of detectable NiV IgG antibodies in recaptured individual free-ranging bats, which supports our  
271 observation of population level waning immunity. The consistently lower and decreasing seroprevalence  
272 that we observed in juveniles suggests that they lose maternal antibodies over their first year, and likely  
273 in the first 6-7 months, consistent with other studies of maternal antibodies against henipaviruses in  
274 pteropodid bats (43, 52, 56, 66). However, our data and analysis do not support the hypothesis that  
275 seasonal pulses of these new seronegative individuals are the primary driver of new outbreaks in adults  
276 (41).

277 Our model outputs suggest that spikes in viral transmission occur within colonies after immunity  
278 has waned. Nipah virus reintroduction within a colony may occur from a persistently infected (e.g.  
279 recrudescence) or the introduction of an infected individual via immigration. Recrudescence of  
280 henipavirus infection has been observed for NiV in captive *P. vampyrus* (55), for henipavirus in captive *E.*  
281 *helvum* (52, 57), and has also been observed in humans infected by NiV (67) and Hendra virus (68). It is  
282 difficult to know from serology alone whether wild-caught seronegative bats had been previously  
283 infected. Experimental infection of naïve and previously infected *Pteropus medius* that have sero-  
284 reverted would provide a better understanding of how humoral immunity influences individual  
285 susceptibility to infection, and inform dynamics models attempting to explain viral maintenance within  
286 bat populations (65).

287 Our longitudinal study is limited in that it may not reflect temporal infection dynamics in all bat  
288 populations across Bangladesh. Our roost count data and recapture data from microchipped bats  
289 showed how roost sizes can fluctuate, and local roost shifting can occur. The observation of individual  
290 bats using multiple roost sites suggests that changes in roost count, which our models suggest impacts  
291 transmission dynamics, could reflect local shifts in densities rather than fluctuations in regional  
292 populations.

293 Understanding how bat populations connect across landscapes is important for understanding  
294 viral maintenance, and studying local and migratory bat movements can provide important ecological  
295 information related to viral transmission, including how bats move between different colonies (53, 69).  
296 Our satellite telemetry data suggest that *P. medius* exists as a metapopulation, like other pteropid  
297 species (10, 63). However, *P. medius* appear to travel shorter distances and remain within a smaller  
298 home range (321.46km<sup>2</sup> and 2,865.27km<sup>2</sup> for two groups) compared to *P. vampyrus* in Malaysia (64,000  
299 km<sup>2</sup> and 128,000 km<sup>2</sup>) and *Acerodon jubatus* in the Philippines which are similarly sized fruit bats (53,  
300 70). Pteropodid bat migration is primarily driven by seasonal food resource availability (54, 71-73). In  
301 Bangladesh, *P. medius* prefer to roost in human-dominated environments in highly fragmented forests  
302 (74). The anthropogenic colonization and conversion of land over recent human history has likely led to  
303 increased food availability for *P. medius* and reduced the impetus for long-distance migration (34). This  
304 may reflect a similar adaptation to anthropogenic food resources as observed over the last few decades  
305 in Australian *Pteropus* species (63). Genetic analysis of *P. medius* across Bangladesh has shown that the  
306 population is panmictic – that historically, there has been extensive gene flow and intermixing among  
307 populations across Bangladesh(69). However, if bat dispersal is currently more localized than population  
308 genetic data suggest, as shown in satellite-tracked individuals, then less connectivity among populations  
309 may influence Nipah transmission by creating longer inter-epidemic periods and larger amplitude  
310 fluctuations in population level immunity compared to more migratory species (63).

311 Bat movement and population connectivity may also influence the genetic diversity of Nipah  
312 virus found in different locations, and genotypic variation has been associated with different clinical  
313 outcomes in people. While the overall strain diversity among Nipah virus has not been well  
314 characterized due to a dearth of isolates, two distinct NiV clades have been described: A Bangladesh  
315 clade, that includes sequences identified in India and Bangladesh; and a Malaysian clade, that comprises  
316 sequences from Malaysia, Cambodia, The Philippines and Thailand (16, 58, 75). Strains of NiV from these  
317 two clades are associated with differences in pathogenesis, epidemiological and clinical profiles in

318 humans and animal models and observed shedding patterns in bats (45, 76-80). Phenotypic variation in  
319 Nipah virus could influence observed human outbreak patterns by altering transmission to, or  
320 pathogenesis in, humans, and the likelihood of smaller outbreaks being identified or reported (81).  
321 Human-to-human NiV transmission via contact with respiratory and other secretions has been regularly  
322 observed in Bangladesh and India, including the recent 2018 outbreak in Kerala (12, 59, 82), whereas  
323 transmission among people was not a common feature of the Malaysia outbreak, despite close contact  
324 between cases and health care providers (83, 84). Nipah virus cases in Bangladesh have shown more  
325 strain diversity than in the Malaysia outbreak (85).

326         Until now, there have been very few Nipah sequences obtained from *P. medius*. We found that  
327 Nipah N-gene sequence from bats from the Faridpur population were nearly identical over time,  
328 compared to variation in N-gene sequences from bats and humans from other locations observed over  
329 the same time period (2006-2010). This suggests that there may be locally prevalent and stable NiV  
330 genotypes that persist within bat colonies. Human NiV genotype diversity is likely a reflection of the  
331 relative diversity of the NiV strains in the local bats that seed outbreaks (9). This is also supported by  
332 viral sequences obtained from human and bats associated with the 2018 NiV outbreak in Kerala, India,  
333 where human NiV sequences were most closely related to local *P. medius* sequences (86). We found a  
334 significantly divergent NiV strain in Comilla, which clustered within the Malaysia NiV clade, suggesting  
335 that strains from both clades are circulating in bats in Bangladesh.

336         Connectivity of pteropid bats in Bangladesh with those in Southeast Asia could explain the  
337 observed strain diversity in our study. Historical interbreeding of *P. medius* with pteropid species found  
338 in Myanmar, Thailand, and Malaysia and our telemetry findings showing bats are capable of flying  
339 hundreds of kilometers, could explain our discovery of a Malaysia clade NiV sequence in bats from  
340 Comilla (69). NiV Bangladesh strains have also been found in *P. lylei* in Thailand (87). The N gene of the  
341 Comilla NiV strain differs from those reported from bats in the Nipah belt by 20%, whereas NiV Malaysia  
342 and NiV Bangladesh differ by only 6-9% and are associated with different clinical profiles. Whole  
343 genome sequence (which could not be obtained) would have allowed for better characterization of the  
344 Comilla strain, but the N gene is generally conserved relative to other genes, and suggests the rest of the  
345 genome may also be highly divergent. It is therefore plausible that the clinical profile of a 20% divergent  
346 NiV strain differs significantly from known strains. Sequence information from an isolated human NiV  
347 case in Comilla has not been reported, so comparison to sequence we found in bats was not possible  
348 (37). Studies linking viral genotype to clinical phenotype in people would provide insight into the  
349 implications of strain diversity in bats for human outbreaks.

350         Finally, our study sheds light on the sporadic nature of NiV outbreaks with multi-year inter-  
351 epidemic periods in South Asia. PCR results show that overall NiV incidence in *P. medius* is low,  
352 consistent with previous studies of Hendra and Nipah virus (43, 48, 88, 89). Our modeling suggests that  
353 PCR-positive samples are more likely to be identified during viral transmission spikes after periodic  
354 reintroduction into populations that have become susceptible through waning immunity (10). Viral  
355 detection in bats has also coincided with human outbreaks (58, 86). This is likely a rare or at least  
356 sporadic event. In the current study, observed seroprevalence patterns and the fitted model suggest  
357 that three periods of transmission occurred over the 6 years of sampling, each of which followed periods  
358 of low adult seroprevalence, though not all measurements of low seroprevalence were followed by

359 outbreaks. We detected NiV RNA during periods of both increasing and decreasing seroprevalence,  
360 supporting the fitted model that suggested that shedding can occur even in periods without sustained  
361 transmission. This could explain variation in the number of human outbreaks (e.g. spillover events) from  
362 year-to year in Bangladesh. Thus, the timing of multiple factors involved in driving transmission  
363 dynamics needs to align for intra-colony NiV transmission events and further align with human behavior  
364 and availability of a route of spillover for human outbreaks to occur, as previously hypothesized (90).  
365 Thus, bat NiV dynamics combined with the seasonality and specific geography of date palm sap  
366 consumption in Bangladesh likely explains the sporadic nature of human outbreaks in the region (35).

367 These findings suggest that Nipah virus outbreaks in other regions of Bangladesh where  
368 *Pteropus* spp. bats occur, are also likely to be sporadic and rare, leading to under-reporting or a lack of  
369 reporting, particularly given that human neurologic symptoms are similar to other common infections,  
370 such as Japanese encephalitis, malaria, and measles (91). Understanding whether some NiV strains are  
371 capable of causing mild or asymptomatic cases will provide important insights about why outbreaks may  
372 not have been detected in areas such as eastern Bangladesh or other parts of Asia, where host, virus,  
373 and potential routes of spillover exist. Mild or asymptomatic cases would be unlikely to be detected by  
374 current surveillance systems and it's possible that cryptic spillovers have occurred in Bangladesh, where  
375 about half of all outbreaks between 2007 and 2014 were unreported (92). Our work and other reports  
376 suggest that Nipah virus transmission is possible wherever *Pteropus* spp. bats and humans live in close  
377 association and at any time of year, provided there is an available route of transmission. The 2018 and  
378 2019 spillover events in Kerala, India, which were linked to local *P. medius* colonies and which occurred  
379 in an area that does not cultivate date palm sap, further emphasize this point.

380 Identifying areas where high risk interfaces exist between pteropid bats and people, throughout  
381 their range, will be important for monitoring Nipah spillover events and quickly responding to  
382 outbreaks, as well as establishing interventions to prevent spillover. Raising awareness of the potential  
383 for contaminated food to be a route of Nipah virus transmission and in protecting food resources to  
384 limit human or livestock exposure, may be effective in reducing the risk of a more transmissible strain of  
385 Nipah virus from emerging and causing an epidemic with significant human and animal mortality.

386

## 387 **Methods**

388 The study period was between January 2006 and November 2012. The study was conducted under Tufts  
389 University IACUC protocol #G929-07 and icddr,b AEEC protocol 2006-012 with permission from the  
390 Forest Department, Government of Bangladesh. Locations were selected based on whether the district  
391 had any previously recorded human NiV encephalitis clusters at the time of this study and was therefore  
392 inside the Nipah Belt (e.g. Rajbari, Tangail, Thakurgaon, and Kushtia) or whether they had not and were  
393 outside the Nipah Belt (e.g. Comilla, Khulna, Sylhet, and Chittagong). The Thakurgaon study was  
394 conducted as part of an NiV outbreak investigation, and coincided with ongoing human transmission  
395 (93). Between 2006-2012, three different studies of *Pteropus medius*, with similar bat sampling  
396 protocols were performed: 1) a cross-sectional spatial study with a single sampling event in each of the  
397 eight locations listed above; 2) a longitudinal study of a Faripur bat colony with repeated sampling  
398 approximately every 3 months from July 2007 to November 2012; and 3) a longitudinal study of the  
399 Rajbari colony with repeated sampling at a monthly interval between 12 month period between April  
400 2010 and May 2011. Opportunistic sampling of *Pteropus medius* was also performed during this time

401 period during NiV outbreak investigations [Bangha, Faridpur (Feb 2010), Joypurhat (Jan 2012), Rajbari  
402 (Dec 2009), West Algi, Faridpur (Jan 2010)]. Bats were captured using mist nets at locations within eight  
403 different districts across Bangladesh between January 2006 and December 2012 (**Figure 1**).

404

#### 405 *Capture and sample collection*

406 For the country-wide cross-sectional and Faridpur longitudinal study, approximately 100 bats  
407 were sampled at each sampling event, which lasted 7-10 days. This sample size allowed us to detect at  
408 least one exposed bat (IgG antibody-positive) given a seroprevalence of 10% with 95% confidence. Bats  
409 were captured using a custom-made mist net of approximately 10 m x 15 m suspended between  
410 bamboo poles which were mounted atop trees close to the target bat roost. Catching occurred between  
411 11 pm and 5 am as bats returned from foraging. To minimize bat stress and chance of injury, nets were  
412 continuously monitored and each bat was extracted from the net immediately after entanglement.  
413 Personal protective equipment was worn during capture and sampling, which included dedicated long-  
414 sleeve outerwear or Tyvek suits, P100 respirators (3M, USA), safety glasses, nitrile gloves, and leather  
415 welding gloves for bat restraint. Bats were placed into cotton pillowcases and held for a maximum of 6  
416 hours before being released at the site of capture. Bats were sampled at the site of capture using a field  
417 lab setup. Bats were anesthetized using isoflurane gas (94) and blood, urine, oropharyngeal swabs, and  
418 wing membrane biopsies (for genetic studies) were collected. For some sampling periods, rectal swabs  
419 were collected but due to resource constraints, these samples were deemed to likely be lower yield than  
420 saliva and urine for NiV, and were discontinued during the study. For each bat sampled we recorded  
421 age, weight, sex, physiologic and reproductive status, and morphometric measurements as described  
422 previously (25). Bats were classified as either juveniles (approximately four to six months - the age by  
423 which most pups are weaned) to two years old (the age when most *Pteropus* species reach sexual  
424 maturity) or adults (sexually mature) based on body size and the presence of secondary sexual  
425 characteristics, pregnancy, or lactation - indicating reproductive maturity (25, 95).

426 Up to 3.0 mL of blood were collected from the brachial vein and placed into serum tubes with  
427 serum clot activator (Vacutainer, USA). Blood tubes were stored vertically on ice packs in a cold box  
428 and serum was allowed to separate overnight. Serum was drawn from the tube after 24 hours and  
429 placed in a screw-top cryovial (Corning, USA) and stored in a liquid nitrogen dewar (Princeton  
430 Cryogenics, NJ, USA). Sterile pediatric swabs with polyester tips and aluminum shafts were used to  
431 collect urogenital and rectal samples, and larger polyester swabs with plastic shafts (Fisher, USA) were  
432 used to collect oropharyngeal samples. All swabs were collected in duplicate, with one set being placed  
433 individually in cryotubes containing lysis buffer (either tri-reagent or NucliSENS Lysis buffer,  
434 BIOMERIEUX, France) and the second set in viral transport medium. All tubes were stored in liquid  
435 nitrogen in the field then transferred to a -80C freezer.

436 During each sampling event, pooled urine samples were collected beneath bat roosts using  
437 polyethylene sheets (2' x 3') distributed evenly under the colony between 3 am and 6 am. Urine was  
438 collected from each sheet either using a sterile swab to soak up droplets, or a sterile disposable pipette.  
439 Swabs or syringed urine from a single sheet were combined to represent a pooled sample. Each urine  
440 sample was divided in half and aliquoted into lysis buffer or VTM at an approximate ratio of one part  
441 sample to two parts preservative.

442

443 *Serological and molecular assays*

444 Sera from the cross-sectional survey were heat inactivated at 56°C for 30 minutes, as described  
445 (96) prior to shipment to the Center for Infection and Immunity at Columbia University (New York, USA)  
446 for analysis. Samples were screened for anti-NiV IgG antibodies using an enzyme linked immunosorbent  
447 assay (ELISA) as described in (25). Sera from the longitudinal studies were sent to the Australian Animal  
448 Health Laboratory and were gamma irradiated upon receipt. Because of the large sample size and  
449 development of a high throughput multiplex assay of comparable specificity and sensitivity, for these  
450 samples we used a Luminex®-based microsphere binding assay to detect anti-Nipah G IgG antibodies  
451 reactive to a purified NiV soluble G protein reagent, as described previously (97, 98). Samples resulting  
452 in a Median Fluorescent Intensity (MFI) value of over 1000 were considered positive for NiV antibodies  
453 in this study. An MFI of 250 and below is considered negative for other bat species and previous studies  
454 have reported using a threshold of at least three times the mean MFI of negative sera to determine the  
455 cutoff (43, 99-101). This approach is considered appropriate for research purposes for bats, and was  
456 used to determine the cutoff in this study.

457 Total nucleic acids from swabs and urine samples were extracted and cDNA synthesized using  
458 Superscript III (Invitrogen) according to manufacturer's instructions. A nested RT-PCR and a real-time  
459 assay targeting the N gene were used to detect NiV RNA in samples (102). A RT-qPCR designed to detect  
460 the nucleocapsid gene of all known NiV isolates was also utilized (103). Oligonucleotide primers and  
461 probe were as described (103). Assays were performed using AgPath-ID One-StepRT-PCR Reagents  
462 (ThermoFisher) with 250 nM probe, 50 nM forward and 900 nM reverse primers. Thermal cycling was  
463 45°C for 10 min, followed by 45 cycles of 95°C for 15 s and 60°C for 45 s. Cut-off values were cycle  
464 threshold ( $C_T$ )  $\leq 40$  for positive and  $C_T \geq 45$  for negative. Results with  $C_T$  values between 40 and 45 were  
465 deemed indeterminate, i.e. not conclusively positive or negative. Samples with NiV RNA detected by real  
466 time PCR were confirmed by gel electrophoresis and product sequencing.

467 A subset of NiV-positive samples was processed by high-throughput sequencing (HTS) on the Ion  
468 Torrent PGM platform in order to obtain additional NiV genomic sequence. Libraries were prepared  
469 according to the manufacturer's instructions, and 1 million reads allocated per sample. HTS reads were  
470 aligned against host reference databases to remove host background using bowtie2 mapper, and host-  
471 subtracted reads primer trimmed and filtered based on quality, GC content and sequence complexity.  
472 The remaining reads were de novo assembled using Newbler (v2.6) and mapped to the full length NiV  
473 genome. Contigs and unique singletons were also subjected to homology search using MegaBlast  
474 against the GenBank nucleotide database, in case variance in parts of the genome precluded efficient  
475 mapping. From these data, N gene consensus sequences were constructed using Geneious v 7.1, and  
476 used for phylogenetic analyses.

477

478 *Phylogenetic analysis*

479 All *P. medius* NiV sequences have been submitted to Genbank and accession numbers are  
480 included in **Figure 6**. Sequence alignments were constructed using ClustalW in Geneious Prime software  
481 (104). Phylogenetic trees of NiV N-gene sequences were constructed using Neighbor-Joining algorithms  
482 and figures constructed in FigTree 1.4.2.

483

484 *Satellite telemetry and home range analysis*

485 We developed a collar system to attach 12g solar-powered Platform Terminal Transmitters (PTT)  
486 (Microwave Telemetry, Colombia, MD, USA) to adult bats using commercial nylon feline collars with the  
487 buckle removed and 0-gauge nylon suture to attach the PTT to the collar and to fasten the collar around  
488 the bat's neck. Collars were fitted to the bat such that there was enough space to allow for normal neck  
489 movement and swallowing, but so that the collar would not slip over the head of the animal (**Figure S6**).  
490 PTTs were programmed with a duty cycle of 10 hours on and 48 hours off. Data was accessed via the  
491 Argos online data service (argos-system.org; France). A total of 14 collars were deployed as follows: Feb  
492 2009: 3 males, 3 females from a colony in Shuvarampur, Faridpur district; Feb 2011: 3 males, 2 females  
493 from the same colony; and April 2011 Cox's Bazaar, 3 bats from a colony in Cox's Bazaar, Chittagong  
494 district. Bats were selected based on size such that the total weight of the collar (~21g) was less than 3%  
495 of the bat's body mass (Table S3).

496 The individual telemetry dataset was combined for each region and its aggregate utilization  
497 distributions (UD) computed in R using package 'adehabitatHR' (105). Population-specific home range is  
498 represented by the \*95% area enclosure of its UD's volume. The volume of intersection between the  
499 colonies quantifies the extent of home range overlap. To evaluate the potential for contact with the  
500 Sylhet colony, we calculated the most likely distance moved ('mldm') for each sampled bat at Faridpur  
501 where the population was more intensively monitored. Movement distance was measured in kilometers  
502 with respect to a centroid location ( $\omega$ ) shared by the whole colony; assuming random spatial distribution  
503 in tracking rate, we estimated its kernel density function per individual and defined mldm as the mode.

504

#### 505 *Statistical approach – cross-sectional study*

506 We fit a Bayesian generalized linear model with a logit link and a Bernoulli outcome to identify  
507 potential predictors which influenced a bat's serostatus. We included age, sex, age- and sex-normalized  
508 mass and forearm length, mass:forearm ratio, body condition, and whether the bat was pregnant,  
509 lactating, or carrying a pup, using weak zero-centered normal priors for all (normalized) coefficients. We  
510 included location of sampling as a group effect (similar to a random effect in a frequentist context)  
511 nested within Nipah Belt or non-Nipah Belt regions. We fit the models and performed posterior  
512 predictive checks in R 3.4.3, using the **rstanarm** and **rstan** packages.

513

514

515

#### 516 *Statistical approach – longitudinal study*

517 We fit binomial general additive models (GAMs) (106) to the time series of adult and juvenile  
518 seroprevalence in the longitudinal study. We included annual, synchronous birthing that occurred  
519 between March and April. We assumed that pups weaned from their dams at 3 months, and became  
520 independent flyers, and that maternal antibodies waned after 6 months at which point pups  
521 transitioned into the "juvenile" class (61, 66). We assumed that juveniles became sexually mature at 24  
522 mo., and entered the "adult" class based on other pteropid species (43, 61, 107). For juveniles, we  
523 modeled the birth cohort of bats as separate random effects in a pooled model of juveniles' dynamics  
524 starting from June of their birth year, June being the earliest month we sampled free-flying juveniles in  
525 any cohort. We determined the cohort year of juveniles by using cluster analysis to group individuals by  
526 weight, assuming those in the smallest group were born in the current year and those in the larger

527 group were born the previous year. 92% of juveniles captured were yearlings. For adults, we modeled  
 528 dynamics of adults as a single pool over the entire course of the study. We tested models with and  
 529 without annual cyclic effects.

530 Where time series had significant temporal autocorrelation (adults only), we aggregated data by  
 531 week. We determined periods of significant increase in decrease as those where the 95% confidence  
 532 interval of the GAM prediction's derivative did not overlap zero. We fit the models and performed  
 533 checks in R 3.4.3, using the **mgcv** package.

534 To examine the importance of different biological mechanisms in transmission, we fit an age-  
 535 structured (adult and juvenile) maternally immune (M)-susceptible (S)-infected (I)-recovered (R) model  
 536 with recrudescence (R to I) and loss of immunity (R to S) to the seroprevalence data on a weekly  
 537 timescale:

$$\frac{dS_J}{dt} = -S_J(\beta_{JJ}I_J + \beta_{AJ}I_A) - \mu_J S_J + bN_A(t-5)\frac{S_A}{N_A} - bN_A(t-52)\frac{S_J}{N_J}(1-\mu_J)^{52} + \lambda M_J$$

$$\frac{dI_J}{dt} = S_J(\beta_{JJ}I_J + \beta_{AJ}I_A) - \gamma I_J - bN_A(t-52)\frac{I_J}{N_J}(1-\mu_J)^{52}$$

$$\frac{dR_J}{dt} = \gamma I_J - \mu_J S_J - \mu_J R_J - bN_A(t-52)\frac{R_J}{N_J}(1-\mu_J)^{52}$$

538 
$$\frac{dM_J}{dt} = bA(t-5)\frac{R_A}{N_A} - \lambda M_J - \mu_J M_J - bN_A(t-52)\frac{R_A}{N_A}(1-\mu_J)^{52} \lambda^{52}$$

$$\frac{dS_A}{dt} = -S_A(\beta_{AA}I_A + \beta_{JA}I_J) - \mu_A S_A + \tau R_A + bN_A(t-52)\frac{S_J}{N_J}(1-\mu_J)^{52}$$

$$\frac{dI_A}{dt} = S_A(\beta_{AA}I_A + \beta_{JA}I_J) - \gamma I_A - \mu_A I_A + bN_A(t-52)\frac{I_J}{N_J}(1-\mu_J)^{52} + \Delta R_A$$

$$\frac{dR_A}{dt} = \gamma I_A - \mu_A R_A + bN_A(t-52)\frac{R_J}{N_J}(1-\mu_J)^{52} - \tau R_A - \Delta R_A$$

539 We included a class M for the density of juvenile bats with maternal antibodies to allow for the biological  
 540 possibility that maternal antibodies are lost at a much higher rate than antibodies acquired following  
 541 infection. The subscripts J refer to juveniles and A to adults,  $\beta$  is the transmission rate,  $\gamma$  is the recovery  
 542 rate,  $\mu$  is the mortality rate,  $\tau$  is the rate of loss of adult immunity,  $\lambda$  is the rate of loss of maternal  
 543 antibodies(66),  $\Delta$  is the adult recrudescence rate (R to I),  $b$  is the birth rate (pups join the juvenile  
 544 population after 5 weeks). Juveniles transition to adults after 52 weeks. We included terms for loss of  
 545 antibody in adults ( $\tau$ , S to R), and viral recrudescence ( $\Delta$ , R to I) based on previous studies on captive bats  
 546 that demonstrated the existence of these processes without providing enough data to characterize them  
 547 precisely (55, 56). We fit this deterministic model to the seroprevalence data by maximum likelihood,  
 548 which assumes that deviations from the model are due to observation error. We estimated the confidence  
 549 intervals around maximum likelihood parameter estimates using likelihood profiles using the *profile*  
 550 function in package *bbmle* in R v3.2.2.

551 We used model fitting and model comparison to examine the need for several of the biological  
 552 processes in the model above that could influence NiV dynamics. First, we examined both density and  
 553 frequency-dependent transmission by comparing the fit of the model above to one with transmission

554 terms that have population size ( $N_A$  or  $N_J$ ) in the denominator. Second, we examined the confidence  
555 intervals of the parameters describing viral recrudescence, loss of antibodies in adult bats, and loss of  
556 antibodies in juvenile bats. If the confidence bounds for these parameters included zero, then these  
557 biological processes are not needed to explain the serological dynamics. Finally, we examined the  
558 confidence bounds for parameters describing the loss of maternal and non-maternal antibodies ( $\tau$  and  
559  $\lambda$ ), to determine if the rate of loss of these two types of immunity were different. We note that this  
560 model structure has similarities to a susceptible-infected-latently infected(L)-infected (SILI) model (if  
561 latently infected individuals are seropositive), but the model above differs in allowing for the possibility  
562 of individuals to transition from the R class back to the S class.

#### 563 *Code availability*

564 SIR model code written in R is available upon request.

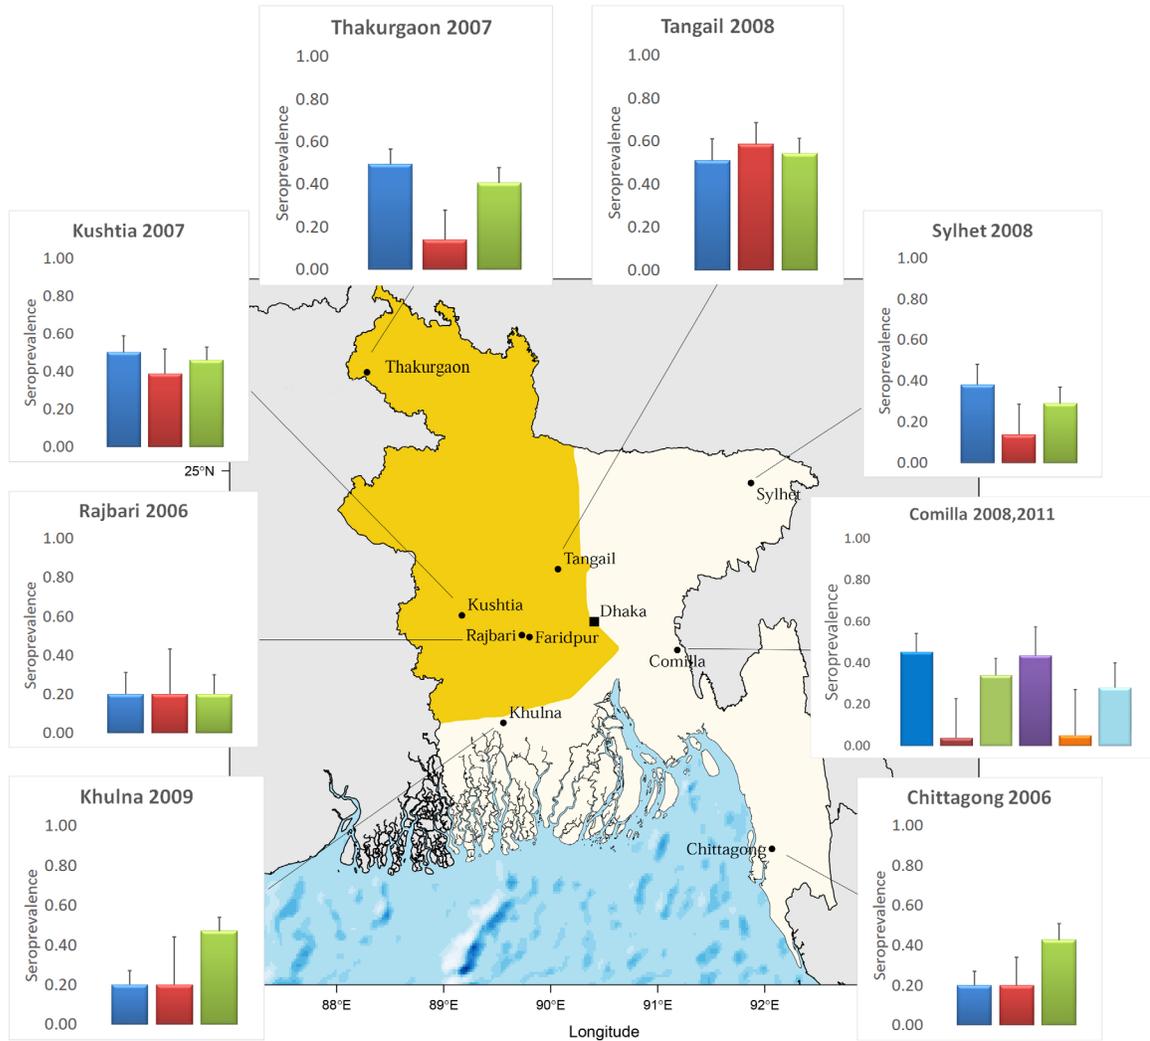

565

#### 566 *Data availability*

567 All molecular sequences are available via Genbank. The datasets generated during and/or analyzed  
568 during the current study are available from the corresponding author on reasonable request.

569

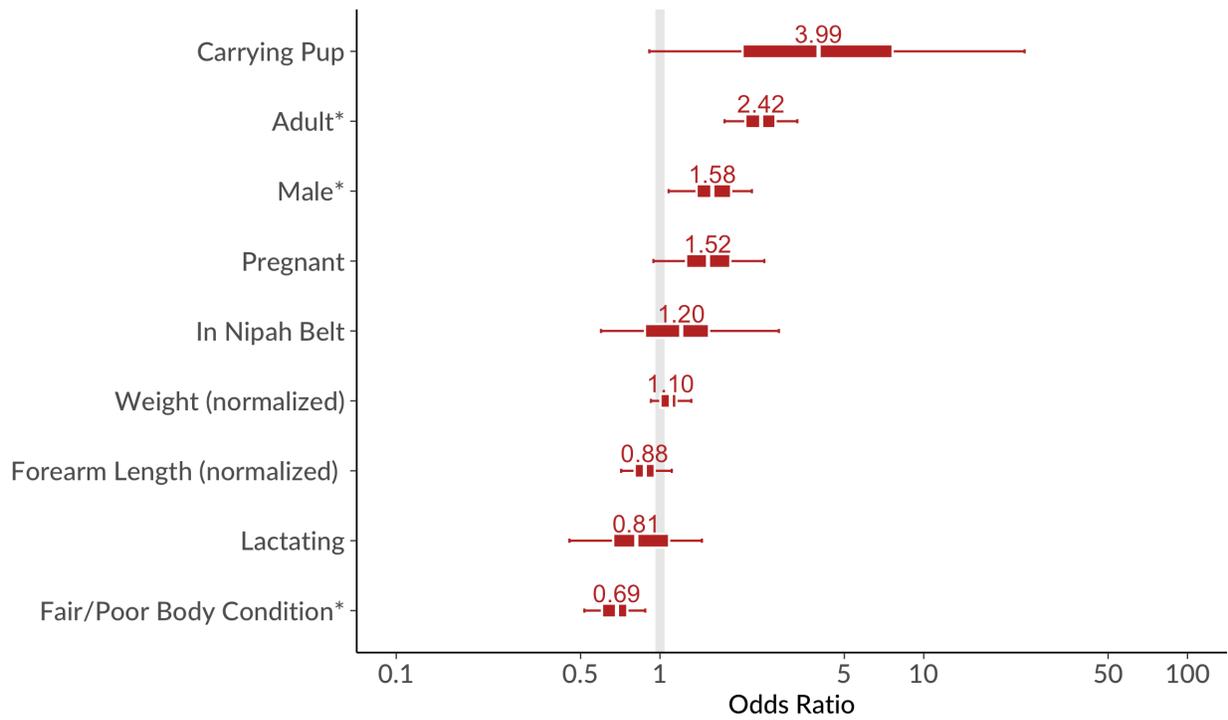

570 **Acknowledgements:** We thank Pitu Biswas, Md. Sheikh Gofur, Abdul Hai, and Craig Smith for assistance  
571 in the field, Toph Allen, and Parvize Hosseini for technical input, Eliza Choi; Yan-Ru Feng and Lianying  
572 Yan for preparing recombinant viral glycoproteins; Jennifer Barr, Vishal Kapoor, Neil Renwick, and  
573 Mohammad Ziadur for laboratory diagnostic and technical support, anonymous reviewers for their  
574 useful comments, and the Government of Bangladesh for permits and logistical support that made this  
575 work possible. This study was funded by an NIH NIAID awards to JHE (AI067549) and CCB (AI054715), an  
576 NIH Fogarty International Center Ecology and Evolution of Infectious Diseases (EEID) award to PD (R01  
577 TW005869) a NSF-NIH EEID award to AMK (EF-0914866), a NIH NIAID award to Lipkin (U19 AI109761), a

584 GC, SPL, WIL & PD). The authors have no competing interests.

585 **Figure 1.** Map showing age-stratified seroprevalence in *Pteropus medius* colonies, Bangladesh. Bats from eight  
 586 colonies were sampled and tested for anti-NiV IgG antibodies: four within the “Nipah Belt” (orange shaded) and  
 587 four outside. Seroprevalence of adults (blue, purple (2011)), juveniles (red, orange (2011)) and total  
 588 seroprevalence (green, light blue (2011)) are shown. Number (n) of Adult, Juvenile, and Total bats sampled  
 589 (clockwise): Tangail [53,41,94], Sylhet [63, 37, 100], Comilla 2008 [73,27,100], Comilla 2011 [30,20,50], Chittagong  
 590 [72,24,96], Khulna[85,15,100], Rajbari [65,15, 80], Kushtia [64,36,100], Thakurgaon [89,29,118]. The shaded region  
 591 represents the “Nipah Belt” where previous human NiV outbreaks have been reported.

592

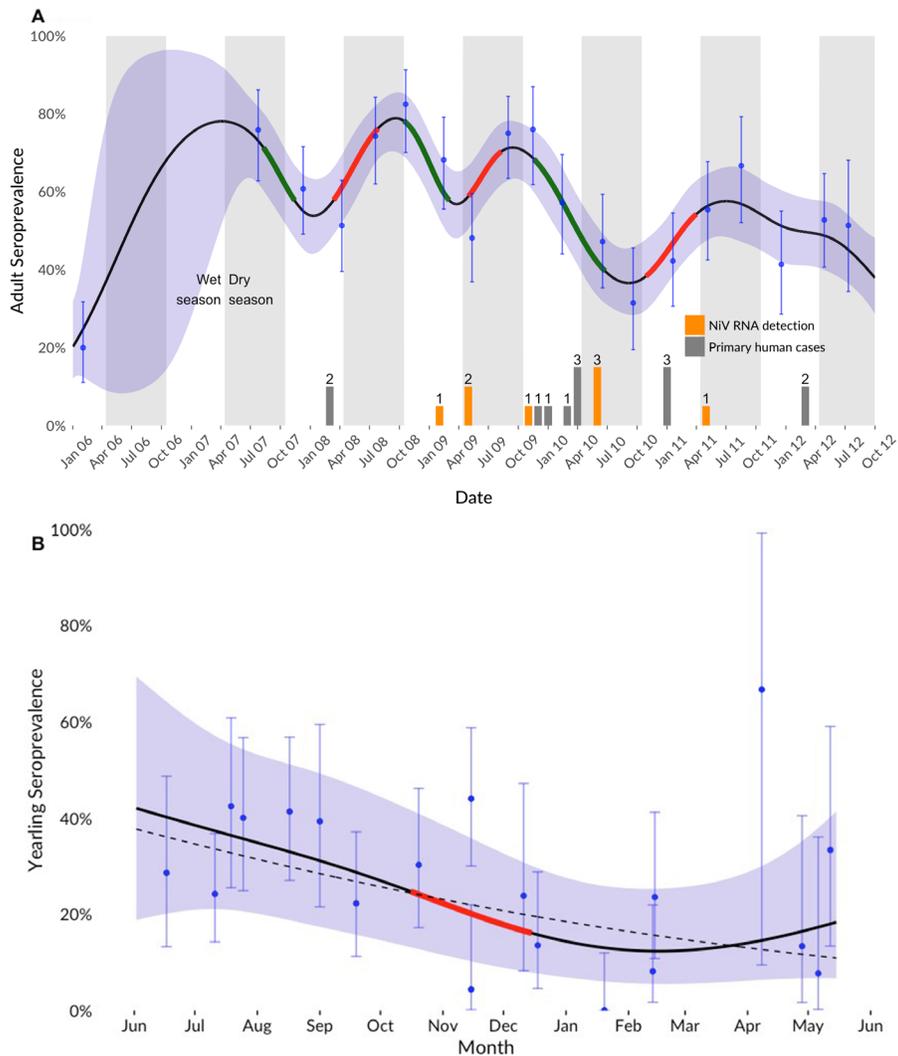

### GLM Estimates: Factors Affecting Nipah Serostatus

593

599

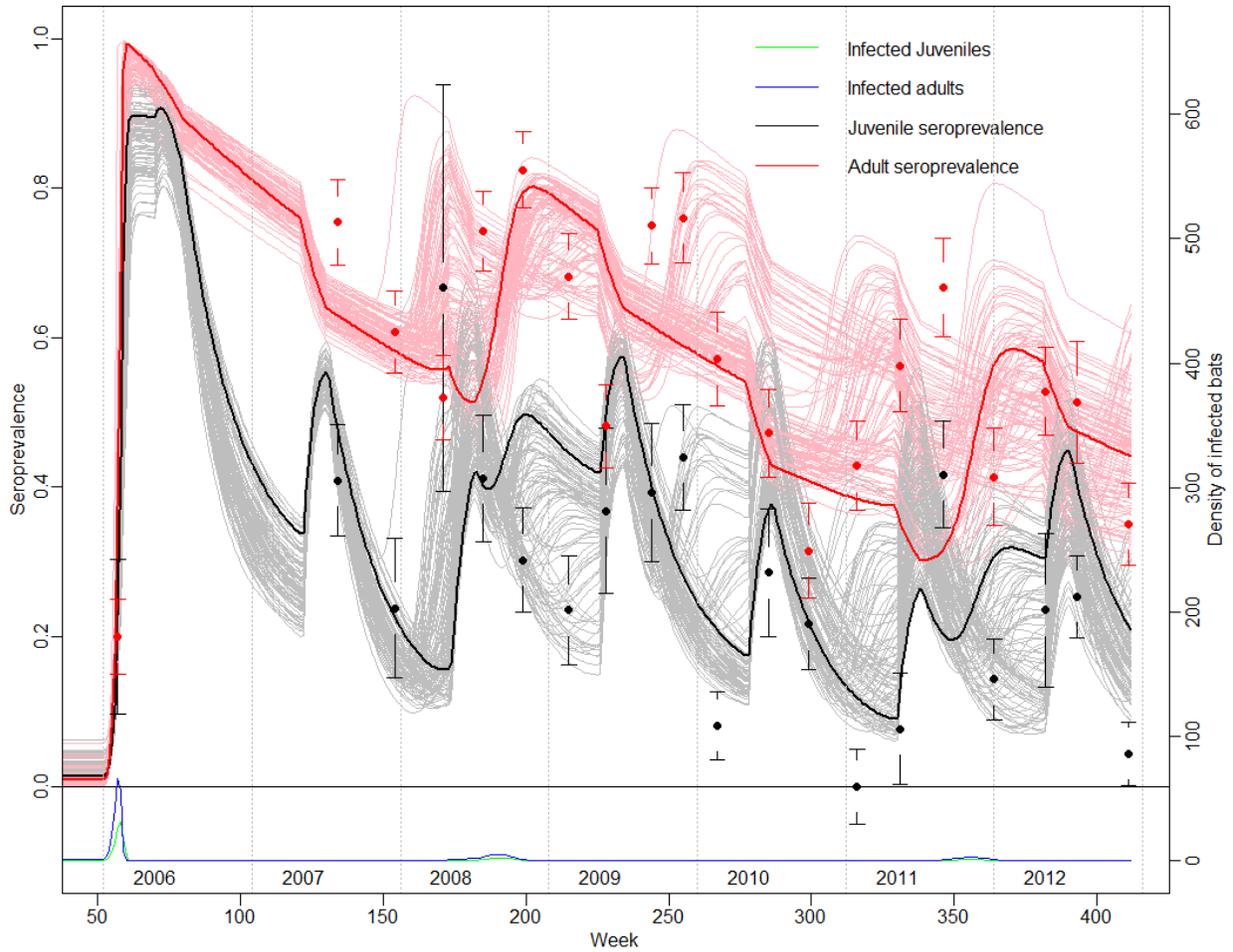

**Figure 2.** Results of Bayesian GLM of factors affecting Nipah serostatus in bats in cross-sectional study. Bars indicate odds ratios and 50% (inner) and 95% (outer) credible intervals for model parameters. Factors with asterisks (\*) have 95% CIs that do not overlap 1. Model intercept (predicted probability of seropositivity for a juvenile, female, bat outside the Nipah belt of mean size and good body condition) was 0.26, (95% CI 0.12-0.56). Random effect of location (not shown) had an estimated SD of 0.63 (95% CI 0.29-1.27)

Nipah virus IgG antibody serodynamics in adult and juvenile *Pteropus medius*, Faridpur, Bangladesh 2006-2012

600 **Figure 3 A & B.** Serodynamics of the Faridpur bat population. (A) Adult serodynamics, with measured values and  
 601 95% CI in blue, and mean GAM prediction and 95% shown with line and surrounding shaded areas. Periods of  
 602 significant increase (red) and decrease (green) shown where the GAM derivative's 95% CI does not overlap zero.  
 603 Counts of primary human cases from local district (dark gray, and bat viral detections of approx. 100 sampled  
 604 (orange, see Table 1), shown on bottom. (B) Juvenile serodynamics during the first year of life ("yearlings"), with all  
 605 years' measurements overlain to show cohort-level dynamics across all study years. Measured values and 95% CI in  
 606 blue, and mean and 95% CI for the GAM model pooled across cohorts shown with line and surrounded shaded  
 607 areas. The period of significant decline in the GAM is shown in red. Also shown is the mean prediction of a model  
 608 with only a linear mean term, with similar fit ( $\Delta AIC < 1$ ) as the GAM (dotted line).

877 Supporting Information

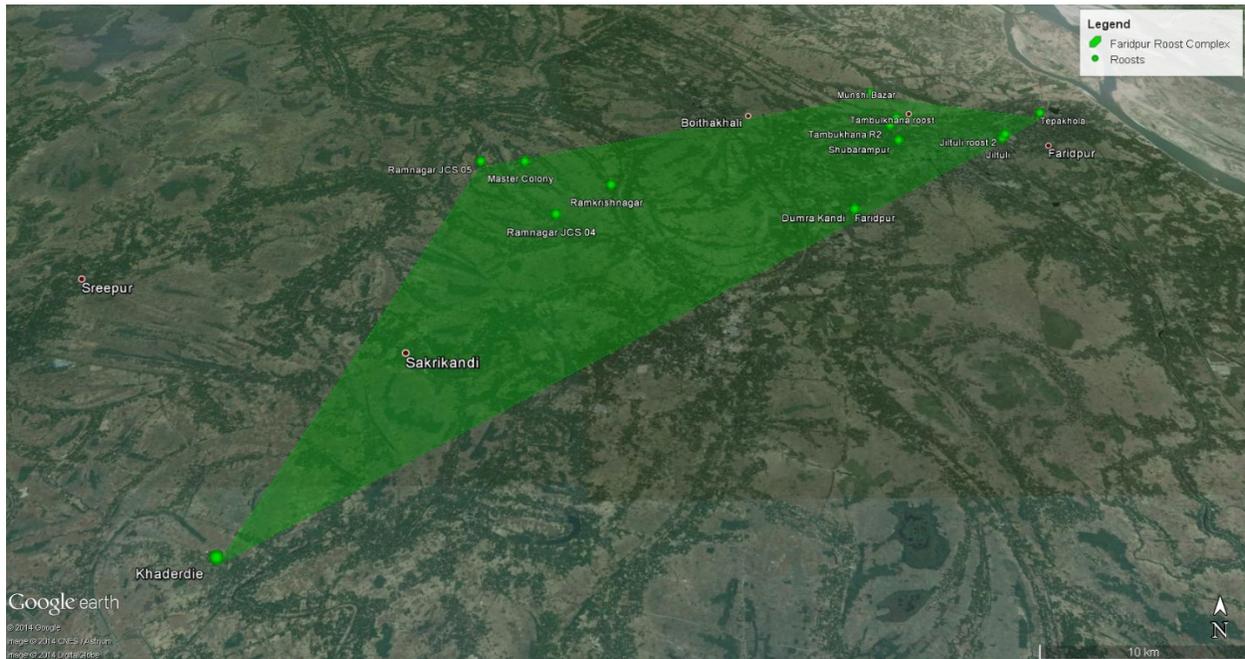

878

879 **Figure S1.** *Pteropus medius* counts from selected roosting sites within the Faridpur Roost Complex: 2008-2012.

880 Sites were included if repeated counts were conducted. Domrakandi and Kaderdi were the two primary roost sites

881 sampled for the longitudinal study and counts were used for the model parameter.

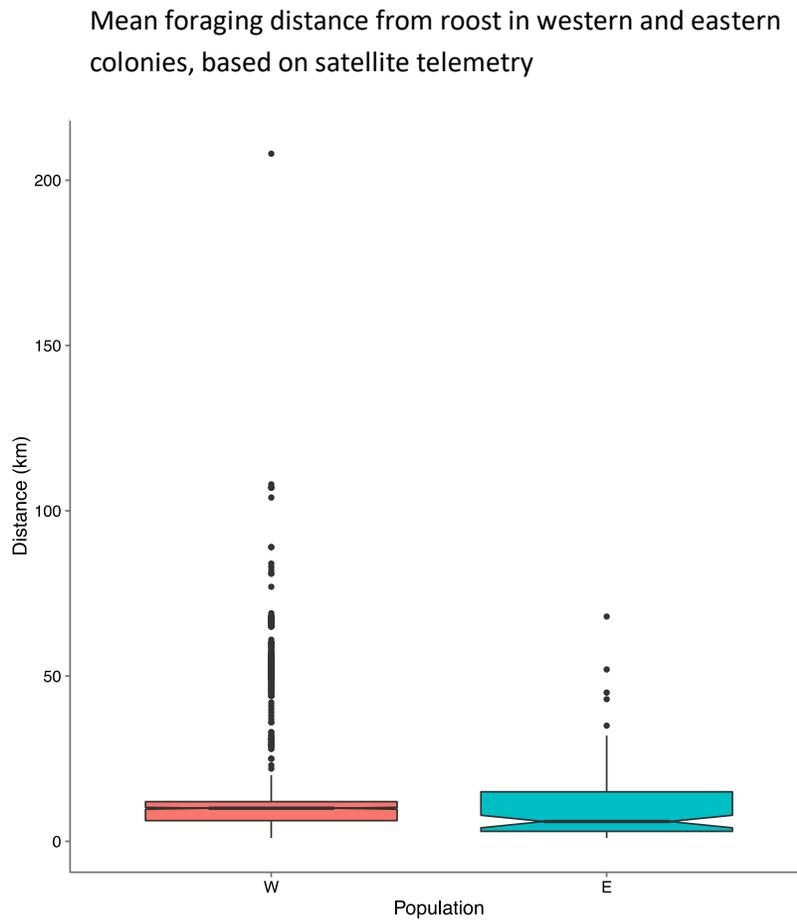

882

884

885 **Figure S2.** Faridpur Roost Complex. 51 Individual bats were recaptured during the longitudinal study at various  
 886 locations. 33 bats were recaptured at a different site from where they were originally sampled. 15 unique roosts  
 887 within an 80km<sup>2</sup> area were identified.

**Figure S5. Nipah Virus phylogenetic tree, N gene:** Clustal W alignment using nearly whole N gene consensus sequence from *P. medius* (1,592 nt) using Geneious Prime 2019 (108). The evolutionary history was inferred by using the Maximum Likelihood method and Hasegawa-Kishino-Yano model (109). The percentage of trees in which the associated taxa clustered together is shown next to the branches. The tree is drawn to scale, with branch lengths measured in the number of substitutions per site. Evolutionary analyses were conducted in MEGA X (110). Genbank accession numbers for sequences (from top to bottom): *P. medius* Maniganj & Sylhet pending (63); JN808864, AY988601, MH396625, FJ513078, JN808863, JN808857, AY858110, FN869553, AJ627196, AJ564623, AY029767, AF376747, AY029768, JN255803.

Dear co-authors,

Our paper has been submitted to PNAS! Thank you all for your thoughtful and helpful comments.

I think you've each received a link to the submission from PNAS, but if not, here's the version that was submitted.

I'll be in touch when I hear anything.

Cheers,

Jon

On Wed, Dec 18, 2019 at 3:00 PM Jon Epstein <[epstein@ecohealthalliance.org](mailto:epstein@ecohealthalliance.org)> wrote:

All,

I hope this email finds you well. Attached is a draft of our manuscript entitled Nipah virus dynamics in bats and implications for spillover to humans. After multiple protracted periods of review in Science Advances, and ultimately a rejection, I've prepared this draft for submission to PNAS. I've revised the manuscript and updated figures and supplemental data in response to the last round of review (comments below, if you're interested).

I have an editor at PNAS willing to send this for review, so please send me any input you may have by December 28th so that I can submit by the 31st. Unless I hear otherwise, I will assume you still consent to co-authorship.

Thank you for your patience, and happy holidays!

Cheers,

Jon

Reviewer: 1

Epstein et al aim to better understand the distribution and drivers of Nipah virus infection dynamics in *Pteropus medius* in Bangladesh by analysing a large set of serological, virological and movement data over a commendable spatial and temporal scale. Overall, this is a highly exciting study with valuable results that are well-deserving of publication. I have a number of minor comments regarding the addition of detail for clarity (and to ensure transparency in the interpretation of results). I think that the conclusions are mostly justified, however, my major criticism is that the integration and interpretation of the results (particularly those presented in the first paragraph of the discussion) requires a little further thought and explanation. The assumptions surrounding the serological implications of within-host persistence and recrudescence needs to be clearly stated. This is likely to become a 'classic' paper, and there are so few studies in this area supported by data that it is important to ensure that the results are not over-interpreted.

Specific comments:

Abstract:

Line 32- 33: The wording here is too strong regarding recrudescence. Suggest inserting "model results indicated that" prior to "local transmission dynamics."

Line 33-34: Similarly - this is too strong. Suggest "likely due to "

Results:

Figure 1 - presumably the first three bats in the Comilla represent 2008 and the second three represent 2011, but this is not clear. This should be annotated on the plot

Figure 1 - "Adult bats had equal or greater seroprevalence than juveniles in each location."

- except Tangail?

Line 129: "detected NiV RNA in 11 individuals, 3 pooled" - insert 'from' before 3

Line 131: - describe "pooled samples" - pooled under-roost urine samples?

Line 132 and 137: This 'figure 2' seems to be missing? Figure 2 refers to serological analyses

Line 145: I suggest that the reference to Figure 2 in line 146 should go in the sentence ending on line 145

Line 149: the significant negative association with body condition warrants mentioning in these results.

Line 154-155 and Figure 3: Additional clarity here regarding juvenile vs. yearling terms. Suggest saying "Juveniles in their first year of life (yearlings)" at first mentioning in the text, as well in the figure legend.

Line 159 - incomplete sentence

Lines 160-164: Fascinating results!

Lines 170-171: This information would be helpful to include earlier, with the serological results

Figure 3 and Figure S1 - It would be helpful to have a "total population" size from this roost complex included on Figures 3 and 4. Understanding more about the bat ecology and the size and stability of these populations over time would be a tremendous help to aid interpretation of these results by researchers working in other systems.

Lines 175-176: "Serodynamics in juveniles were strongly driven by inheritance and loss of maternal antibodies". Supported by what result? This should be explained further, and/or it would be helpful to include the serology (fig 3), model output (fig 4) and population size (Figure s1) together as a series of vertical panels in the one figure to aid interpretation

Lines 178-180: I can't see this information in the supplementary information

Line 182 - this paragraph (and ideally also table S2) should provide information on the duration of tracking for each bat. This would be very helpful in assessing the home range information

Line 195 - should the 'of' be 'if'?

Figure 6 - the utility of this figure would be greatly improved with some annotation and colouring to help identify the new sequences from this study, and their source location, and the 'groups' that are referred to in the text

Lines 238 - 240 - So, your data has found cyclical serodynamics, but no clear links between those dynamics and detection of NiV in bats or in people. Based on experimental studies, it is still a bit unclear exactly what seropositivity in flying foxes represents. If there is within-host persistence of infection, a cycle of infection > seroconversion (in the absence of clearance) > seroreversion > then recrudescence with seroconversion may occur in the absence of ongoing transmission. Additionally, this does not take into account drivers of recrudescence - if this is stress related, then transmission at the population level will also be affected by these broader drivers. Given all the uncertainty around this topic, I think that the wording here needs to be precise. e.g the first sentence should first state the assumption "Assuming that seroconversion results only from new infections, then ...". This could be followed up with a sentence along the lines of "If however, seroconversion can result from recrudescence in the absence of transmission, then broader drivers of recrudescence would also need to be assessed". More clarity here would also help to assess the claims being made in the paragraph beginning 315.

Lines 240 onwards - consider restructuring this paragraph to more clearly step through each stage of the viral dynamics that you are proposing and your assumptions and evidence along the way. For example, you assume infection results in seroconversion, and that antibodies then wane after ~4 years. Are you assuming that all individuals are persistently infected, and it is only when Ab wane that recrudescence can occur? And following that, the individual seroconverts again?

Lines 243 - 245: Not correct - See Brooks et al 2019 JAE Figure S5. That study also involved modelling and has implications for this study more broadly

Lines 245-247: "via recrudescence FROM bats that have previously been infected"? It's also not clear how this links to lines 238-240

Lines 257-259: Consider also cite Peel et al (2018). Scientific Reports, 8(1), e0004796.

This study examines waning maternal immunity and waning acquired immunity against henipaviruses in African fruit bats, finding a similar duration of immunity for both  
Line 267 - insert "in our study area" after 'Pteropus medius' as you cannot infer whether these patterns hold true for the species across its range. It may be highly dependent on available food resources - as you go on to discuss

Line 277 - replace 'be' with 'result in'

Lines 295-296 - this links with the SILI hypotheses in Plowright et al (2016) PLoS NTD (see Figure 3)

Line 321- suggest "three periods of transmission (significant at the population level) occurred"

Line 315 See my comments re: paragraph beginning Line 238. The sporadic nature of detections is challenging to draw conclusions and much of the paragraph here (starting line 315) seems over-stated. However, that may become clearer if the comments for the earlier paragraph are addressed.

Methods:

Line 364: I can't see reference to the Faripur colony in the list of colonies in lines 358-359. What are its characteristics? Also, I presume it should be "Faridpur"? Also, it would be helpful if the "Faridpur roost complex:" could be described in more detail in the methods as to the structure of this population and what this term means.

Line 366: Delete the first 'between'

Lines 388-390 - check the placement of parentheses here

Line 417: what cutoff was used for the Luminex assay and how was it determined?

Line 425 - fix formatting of second Ct

Line 493- 504: More information on the underlying population dynamic model is required e.g. Were births seasonal or continuous in your model? I can't see where this is stated.

If not seasonal, then the effect of this on model output should be addressed. How was the death rate modelled? Was the total population size kept stable inter annually? The latter, in particular, may have implications for interpretation of the density-dependent vs frequency dependent results. The population size is touched on in the discussion in lines 288-291 but never really explained.

Table S1 - there is extra text below Table S1 that looks like it's not supposed to be there

Table S2 - Include what serostatus 0/1 refers to in the table caption

Reviewer: 2

Dear editor, I have reviewed the manuscript entitled "Nipah virus dynamics in bats and implications for zoonotic spillover to humans". The manuscript describes a longitudinal surveillance in Pteropid spp. Bats from 2006 until 2012. Biometric data was collected, sera and swabs/urine were analyzed, and inferences were made largely based on serological data. The manuscript is a compendium of relatively loosely compiled data, ranging from seroprevalence in a variety of different sampling sites, but the majority of the samples stem from Faridpur. The problem is that most of the claims by the authors within the paper are not directly supported by the data. The direct problem of the data is the limited amount of detected virus shedding, out of 2789 animals sampled only 11 were found to be shedding the virus. From this only 8 were from the larger study cohort from Faridpur. This directly hampers some of the conclusion of potential spillover dynamics as this cannot be directly inferred from serological data alone. In addition, it does not provide any answers on the occurrence of Nipah spillover in the Nipah belt vs the other regions. Moreover, the significant spillover events in Kerala, India from the last two years, are not discussed. Most emphasis has been put on analyzing the serological results from the Pteropus medius bats. The authors show variation in the seroprevalence within the population based on timing and age status of the animal. The results have been reported before in other natural reservoir-pathogen systems like avian influenza, however even within these systems inferences on spillover can rarely be made. It is interesting that the authors did not correlate the positive individual bats in Faridpur and Rajbari with their respective serostatus? Is this data not available? It is unclear to me why the authors have not put more effort in trying to perform full genome analyses on the positive samples obtained throughout this study. Currently there are only 27 full genomes available from Nipah virus

and relatively limited amount are from the natural reservoir. Performing phylogenetic analyses on a 224 nucleotide fragment of a 19kb virus is really not up to standard. Where it might be suitable for identification of the lineage no additional data can be inferred from this. Interestingly, there appears to be full genome sequencing performed but only N is shown in the supplemental data.

Although I do understand the logistics involved with this kind of work, unfortunately some of the claims, especially regarding spillover, need to be supported by more additional data rather than just serology.

Minor points:

Line 65: pandemic potential, given the limited amount of h-to-h transmission the pandemic potential of this particular virus appears to relatively limited.

Line 143: n=844 or n=883? Why do the numbers not match-up?

Line 410, include level of biosecurity involved in sample analyses. In addition, heatinactivation is typically to inactivate complement and not inactivation of the pathogen.

>From the current wording it is unclear what the authors mean by this? Complement inactivation or pathogen inactivation?

Line 428, is this data missing? Where is the NSG data? Why not data on the full genomes? I only was able to find the full N gene data in the supplemental figures.

Line 509, given that actual recrudescence in the context of virus shedding in the natural reservoir has never been shown it would be good to treat this a little bit more carefully.

Although obviously a good hook, the data we present are only weakly useful for this since we find no correlation b/w bat dynamics and human cases. If the editor will already send it out for review I'd cut this. Overselling what the paper is about is why the paper was rejected at Science Advances.

24 **Abstract**

25 Nipah virus (NiV) is an emerging bat-borne zoonotic virus with pandemic potential that causes near-  
26 annual outbreaks of fatal encephalitis in South Asia – one of the most populous regions on Earth. In  
27 Bangladesh, infection occurs when people drink date palm sap contaminated with bat excreta, but a  
28 recent outbreak in India involved a different, but yet unknown, route of spillover. Outbreaks are  
29 sporadic and the influence of viral dynamics in bats on their temporal and spatial distribution is poorly  
30 understood. We analyzed data on host ecology, molecular epidemiology, serological dynamics, and viral  
31 genetics to characterize spatio-temporal patterns of NiV dynamics in its wildlife reservoir, *Pteropus*  
32 *medius* bats, in Bangladesh. We found that NiV transmission occurred throughout the country and  
33 throughout the year. Model results indicated that local transmission dynamics were driven by density-  
34 dependent transmission, acquired immunity which is lost over time, and recrudescence. Increased  
35 transmission followed multi-year periods of declining seroprevalence due to bat population turnover  
36 and individual loss of humoral immunity. Individual bats had smaller host ranges than other *Pteropus*  
37 spp., although movement data and the discovery of a Malaysia-clade NiV strain in eastern Bangladesh  
38 suggest connectivity with bats east of Bangladesh. These data suggest that discrete multi-annual local  
39 epidemics in bat populations contribute to the sporadic nature of Nipah virus outbreaks in South Asia. At  
40 the same time, the broad spatial and temporal extent of NiV transmission, including the recent outbreak  
41 in Kerala, India, highlights the continued risk of spillover to humans wherever they may interact with  
42 pteropid bats, and the importance of improving Nipah virus surveillance throughout *Pteropus's* range.

This is interesting but isn't relevant to this paper and we have no data to address it so I'd remove this, especially in the abstract. The mention of it below doesn't require this text. Mentioning it here makes the reader expect us to address it and we can't.

47 **Introduction.**

48 Outbreaks of zoonotic diseases are often sporadic, rare events that are inherently difficult to predict,  
49 but can have devastating consequences (1). Several emerging viral zoonoses with wildlife reservoirs  
50 have become pandemics, including HIV/AIDS, SARS coronavirus, and 1918 Pandemic Influenza H1N1 (2-  
51 4). Bats are important hosts for many zoonotic viruses (5) including Ebola virus, SARS-CoV, and Nipah  
52 virus, but the ecological drivers and transmission dynamics of these viruses in their reservoir hosts are  
53 poorly understood (6-10). A better understanding of the transmission dynamics of zoonotic pathogens in  
54 their natural reservoirs may help anticipate and prevent outbreaks (9, 11).

55 Nipah virus (NiV) is an emerging zoonotic paramyxovirus (genus *Henipavirus*) that has  
56 repeatedly spilled over from bats to cause outbreaks in people and livestock with high case fatality rates  
57 across a broad geographic range, making it a significant threat to global health. It has caused repeated  
58 outbreaks in Bangladesh and India, with a mean case fatality rate greater than 70% (12-14). A single  
59 genus of frugivorous bats (*Pteropus*) appears to be the main reservoir for henipaviruses throughout Asia  
60 and Australia (15-19), including *Pteropus medius* (formerly *Pteropus giganteus* (20)) in Bangladesh and  
61 India (21-24). Nipah virus has several characteristics that make it a significant threat to human and  
62 animal health (25-27): 1) its bat reservoir hosts are widely distributed throughout Asia, overlapping  
63 dense human and livestock populations, providing broad opportunity to cause outbreaks; 2) it can be  
64 transmitted directly to humans by bats or via domestic animals; 3) it can be transmitted from person to  
65 person; 4) spillover has repeatedly occurred in highly populous and internationally connected regions,  
66 giving it pandemic potential; 5) it is associated with high mortality rates in people; and 6) there are  
67 currently no commercially available vaccines or therapeutics. As a result, the World Health Organization  
68 has listed Nipah virus among the ten most significant threats to global health (28). To date, human  
69 Nipah virus infections have been identified in India, Bangladesh, Malaysia, Singapore, and the  
70 Philippines (12, 22, 29-31). In May 2018, an outbreak of Nipah virus encephalitis associated with a 91%  
71 mortality rate occurred in a new location - Kerala, India - more than 1,200 km southwest of previous  
72 Indian and Bangladeshi outbreaks (32). A single case was subsequently reported in Kerala in 2019, and  
73 while local *P. medius* populations have been implicated as the local source of infection, the route of  
74 spillover in both instances remains unknown (32, 33).

75 In Malaysia and Bangladesh, consumption of cultivated food resources contaminated with bat  
76 excreta such as mangoes in Malaysia and date palm sap in Bangladesh and northeastern India have been  
77 identified as the predominant cause of spillover to pigs and people respectively (34). Human outbreaks

Error D7. Since you repeat this with further qualification in the next sentence. Best to drop it here.

---

Number: 2      Author: Author      Date: Indeterminate

I'd put the refs after the statements (even if you cite the same ref multiple times), because otherwise it's hard to know which paper to find the info.

78 occur almost annually in Bangladesh and the seasonal timing (November-April) and spatial distribution  
79 of outbreaks coincide with patterns of raw date palm sap consumption in a region termed the “Nipah  
80 belt” (35). However, the <sup>1</sup> is variability in the number of spillover events and magnitude of the  
81 outbreaks that occur each year (36), and spillover has occasionally occurred outside the predominant  
82 season and region of date-palm sap consumption (37). Further, date palm sap harvesting and  
83 consumption also occurs in eastern Bangladesh, yet no human outbreaks have been reported, while  
84 date palm sap is not cultivated in Kerala, India at all, suggesting an alternate route of spillover (35).  
85 While the full range of mechanisms for zoonotic transmission remain unknown, so too are the  
86 underlying viral infection dynamics in bats and the extent of genetic diversity within the virus – each of  
87 which may influence the timing, location and epidemiology of human outbreaks (35).

88 Previous research on the transmission dynamics of Nipah and Hendra viruses in *Pteropus* spp.  
89 bats have produced mixed and sometimes contradictory findings. Nipah virus, like Ebola, Marburg,  
90 Hendra and some bat coronaviruses, has been hypothesized to have seasonal spikes in infection that  
91 coincide with annual or semi-annual synchronous birth pulses (15, 38-44). Seasonal periods of Nipah  
92 virus shedding were observed in *P. lylei* in Thailand and seasonal spikes in NiV (or a related henipavirus)  
93 seroprevalence coinciding with pregnancy periods were observed in *Eidolon dupreanum* in Madagascar  
94 (45, 46), but not in *P. vampyrus* or *P. hypomelanus* in Peninsular Malaysia (19). Hendra virus prevalence  
95 in Australian pteropid bats has shown multi-year inter-epidemic periods where very little virus can be  
96 detected, followed by periods of increased viral shedding, suggesting that viral dynamics are not annual  
97 (47-49). It has been hypothesized that multi-year periodicity in henipavirus infection dynamics could  
98 arise from a build-up and waning of herd immunity in the reservoir host, with re-introduction of virus via  
99 immigration or recrudescence or viral persistence (10, 50-52). Some pteropid bat species are migratory  
100 and interconnected colonies form a metapopulation which could allow for viral re-introductions (9, 19,  
101 53, 54). In addition, NiV recrudescence has been observed in wild-caught *P. vampyrus* and *Eidolon*  
102 *helvum* and either of these phenomena could allow it to persist regionally during periods of high local  
103 immunity (55). However, no study <sup>2</sup> has yet shown evidence in open, free-ranging bat populations that  
104 favors one or the other hypothesis in driving NiV transmission dynamics.

105 The goal of the current study was to determine the distribution and drivers of NiV infection  
106 dynamics and NiV diversity in *Pteropus medius* in Bangladesh to try to understand patterns of human  
107 outbreaks. We examined spatial, temporal and demographic variation in serological dynamics and viral  
108 shedding in bats over a six-year period to determine the spatio-temporal drivers and dynamics of virus

---

Number: 1      Author: Author      Date: Indeterminate

Isn't there also variation in exactly where there are cases even if there are cases in most years? In short, I think we want to make the pattern of cases in a given place (I'm not sure what scale, but the approximate scale of a bat colony would be useful) as clear as possible. I think the strongest thing we found from the model-fitting analysis is that large epidemics in bats don't occur every year, and thus we wouldn't expect many spill over events in the same communities in consecutive years (although we don't predict zero either, because of recrudescence)). If the human spillover data are consistent with that pattern, it would be suggestive that the bat data and fitted model are telling us something useful.

---

Number: 2      Author: Author      Date: Indeterminate

This reference does not seem appropriate for this point or maybe its because there are 2 sets of references, and I am referring to the "wrong" one.

109 transmission. We also studied movement patterns of individual bats and analyzed NiV phylogenetics to  
110 understand patterns of spatial mixing and virus strain diversity.

111

## 112 **Results**

113 *Comparative Nipah virus prevalence study in bats inside and outside the Nipah Belt and concurrent*  
114 *longitudinal bat study inside the Nipah Belt (2006-2012)*

115 We caught and tested 883 *P. medius* (~100 per district) from eight different districts across  
116 Bangladesh. We detected anti-Nipah IgG antibodies in all colonies (**Figure 1**). Seroprevalence varied by  
117 location ( $\chi^2 = 55.61$ ,  $p < .001$ ), but there was no statistical difference between seroprevalence in bats  
118 inside the Nipah Belt and outside. In all locations except Tangail, adult seroprevalence exceeded juvenile  
119 seroprevalence. Viral detection<sup>1</sup> in individuals was rare; overall, we detected NiV RNA in 11/XXX  
120 individuals as well as 3 pooled oropharyngeal samples (representing 5 bats, but which could not be<sup>2</sup>  
121 resolved to an individual) and 21 or XXX pooled urine samples ("roost urine") collected from tarps  
122 underneath the roost (**Table 1**). We detected<sup>3</sup> viral RNA in individual bats in Faridpur and Rajbari and  
123 from pooled samples from Thakurgaon and roost urine samples from Comilla. Of the 10 PCR positive  
124 individuals, three had detectable IgG antibodies (**Table S1**). We also detected virus in pooled<sup>4</sup> urine  
125 collected from tarps placed below bats at roosts associated with human outbreaks in Bhanga and  
126 Joypurhat. The viral prevalence in Rajbari in January 2006 was 3.8% (95% CI: 0% -11%; n=78). In  
127 Faridpur, where we also conducted an intensive longitudinal study (see below), viral prevalence  
128 estimates ranged from 0% to 3% (95% CI: 0%-10%; n=100 at each of 18 sampling times) (**Table 1**). Nipah  
129 virus RNA was detected in individual bats from inside (Rajbari, Thakurgaon, and Faridpur) and outside  
130 (Comilla) the Nipah Belt. We detected viral RNA in bats both with and without detectable IgG antibodies  
131 (**Table S1**). Urine samples provided<sup>5</sup> the highest NiV detection rate. Detection rates in individual bats by  
132 sample type were: urine/urogenital swab = 4% (n=2,126); oropharyngeal swab 3% (n=2,088); and rectal  
133 swab = 1.3% (n=79). The estimated detection rate from pooled urine samples across the entire study  
134 was 2.7% (+/- 1.6%; n=829).

135

136 *Factors associated with NiV IgG serostatus in P. medius*

137 Among adult and juvenile bats sampled in the aforementioned cross-sectional study from which  
138 we got blood samples (844 of 883), seropositivity was 2.4 times more likely among adults than juveniles,  
139 and 1.6 times more likely among males than females<sup>7</sup> (**Figure 2**). Among females, seropositivity was  
140 higher in pup-carrying<sup>8</sup> (4 times) and pregnant (1.5 times) individuals. Weight or forearm length did not

- Number: 5 Author: Author Date: Indeterminate  
This is already clear from the sentence above. I'd delete this.
- 
- Number: 6 Author: Author Date: Indeterminate  
This needs a statistical test to support it. I think I did the stats for this a while back.
- 
- Number: 7 Author: Author Date: Indeterminate  
Odds ratios don't actually mean the prob of seropositivity (unless the prob of seropositivity is very small in which case they are approximately similar). See this page:  
[https://en.wikipedia.org/wiki/Odds\\_ratio](https://en.wikipedia.org/wiki/Odds_ratio)  
You can predict the actual seroprevalence values using the fitted models and then report these actual ratios of seropositivity, but the odds ratios can't be described this way.
- 
- Number: 8 Author: Author Date: Indeterminate  
Same for all of these.
-

141 consistently correlate with seropositivity, however, body condition (an assessment of pectoral muscle  
142 mass by palpation) was significantly negatively correlated (Poor/Fair body condition OR = 0.69) with  
143 serostatus. Finally, serostatus was strongly correlated in mother-pup pairs, with 71/80 pairs (89%)  
144 having matching status.

145

146 *NiV serodynamics over time in a population of P. medius, Faridpur district (2006-2012)*

147 We conducted an intensive longitudinal study of NiV serology in a population of bats in the  
148 Faridpur district and used flexible generalized additive models (GAMs) to characterize changes over  
149 time. There were significant fluctuations in adult (>24 mo.) and juvenile (6 – 24 mo.) seroprevalence  
150 over the six-year study period (**Figure 3A**). Juvenile seroprevalence ranged from 0% to 44% (95%CI 37%-  
151 51%), and decreased over the first year of life for bats born in each year (“yearlings”), consistent with  
152 loss of maternal antibodies in juveniles. A more pronounced decrease occurred from mid-October to  
153 mid-December. However, the GAM indicating this had only marginal better fit ( $\Delta AIC < 1$ ), than one with  
154 a linear decrease over the whole year (**Figure 3B**). The effect of birth cohort was significant on overall  
155 seroprevalence. <sup>1</sup>

156 Adult seroprevalence ranged from 31% (95% CI: 20%-46%) to 82% (95% CI: 77%-87%) and went  
157 through three periods of significant decrease then increase over the course of the study (**Figure 3A**). We  
158 found no evidence of regular seasonal fluctuations; a GAM with annual cyclic terms fit worse than one  
159 without ( $\Delta AIC > 10$ ). Viral RNA detections occurred in periods of increasing, decreasing, and stable  
160 seroprevalence.

161 We fitted a series of age-stratified mechanistic models to examine different biological processes  
162 influencing serodynamics, including density- vs. frequency-dependent transmission, recrudescence vs.  
163 immigration of infected individuals, and seroreversion (loss of antibodies) in both juveniles and adults  
164 (**Figure 4**). We included annual, synchronous birthing, which occurred between March and April. We  
165 assumed that pups weaned from their dams at 3 months, and became independent flyers, and that  
166 maternal antibodies waned after 6 months at which point we had pups transition into the “juvenile”  
167 class (56, 57). We assumed that juveniles became sexually mature at 24 mo., and entered the “adult”  
168 class based on other pteropid species(43, 56, 58). Density-dependent models were a far better fit to the  
169 data than frequency-dependent models (difference in log-likelihood 10.0;  $\Delta AIC = 20.0$ ), suggesting that  
170 movements of bats and fluctuations in colony size alter spatio-temporal variation in the risk of NiV  
171 epidemic spillover to humans. In this colony (<sup>2</sup>Bomrakhandi/Khaderdi) during the period of sampling, the  
172 roost population declined from approximately 300 bats to 185, which decreased transmission potential

## Page: 6

---

Number: 1      Author: Author      Date: Indeterminate  
What does this mean?

---

Number: 2      Author: Author      Date: Indeterminate  
Given that you already show a nice figure with these values, I'd just report the factors that are positively and negatively correlated with seropositivity and their relative strength but you don't need to give all the individual values.

173 in the fitted model:  $R_0$  in adult bats was estimated to decrease from 3.5 to 2.1 as the number of bats in  
174 the colony decreased. As a result, over the six-year study period, the fitted model predicted that the  
175 number of infected bats increased when the seroprevalence of adults fell below 72% (when bat counts  
176 were highest - in 2006) and 52% (when bat counts were lowest). The fitted model suggested that  
177 serodynamics in juveniles were strongly driven by inheritance and loss of maternal antibodies. The rate  
178 of loss of maternal antibodies was 17.6 weeks (95% CI: 13.7-25.0), which was much quicker than the loss  
179 of antibodies in adults (290.8 weeks, 95% CI: 245.0-476.4) (**Table S2**). Finally, models with recrudescence  
180 fit the data better than models without recrudescence (**Table S2**; difference in log-likelihood 32.6;  $\Delta$ AIC  
181 = 65.1), and models with recrudescence fit the data better than models with immigration ( $\Delta$ AIC = 3.76).

182

### 183 *Mark-recapture and seroconversion/seroreversion*

184 A total of 2,345 bats from the Faridpur/Rajbari region were sampled and microchipped between  
185 2007 and 2012. There were 56 recapture events (**Table S3**). Thirty-one bats were recaptured at a roost  
186 other than the original capture location. This network of roosts or “roost complex” formed a polygon  
187 covering approximately 80 Km<sup>2</sup> and included 15 roosts sampled during the longitudinal study (**Figure**  
188 **S2A and S2B**). Ten instances of seroconversion (change from IgG negative to IgG positive) and nine  
189 instances of seroreversion (positive to negative) were observed (**Table S3**). The mean time between  
190 positive and negative tests in *adults* (excluding juveniles with maternal antibodies) was 588 days (n=6)  
191 (range: 124-1,082 days).

192

### 193 *Home range and inter-colony connectivity analysis*

194 Home range analysis of satellite telemetry data from 14 bats (**Table S4**) showed that the  
195 majority of these bats roosted within 10 km of where the bats were originally collared, in the Faridpur  
196 (Nipah belt) colony, and within 7 km from where the bats in the Cox’s Bazaar colony were originally  
197 collared (3.5 km east of Faridpur). The average foraging radius was 18.7 km (s.d. 21.5 km) for the  
198 Faridpur bats and 10.8 km (s.d. 11.9 km) for the Cox’s Bazaar bats (**Figure S2**). Homorange analysis  
199 suggests that bats in Faridpur and Cox’s Bazar would have a <5% probability of intermingling (**Figure 5**).  
200 Homorange size was significantly larger during the wet season than the dry season (2,746 km<sup>2</sup> vs. 618  
201 km<sup>2</sup>) (**Figures S3 & S4**).

202

### 203 *NiV phylogenetic analysis.*

---

 Number: 1      Author: Author      Date: Indeterminate  
I think this is 2 words. If so, I'd change it throughout.

204 Phylogenetic analysis of NiV sequences from a 224nt section of the N gene (nt position 1290-  
205 1509 [position ref [gb|FJ513078.1](#) India]) suggests that strains from both India and Malaysia clades are  
206 present in Bangladesh bats (**Figure 6**). This finding is supported by an analysis of near-whole N gene  
207 sequences (~1720 nt) from bats, pigs, and humans, including those from a subset of *P. medius* from this  
208 and a more recent study by our group (**Figure S5**) (59). Eleven 224nt N gene sequences obtained from  
209 bats between 2006 and 2012 (all from the Faridpur population) were identical. Overall, the N gene  
210 sequences identified from the Faridpur, Rajbari and Bhanga colonies between 2006 and 2011 had  
211 98.21%-100% shared nucleotide identity. Sequences from Rajbari district obtained five years apart  
212 (January 2006 and January 2011) had only a single nucleotide difference resulting in a synonymous  
213 substitution (G to A) at position 1304, which was found in four other bat NiV sequences from this study,  
214 as well as in the NiV isolate from *P. vampyrus* in Malaysia. Five Human NiV N gene sequences from  
215 various locations within the Nipah belt over the same time period as our bat study show more  
216 nucleotide diversity than those from the Faridpur *P. medius* population. Human sequences throughout  
217 Bangladesh and from Kerala, India, all nested within the diversity found in *P. medius* (**Figure 6**). By  
218 contrast, the sequences found in *P. medius* from Comilla, a location 150Km to the east of Faridpur,  
219 showed 80.8%-82.59% shared nucleotide identity with sequences from *P. medius* in Faridpur and  
220 clustered within the Malaysia group of NiV sequences. The two Comilla sequences were identical to  
221 each other, and had up to 87.95% shared nucleotide identity to sequences from *P. lylei* in Thailand.  
222 *Pteropus lylei* bats in Thailand were also found to carry NiV strains from both Malaysia and Bangladesh  
223 groups.

224

## 225 Discussion

226 Our study provides new insights into Nipah virus transmission dynamics, genetics and host ecology.  
227 Previous studies from Bangladesh suggested that human NiV outbreaks occur only within a defined  
228 region in western Bangladesh, termed the “Nipah belt,” and during a defined season (Nov-Apr), which  
229 raised the question of whether that observation was entirely due to date palm sap consumption, or  
230 whether ecological factors such as the distribution and timing of bat viral infection also influenced the  
231 timing and location of human cases (13, 35, 60). We undertook the most geographically extensive survey  
232 of *Pteropus medius* in Bangladesh to date to understand Nipah virus infection patterns in its putative  
233 reservoir, *Pteropus medius*, which is common in Bangladesh and throughout the Indian subcontinent  
234 (21, 22, 56).

---

 Number: 1      Author: Author      Date: Indeterminate  
I believe we have previously reported the Comilla case.

---

235 Overall, our findings suggest viral circulation is not limited to the Nipah belt, but that NiV  
236 transmission occurs in bat populations throughout the country. We observed that virus can be shed at  
237 any time of year, and that viral dynamics are not annual or seasonal, but driven by demographic and  
238 immunological factors. Analysis of serological data from our longitudinal study suggests that the  
239 underlying mechanism driving the timing of NiV transmission in bats is the waning of herd immunity in  
240 bat populations allowing heightened viral transmission, but recrudescence can result in sporadic  
241 shedding at any time.

242 A number of mechanisms have been proposed for the maintenance of acute viral infections in  
243 bat metapopulations, including synchronous birthing and subsequent loss of maternal antibodies (10,  
244 39, 41), lowered immunity within pregnant females due to stress, nutritional stress and other factors  
245 (43) immigration of infected individuals from other colonies (53, 61, 62), and recrudescence within  
246 previously-infected individuals (10, 55, 63). Our modeling indicates that NiV is primarily driven by  
247 density-dependent transmission dynamics among adult bats, with cycles of higher seroprevalence that  
248 would dampen intra-colony transmission followed by waning of antibody titers within individuals and at  
249 a population level. Waning humoral immunity against Nipah virus is a consistent feature of henipavirus  
250 studies in African pteropodid bats (52, 64). Our recapture data provided the first reported evidence of  
251 the loss of detectable NiV IgG antibodies in recaptured individual free-ranging bats, which supports our  
252 observation of population level waning immunity. The consistently lower and decreasing seroprevalence  
253 that we observed in juveniles suggests that they lose maternal antibodies over their first year, and likely  
254 in the first 6-7 months, consistent with other studies of maternal antibodies against henipaviruses in  
255 pteropodid bats (43, 52, 57, 65). However, our analysis does not support the hypothesis that seasonal  
256 pulses of these new seronegative individuals are the primary driver of new outbreaks in adults (41).

257 Our model outputs suggest that spikes in viral transmission occur after virus is reintroduced into  
258 colonies after immunity has waned. The model fitting suggests that serodynamics are more consistent  
259 with recrudescence, but immigration of infected individuals could also reintroduce the virus.  
260 Recrudescence would presumably occur in individuals with antibody titers that have waned below a  
261 neutralizing titer, if loss of humoral immunity following a primary infection is sufficient to allow a second  
262 infection. Recrudescence of henipavirus infection has been observed for NiV in captive *P. vampyrus* (55),  
263 for henipavirus in captive *E. helvum* (52, 66), and has also been observed in humans infected by NiV (67)  
264 and Hendra virus (68). It is difficult to know from serology alone whether wild-caught seronegative bats  
265 had been previously infected. Experimental infection of naïve and previously infected *Pteropus medius*  
266 that have sero-reverted would provide a better understanding of how humoral immunity influences

This is a bit less aggressive. If the paper goes to one of the authors of ref 41 it'd be better to be more gentle.

---

267 individual susceptibility to infection, and inform dynamics models attempting to explain viral  
268 maintenance within bat populations (64).

269 Our longitudinal study is limited in that it may not necessarily reflect temporal infection  
270 dynamics in all bat populations across Bangladesh. Our roost count data and recapture data from  
271 microchipped bats showed how roost sizes can fluctuate, and local roost shifting can occur. The  
272 observation of individual bats using multiple roost sites suggests that changes in roost count, which our  
273 models suggest impacts transmission dynamics, could reflect local shifts in densities rather than  
274 fluctuations in regional populations.

275 Understanding how bat populations connect across landscapes is important for understanding  
276 viral maintenance, and studying local and migratory bat movements can provide important ecological  
277 information related to viral transmission, including how bats move between different colonies (53). Our  
278 satellite telemetry data suggest that *P. medius* exists as a metapopulation, like other pteropid species  
279 (10, 62). However, *Pteropus*<sup>1</sup>*medius* in Bangladesh appear to travel shorter distances and remain within  
280 a smaller home range (321.46km<sup>2</sup> and 2,865.27km<sup>2</sup> for two groups) compared to *P. vampyrus* in  
281 Malaysia (64,000 km<sup>2</sup> and 128,000 km<sup>2</sup>) and *Acerodon jubatus* in the Philippines which are similarly sized  
282 fruit bats (53, 69). Pteropodid bat migration is primarily driven by seasonal food resource availability (54,  
283 70-72). In Bangladesh, *P. medius* prefer to roost in human-dominated environments in highly  
284 fragmented forests (73). The anthropogenic colonization and conversion of land over recent human  
285 history has likely led to increased food availability for *P. medius* and reduced necessity for long-distance  
286 migration (34). This may reflect a similar adaptation to anthropogenic food resources as observed over  
287 the last few decades in Australian *Pteropus* species (62). Genetic analysis of *P. medius* across Bangladesh  
288 has shown that the population is panmictic – that historically, there has been interbreeding among  
289 populations across Bangladesh(74). If movements are generally more localized, as suggested by  
290 telemetry, then less connectivity among flying fox populations may influence Nipah transmission by  
291 creating longer inter-epidemic periods and larger amplitude fluctuations in population level immunity  
292 compared to more migratory species (62).

293 Bat movement and population connectivity may also influence the genetic diversity of Nipah  
294 virus found in different locations, and genotypic variation has been associated with different clinical  
295 outcomes in people. While the overall strain diversity among Nipah virus has not been well  
296 characterized due to a dearth of isolates, two distinct NiV clades have been described: A Bangladesh  
297 clade, which includes sequences identified in India and Bangladesh; and a Malaysian clade, which  
298 comprises sequences from Malaysia, Cambodia, The Philippines and Thailand (31, 59, 75). Strains of NiV

---

Number: 1      Author: Author      Date: Indeterminate

It's not a limitation in model parameterization – it was a limitation in the data. If we had seroprevalence data in many individual roosts we could examine the importance of local vs regional population processes. But that would be a ton of work!

299 from these two clades are associated with differences in pathogenesis, epidemiological and clinical  
300 profiles in humans and animal models and observed shedding patterns in bats (45, 76-80). Phenotypic  
301 variation in Nipah virus could influence observed human outbreak patterns by altering transmission to,  
302 or pathogenesis in, humans, and the likelihood of smaller outbreaks being identified or reported (81).  
303 Human-to-human NiV transmission via contact with respiratory and other secretions has been regularly  
304 observed in Bangladesh and India, including the recent 2018 outbreak in Kerala (12, 82, 83), whereas  
305 transmission among people was not a common feature of the Malaysia outbreak, despite close contact  
306 between cases and health care providers (84, 85). Nipah virus cases in Bangladesh have shown more  
307 strain diversity than in the Malaysia outbreak (86),.

308           Until now, there have been very few Nipah sequences obtained from *P. medius*. We found that  
309 Nipah N-gene sequence from bats from the Faridpur population were nearly identical over time,  
310 compared to variation in N-gene sequences from bats and humans from other locations observed over  
311 the same time period (2006-2010). This suggests that there may be locally prevalent and stable NiV  
312 genotypes that persist within bat colonies. Human NiV genotype diversity is likely a reflection of the  
313 relative diversity of the NiV strains in the local bats that seed outbreaks (9). This is also supported by  
314 viral sequences obtained from human and bats associated with the 2018 NiV outbreak in Kerala, India,  
315 where human NiV sequences were most closely related to local *P. medius* sequences (87). We found a  
316 significantly divergent NiV strain in Comilla, which clustered within the Malaysia NiV clade, suggesting  
317 that strains from both clades are circulating in bats in Bangladesh.

318           Connectivity of pteropid bats in Bangladesh with those in Southeast Asia could explain the  
319 observed strain diversity in our study. Historical interbreeding of *P. medius* with pteropid species found  
320 in Myanmar, Thailand, and Malaysia and our telemetry findings showing bats are capable of flying  
321 hundreds of kilometers, could explain our discovery of a Malaysia clade NiV sequence in bats from  
322 Comilla (74). NiV Bangladesh strains have also been found in *P. lylei* in Thailand (88). The N gene of the  
323 Comilla NiV strain differs from those reported from bats in the Nipah belt by 20%, whereas NiV Malaysia  
324 and NiV Bangladesh differ by only 6-9% and are associated with different clinical profiles. Whole  
325 genome sequence (which could not be obtained) would have allowed for better characterization of the  
326 Comilla strain, but the N gene is generally conserved relative to other genes, and suggests the rest of the  
327 genome may also be highly divergent. It is therefore plausible that the clinical profile of a 20% divergent  
328 NiV strain differs significantly from known strains. Further studies linking viral genotype to clinical  
329 phenotype would provide insight into the implications of strain diversity in bats for human outbreaks.

330 Finally, our study sheds light on the sporadic nature of NiV outbreaks with multi-year inter-  
331 epidemic periods in South Asia. First, PCR results show that overall NiV incidence in *P. medius* is low,  
332 consistent with previous studies of Hendra and Nipah virus (43, 48, 89, 90). The data and our modeling  
333 suggests that PCR-positive samples are more likely to be identified during viral transmission spikes after  
334 periodic reintroduction into populations that have become susceptible through waning population-level  
335 immunity (10). Viral detection in bats has also coincided with human outbreaks (59, 87). This is likely a  
336 rare or at least sporadic event. In the current study, observed seroprevalence patterns and the fitted  
337 model suggest that three periods of transmission occurred over the 6 years of sampling, each of which  
338 followed periods of low adult seroprevalence, though not all measurements of low seroprevalence were  
339 followed by outbreaks. We detected NiV RNA during periods of both increasing and decreasing  
340 seroprevalence, supporting the fitted model which suggested that shedding can occur through  
341 recrudescence at low levels in bats even in periods without sustained transmission. Our observation that  
342 not every instance of rising seroprevalence resulted in detectable viral shedding suggests that not all  
343 episodes of viral circulation in bats are of equal magnitude, and that other factors (e.g. variation in  
344 human-bat contact and exposure) may affect likelihood of spillover. Together, this evidence suggests  
345 that outbreaks can occur in bats when the population falls below a protective threshold of immunity in  
346 any season, but variability in how many bats become infected may impact the likelihood of spillover to  
347 humans, assuming a route of transmission is available. This could explain variation in the number of  
348 human outbreaks (e.g. spillover events) from year-to year in Bangladesh. Thus, the timing of multiple  
349 factors involved in driving transmission dynamics needs to align for intra-colony NiV transmission events  
350 and further align with human behavior and availability of a route of spillover for human outbreaks to  
351 occur, as previously hypothesized (91). This, and the seasonality and specific geography of date palm sap  
352 consumption in Bangladesh likely explains the somewhat sporadic nature of human outbreaks in the  
353 region, albeit that when spillover occurs, it is within the well-defined date palm sap collection season  
354 and geographic zone (35).

355 These findings suggest that Nipah virus outbreaks in other regions of Bangladesh where  
356 *Pteropus* spp. bats occur, are also likely to be sporadic and rare, leading to under-reporting or a lack of  
357 reporting, particularly given that human neurologic symptoms are similar to other common infections,  
358 such as Japanese encephalitis, malaria, and measles (92). Understanding whether some NiV strains are  
359 capable of causing mild or asymptomatic cases will provide important insights about why outbreaks may  
360 not have been detected in areas such as eastern Bangladesh or other parts of Asia, where host, virus,  
361 and potential routes of spillover exist. Mild or asymptomatic cases would be unlikely to be detected by

362 current surveillance systems and it's possible that cryptic spillovers have occurred in Bangladesh, where  
363 about analysis of health care seeking behavior suggests that half of all outbreaks between 2007 and  
364 2014 were unreported (93). Our work and other reports suggest that Nipah virus transmission is possible  
365 wherever *Pteropus* spp. bats and humans live in close association and at any time of year, provided  
366 there is an available pathway of transmission. The 2018 and 2019 spillover events in Kerala, India, which  
367 were linked to local *P. medius* colonies and which occurred in an area that does not cultivate date palm  
368 sap, further emphasize this point.

369 Identifying areas where high risk interfaces exist between pteropid bats and people, throughout  
370 their range, will be important for monitoring Nipah spillover events and quickly responding to  
371 outbreaks, as well as establishing interventions to prevent spillover. Raising awareness of the potential  
372 for contaminated food to be a route of Nipah virus transmission and in protecting food resources to  
373 limit human or livestock exposure, may be effective in reducing the risk of a more transmissible strain of  
374 Nipah virus from emerging and causing an epidemic with significant human and animal mortality.

375

376 **Methods**

377 The study period was between January 2006 and November 2012. The study was conducted under <sup>1</sup>Tufts  
378 University IACUC protocol #G929-07. Locations were selected based on whether the district had any  
379 previously recorded human NiV encephalitis clusters at the time of this study and was therefore inside  
380 the Nipah Belt (e.g. Rajbari, Tangail, Thakurgaon, and Kushtia) or whether they had not and were  
381 outside the Nipah Belt (e.g. Comilla, Khulna, Sylhet, and Chittagong). The Thakurgaon study was  
382 conducted as part of an NiV outbreak investigation, and coincided with ongoing human transmission  
383 (94). Between 2006-2012, three different studies of *Pteropus medius*, with similar bat sampling  
384 protocols were performed: 1) a cross-sectional spatial study with a single sampling event in each of the  
385 eight locations listed above; 2) a longitudinal study of a Faripur bat colony with repeated sampling  
386 approximately every 3 months from July 2007 to November 2012; and 3) a longitudinal study of the  
387 Rajbari colony with repeated sampling at a monthly interval between 12 month period between April  
388 2010 and May 2011. Opportunistic sampling of *Pteropus medius* was also performed during this time  
389 period during NiV outbreak investigations [Bangha, Faridpur (Feb 2010), Joypurhat (Jan 2012), Rajbari  
390 (Dec 2009), West Algi, Faridpur (Jan 2010)]. Bats were captured using mist nets at locations within eight  
391 different districts across Bangladesh between January 2006 and December 2012 (**Figure 1**).

392

393 *Capture and sample collection*

394 For the country-wide cross-sectional and Faridpur longitudinal study, on average, 100 bats were  
395 sampled at each sampling event, which lasted 7-10 days. This sample size allowed us to detect at least  
396 one exposed bat (IgG antibody-positive) given a seroprevalence of 10% with 95% confidence. Bats were  
397 captured using a custom-made mist net of approximately 10 m x 15 m suspended between bamboo  
398 poles which were mounted atop trees close to the target bat roost. Catching occurred between 11 pm  
399 and 5 am as bats returned from foraging. To minimize bat stress and chance of injury, nets were  
400 continuously monitored and each bat was extracted from the net immediately after entanglement.  
401 Personal protective equipment was worn during capture and sampling, which included dedicated long-  
402 sleeve outerwear or Tyvek suits, P100 respirators (3M, USA), safety glasses, nitrile gloves, and leather  
403 welding gloves for bat restraint. Bats were placed into cotton pillowcases and held for a maximum of 6  
404 hours before being released at the site of capture. Bats were sampled at the site of capture using a field  
405 lab setup. Bats were anesthetized using isoflurane gas (95) and blood, urine, oropharyngeal swabs, and  
406 wing membrane biopsies (for genetic studies) were collected. For some sampling periods, rectal swabs  
407 were collected but due to resource constraints, these samples were deemed to likely be lower yield than

---

 Number: 1      Author: Author      Date: Indeterminate  
Recommend including local institutional approval.

408 saliva and urine for NiV, and were discontinued during the study. For each bat sampled we recorded  
409 age, weight, sex, physiologic and reproductive status, and morphometric measurements as described  
410 previously (21). Bats were classified as either juveniles (approximately four to six months - the age by  
411 which most pups are weaned) to two years old (the age when most *Pteropus* species reach sexual  
412 maturity) or adults (sexually mature) based on body size and the presence of secondary sexual  
413 characteristics, pregnancy, or lactation - indicating reproductive maturity (21, 96).

414 Up to 3.0 mL of blood were collected from the brachial vein and placed into serum tubes with  
415 serum clot activator (Vacutainer, USA). Blood tubes were stored vertically on ice packs in a cold box  
416 and serum was allowed to separate overnight. Serum was drawn from the tube after 24 hours and  
417 placed in a screw-top cryovial (Corning, USA) and stored in a liquid nitrogen dewar (Princeton  
418 Cryogenics, NJ, USA). Sterile pediatric swabs with polyester tips and aluminum shafts were used to  
419 collect urogenital and rectal samples, and larger polyester swabs with plastic shafts (Fisher, USA) were  
420 used to collect oropharyngeal samples. All swabs were collected in duplicate, with one set being placed  
421 individually in cryotubes containing lysis buffer (either tri-reagent or NucliSENS Lysis buffer,  
422 BIOMERIEUX, France) and the second set in viral transport medium. All tubes were stored in liquid  
423 nitrogen in the field then transferred to a -80C freezer.

424 During each sampling event, pooled urine samples were collected beneath bat roosts using  
425 polyethylene sheets (2' x 3') distributed evenly under the colony between 3 am and 6 am. Urine was  
426 collected from each sheet either using a sterile swab to soak up droplets, or a sterile disposable pipette.  
427 Swabs or syringed urine from a single sheet were combined to represent a pooled sample. Each urine  
428 sample was divided in half and aliquoted into lysis buffer or VTM at an approximate ratio of one part  
429 sample to two parts preservative.

430

#### 431 *Serological and molecular assays*

432 Sera from the cross-sectional survey were heat inactivated at 56°C for 30 minutes, as described  
433 (97) prior to shipment to the Center for Infection and Immunity at Columbia University (New York, USA)  
434 for analysis. Samples were screened for anti-NiV IgG antibodies using an enzyme linked immunosorbent  
435 assay (ELISA) as described in (21). Sera from the longitudinal studies were sent to the Australian Animal  
436 Health Laboratory and were gamma irradiated upon receipt. Because of the large sample size and  
437 development of a high throughput multiplex assay of comparable specificity and sensitivity, for these  
438 samples we used a Luminex-based assay to detect anti-Nipah G IgG antibodies reactive to a purified NiV  
439 soluble G protein reagent (98, 99). 1

---

Number: 1      Author: Author      Date: Indeterminate

Jen Barr – please insert language about MFI cutoff that was used for each protein. We used the NiVsG value to decide positive or negative status, but should we discuss NiVsF status, or just focus on G?

440 Total nucleic acids from swabs and urine samples were extracted and cDNA synthesized using  
441 Superscript III (Invitrogen) according to manufacturer's instructions. A nested RT-PCR and a real-time  
442 assay targeting the N gene were used to detect NiV RNA in samples (100). A RT-qPCR designed to detect  
443 the nucleocapsid gene of all known NiV isolates was also utilized (101). Oligonucleotide primers and  
444 probe were as described (101). Assays were performed using AgPath-ID One-StepRT-PCR Reagents  
445 (Thermofisher) with 250 nM probe, 50 nM forward and 900 nM reverse primers. Thermal cycling was  
446 45°C for 10 min, followed by 45 cycles of 95°C for 15 s and 60°C for 45 s. Cut-off values were cycle  
447 threshold ( $C_T$ )  $\leq 40$  for positive and  $C_T \geq 45$  for negative. Results with  $C_T$  values between 40 and 45 were  
448 deemed indeterminate, i.e. not conclusively positive or negative. Samples with NiV RNA detected by real  
449 time PCR were confirmed by gel electrophoresis and product sequencing.

450 A subset of NiV-positive samples was processed by high-throughput sequencing (HTS) on the Ion  
451 Torrent PGM platform in order to obtain additional NiV genomic sequence. Libraries were prepared  
452 according to the manufacturer's instructions, and 1 million reads allocated per sample. HTS reads were  
453 aligned against host reference databases to remove host background using bowtie2 mapper, and host-  
454 subtracted reads primer trimmed and filtered based on quality, GC content and sequence complexity.  
455 The remaining reads were de novo assembled using Newbler (v2.6) and mapped to the full length NiV  
456 genome. Contigs and unique singletons were also subjected to homology search using MegaBlast  
457 against the GenBank nucleotide database, in case variance in parts of the genome precluded efficient  
458 mapping. From these data, N gene consensus sequences were constructed using Geneious v 7.1, and  
459 used for phylogenetic analyses.

460

#### 461 *Phylogenetic analysis*

462 All *P. medius* NiV sequences have been submitted to Genbank and accession numbers are  
463 included in **Figure 6**. Sequence alignments were constructed using ClustalW in Geneious Prime software  
464 (102). Phylogenetic trees of NiV N-gene sequences were constructed using Neighbor-Joining, Maximum-  
465 Likelihood algorithms and figures constructed in FigTree 1.4.2.

466

#### 467 *Satellite telemetry and homerange analysis*

468 We developed a collar system to attach 12g solar-powered Platform Terminal Transmitters (PTT)  
469 (Microwave Telemetry, Colombia, MD, USA) to adult bats using commercial nylon feline collars with the  
470 buckle removed and 0-gauge nylon suture to attach the PTT to the collar and to fasten the collar around  
471 the bat's neck. Collars were fitted to the bat such that there was enough space to allow for normal neck

472 movement and swallowing, but so that the collar would not slip over the head of the animal (**Figure S6**).  
473 PTTs were programmed with a duty cycle of 10 hours on and 48 hours off. Data was accessed via the  
474 Argos online data service (argos-system.org; France). A total of 14 collars were deployed as follows: Feb  
475 2009: 3 males, 3 females from a colony in Shuvarampur, Faridpur district; Feb 2011: 3 males, 2 females  
476 from the same colony; and April 2011 Cox's Bazaar, 3 bats from a colony in Cox's Bazaar, Chittagong  
477 district. Bats were selected based on size such that the total weight of the collar (~21g) was less than 3%  
478 of the bat's body mass (Table S3).

479 The individual telemetry dataset was combined for each region and its aggregate utilization  
480 distributions (UD) computed in R using package 'adehabitatHR' (103). Population-specific home range is  
481 represented by the \*95% area enclosure of its UD's volume. The volume of intersection between the  
482 colonies quantifies the extent of home range overlap. To evaluate the potential for contact with the  
483 Sylhet colony, we calculated the most likely distance moved ('mldm') for each sampled bat at Faridpur  
484 where the population was more intensively monitored. Movement distance was measured in kilometers  
485 with respect to a centroid location ( $\omega$ ) shared by the whole colony; assuming random spatial distribution  
486 in tracking rate, we estimated its kernel density function per individual and defined mldm as the mode.

487

#### 488 *Statistical approach – cross-sectional study*

489 We fit a Bayesian generalized linear model with a logit link and a Bernoulli distribution to  
490 identify potential predictors which influenced a bat's serostatus. We included age, sex, age- and sex-  
491 normalized mass and forearm length, mass:forearm ratio, body condition, and whether the bat was  
492 pregnant, lactating, or carrying a pup. We included location of sampling as a group effect (similar to a  
493 random effect in a frequentist context) nested within Nipah Belt or non-Nipah Belt regions. We fit the  
494 models and performed posterior predictive checks in R 3.4.3, using the **brms** and **rstan** packages.

495

#### 496 *Statistical approach – longitudinal study*

497 We fit binomial general additive models (GAMs) (104) to the time series of adult and juvenile  
498 seroprevalence in the longitudinal study. For juveniles, we modeled the birth cohort of bats as separate  
499 random effects in a pooled model of juveniles' dynamics starting from June of their birth year, June  
500 being the earliest month we sampled free-flying juveniles in any cohort. We determined the cohort year  
501 of juveniles by using cluster analysis to group individuals by weight, assuming those in the smallest  
502 group were born in the current year and those in the larger group were born the previous year. 92% of

---

Number: 1      Author: Author      Date: Indeterminate

If you used a Bayesian approach you need to specify what priors you used for each coefficient and whether the predictors were standardized, since this determines how informative those priors are.

503 juveniles captured were yearlings. For adults, we modeled dynamics of adults as a single pool over the  
 504 entire course of the study. We tested models with and without annual cyclic effects.

505 Where time series had significant temporal autocorrelation (adults only), we aggregated data by  
 506 week. We determined periods of significant increase in decrease as those where the 95% confidence  
 507 interval of the GAM prediction's derivative did not overlap zero. We fit the models and performed  
 508 checks in R 3.4.3, using the **mgcv** package.

509 To examine the importance of different biological mechanisms in transmission, we fit an age-  
 510 structured (adult and juvenile) maternally immune (M)-susceptible (S)-infected (I)-recovered (R) model  
 511 with recrudescence (R to I) and loss of immunity (R to S) to the seroprevalence data on a weekly  
 512 timescale:

513

$$\frac{dS_J}{dt} = -S_J(\beta_{JJ}I_J + \beta_{AJ}I_A) - \mu_J S_J + bN_A(t-5)\frac{S_A}{N_A} - bN_A(t-52)\frac{S_J}{N_J}(1-\mu_J)^{52} + \lambda M_J$$

$$\frac{dI_J}{dt} = S_J(\beta_{JJ}I_J + \beta_{AJ}I_A) - \gamma I_J - bN_A(t-52)\frac{I_J}{N_J}(1-\mu_J)^{52}$$

$$\frac{dR_J}{dt} = \gamma I_J - \mu_J S_J - \mu_J R_J - bN_A(t-52)\frac{R_J}{N_J}(1-\mu_J)^{52}$$

514 
$$\frac{dM_J}{dt} = bA(t-5)\frac{R_A}{N_A} - \lambda M_J - \mu_J M_J - bN_A(t-52)\frac{R_A}{N_A}(1-\mu_J)^{52} \lambda^{52}$$

$$\frac{dS_A}{dt} = -S_A(\beta_{AA}I_A + \beta_{JA}I_J) - \mu_A S_A + \tau R_A + bN_A(t-52)\frac{S_J}{N_J}(1-\mu_J)^{52}$$

$$\frac{dI_A}{dt} = S_A(\beta_{AA}I_A + \beta_{JA}I_J) - \gamma I_A - \mu_A I_A + bN_A(t-52)\frac{I_J}{N_J}(1-\mu_J)^{52} + \Delta R_A$$

$$\frac{dR_A}{dt} = \gamma I_A - \mu_A R_A + bN_A(t-52)\frac{R_J}{N_J}(1-\mu_J)^{52} - \tau R_A - \Delta R_A$$

515 We included a class M for the density of juvenile bats with maternal antibodies to allow for the biological  
 516 possibility that maternal antibodies are lost at a much higher rate than antibodies acquired following  
 517 infection. The subscripts J refer to juveniles and A to adults,  $\beta$  is the transmission rate,  $\gamma$  is the recovery  
 518 rate,  $\mu$  is the mortality rate,  $\tau$  is the rate of loss of adult immunity,  $\lambda$  is the rate of loss of maternal  
 519 antibodies(57),  $\Delta$  is the adult recrudescence rate (R to I), b is the birth rate (pups join the juvenile  
 520 population after 5 weeks). Juveniles transition to adults after 52 weeks. We included terms for loss of  
 521 antibody in adults ( $\tau$ , S to R), and viral recrudescence ( $\Delta$ , R to I) based on previous studies on captive bats  
 522 that demonstrated the existence of these processes without providing enough data to characterize them  
 523 precisely (55, 65). We fit this deterministic model to the seroprevalence data by maximum likelihood,

524 which assumes that deviations from the model are due to observation error. We estimated the confidence  
525 intervals around maximum likelihood parameter estimates using likelihood profiles using the *profile*  
526 function in package *bbmle* in R v3.2.2.

527 We used model fitting and model comparison to examine the need for several of the biological  
528 processes in the model above that could influence NiV dynamics. First, we examined both density and  
529 frequency-dependent transmission by comparing the fit of the model above to one with transmission  
530 terms that have population size ( $N_A$  or  $N_j$ ) in the denominator. Second, we examined the confidence  
531 intervals of the parameters describing viral recrudescence, loss of antibodies in adult bats, and loss of  
532 antibodies in juvenile bats. If the confidence bounds for these parameters included zero, then these  
533 biological processes are not needed to explain the serological dynamics. Finally, we examined the  
534 confidence bounds for parameters describing the loss of maternal and non-maternal antibodies ( $\tau$  and  
535  $\lambda$ ), to determine if the rate of loss of these two types of immunity were different. We note that this  
536 model structure has similarities to a susceptible-infected-latently infected(L)-infected (SILI) model (if  
537 latently infected individuals are seropositive), but the model above differs in allowing for the possibility  
538 of individuals to transition from the R class back to the S class.

#### 539 *Code availability*

540 SIR model code written in R is available upon request.

541

#### 542 *Data availability*

543 All molecular sequences are available via Genbank. The datasets generated during and/or analyzed  
544 during the current study are available from the corresponding author on reasonable request.

545

546 **Acknowledgements:** We thank Pitu Biswas, Md. Sheikh Gofur, Abdul Hai, and Craig Smith for assistance  
547 in the field, Christopher Allen, and Parvize Hosseini for technical input, Eliza Choi; Yan-Ru Feng and  
548 Lianying Yan for preparing recombinant viral glycoproteins; Jennifer Barr, Vishal Kapoor, Neil Renwick,  
549 and Mohammad Ziadur for laboratory diagnostic and technical support, anonymous reviewers for their  
550 useful comments, and the Government of Bangladesh for permits and logistical support that made this  
551 work possible. This study was funded by an NIH NIAID awards to JHE (AI067549) and CCB (AI054715), an  
552 NIH Fogarty International Center Ecology and Evolution of Infectious Diseases (EEID) award to PD (R01  
553 TW005869) a NSF-NIH EEID award to AMK (EF-0914866), a NIH NIAID award to Lipkin (U19 AI109761), a  
554 US Agency for International Development PEER award to MSK (Award 226), and the US Agency for

555 International Development Emerging Pandemic Threats: PREDICT program (PD, JHE, AI, SA, NR, CZT,  
556 KJO). icddr,b is also grateful to the Governments of Bangladesh, Canada, Sweden and the UK for  
557 providing core/unrestricted support. Study development (JHE, SJA, AI, AMK, SUK, EG, MJH, HEF, GC, MR,  
558 SPL, WIL, & PD); Lab and field data collection & analysis (JHE, SJA, AMK, MS, NR, SAK, Aul, IS, CZT, YT,  
559 PLQ, KJO, TB, CCB, LFW & WIL); manuscript writing (JHE, SJA, AI, AMK, NR, CZT, KJO, EG, HEF, MDF, TB,

783

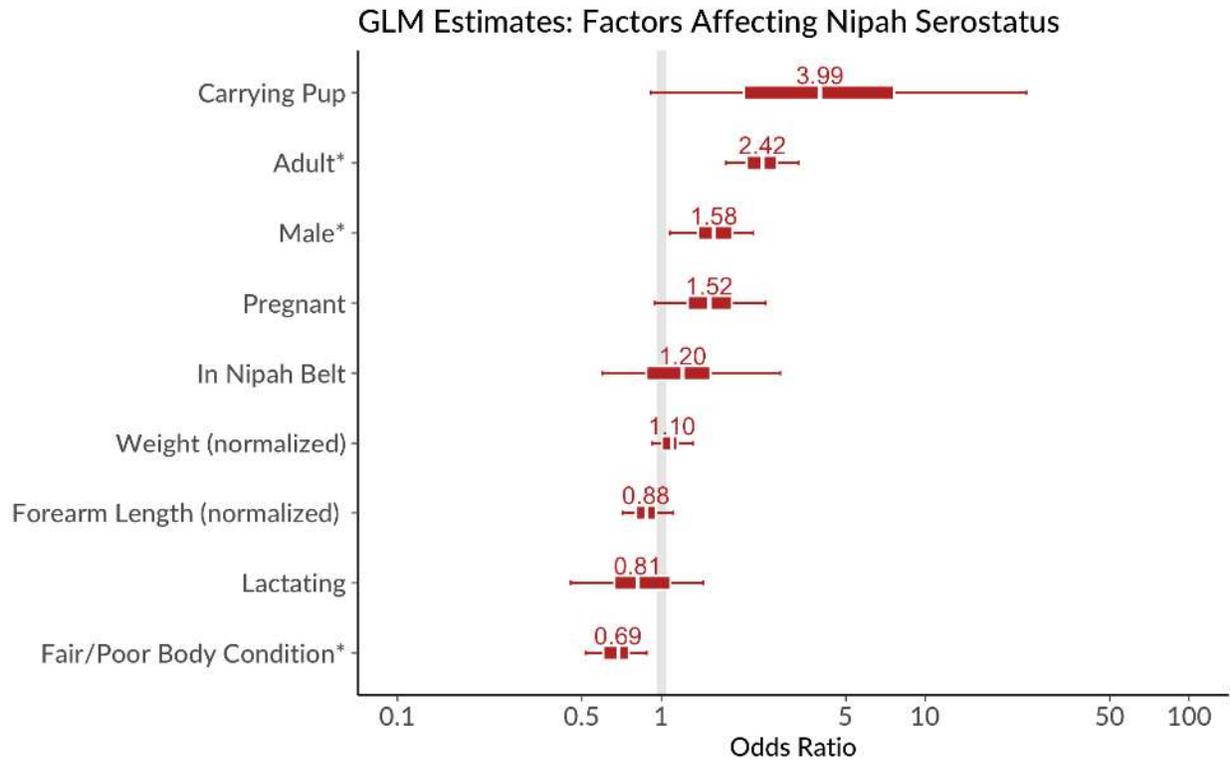

784  
 785 **Figure 1.** Map showing age-stratified seroprevalence in *Pteropus medius* colonies, Bangladesh. Bats from eight  
 786 colonies were sampled and tested for anti-NiV IgG antibodies: four within the “Nipah Belt” (orange shaded) and  
 787 four outside. Seroprevalence of adults (blue, purple), juveniles (red, orange) and total seroprevalence (green, light  
 788 blue) are shown. Number (n) of Adult, Juvenile, and Total bats sampled (clockwise): Tangail [53,41,94], Sylhet [63,  
 789 37, 100], Comilla 2008 [73,27,100], Comilla 2011 [30,20,50], Chittagong [72,24,96], Khulna[85,15,100], Rajbari  
 790 [65,15, 80], Kushtia [64,36,100], Thakurgaon [89,29,118]. The shaded region represents the “Nipah Belt” where  
 791 previous human NiV outbreaks have been reported.  
 792

---

Number: 1      Author: Author      Date: Indeterminate

You only need one legend since it is the same for all panels. This would all you to make the panels a little bigger. I would try to reduce the white-space and zoom in on the map a little and make the graphs bigger. Finally I'd add lines b/w the locations on the map and the graphs.

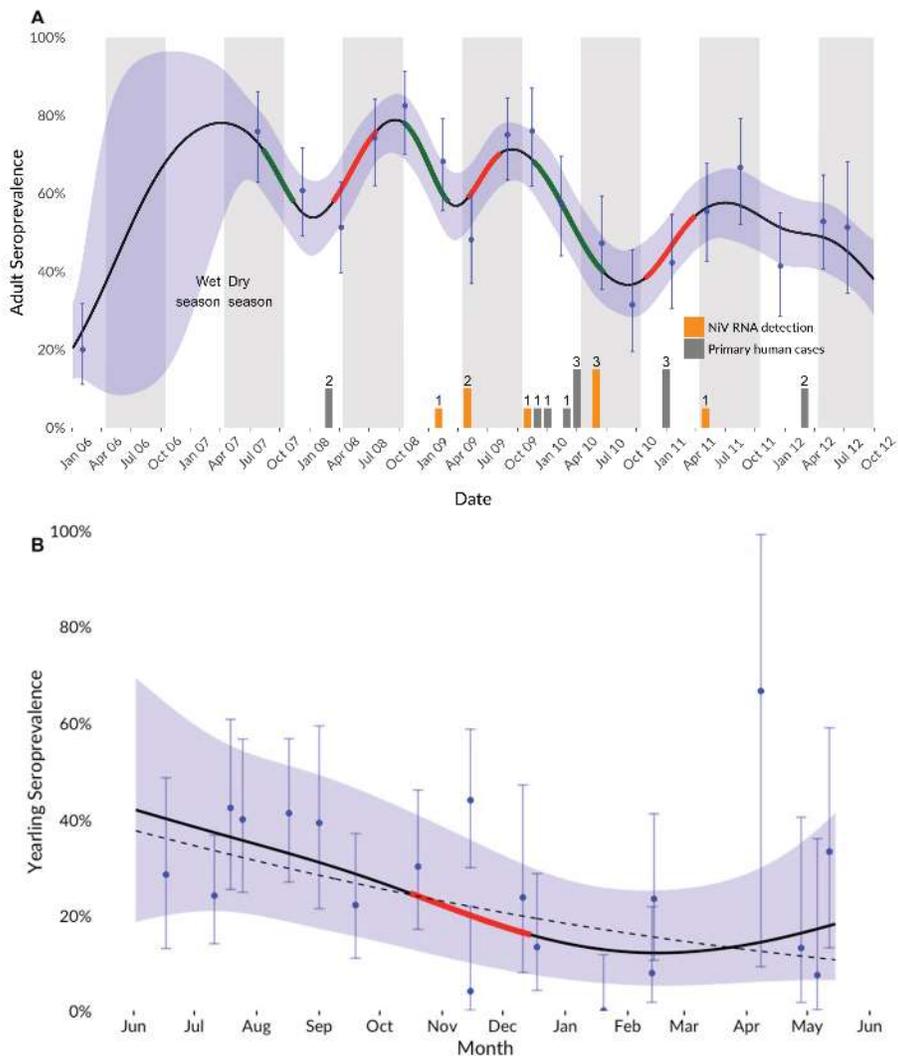

793

794 **Figure 2.** Results of Bayesian GLM of factors affecting Nipah serostatus in bats in cross-sectional study. Bars  
 795 indicate odds ratios and 50% (inner) and 95% (outer) credible intervals for model parameters. Factors with  
 796 asterisks (\*) have 95% CIs that do not overlap 1. Model intercept (predicted probability of seropositivity for a  
 797 juvenile, female, bat outside the Nipah belt of mean size and good body condition) was 0.26, (95% CI 0.12-0.56).  
 798 Random effect of location (not shown) had an estimated SD of 0.63 (95% CI 0.29-1.27)

799

Nipah virus IgG antibody serodynamics in adult and juvenile *Pteropus medius*, Faridpur, Bangladesh 2006-2012

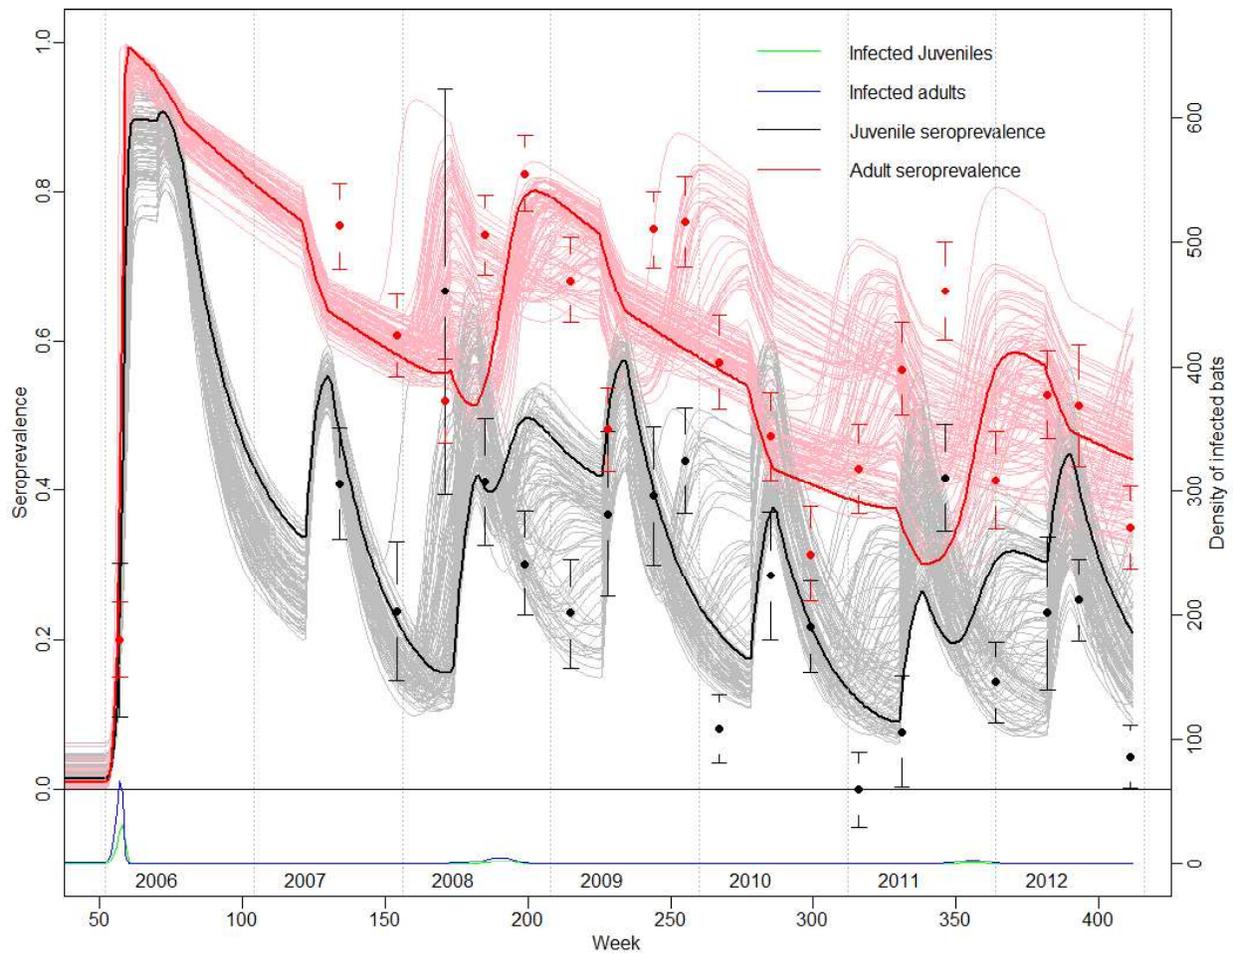

800  
 801 **Figure 3 A & B.** Serodynamics of the Faridpur bat population. (A) Adult serodynamics, with measured values and  
 802 95% CI in blue, and mean GAM prediction and 95% shown with line and surrounding shaded areas. Periods of  
 803 significant increase (red) and decrease (green) shown where the GAM derivative's 95% CI does not overlap zero.  
 804 Counts of primary human cases from local district (orange, and bat <sup>1</sup>al detections (dark grey, see Table 1), shown  
 805 on bottom. (B) Juvenile serodynamics during the first year of life ("yearlings"), with all years' measurements  
 806 overlain to show cohort-level dynamics across all study years. Measured values and 95% CI in blue, and mean and  
 807 95% CI for the GAM model pooled across cohorts shown with line and surrounded shaded areas. The period of  
 808 significant decline in the GAM is shown in red. Also shown is the mean prediction of a model with only a linear  
 809 mean term, with similar fit ( $\Delta AIC < 1$ ) as the GAM (dotted line).  
 810

---

Number: 1      Author: Author      Date: Indeterminate

I'd show these as a % of samples collected, not the raw #. Otherwise you are confounding prevalence with sampling effort, unless the # of samples was the same for every sample.

811

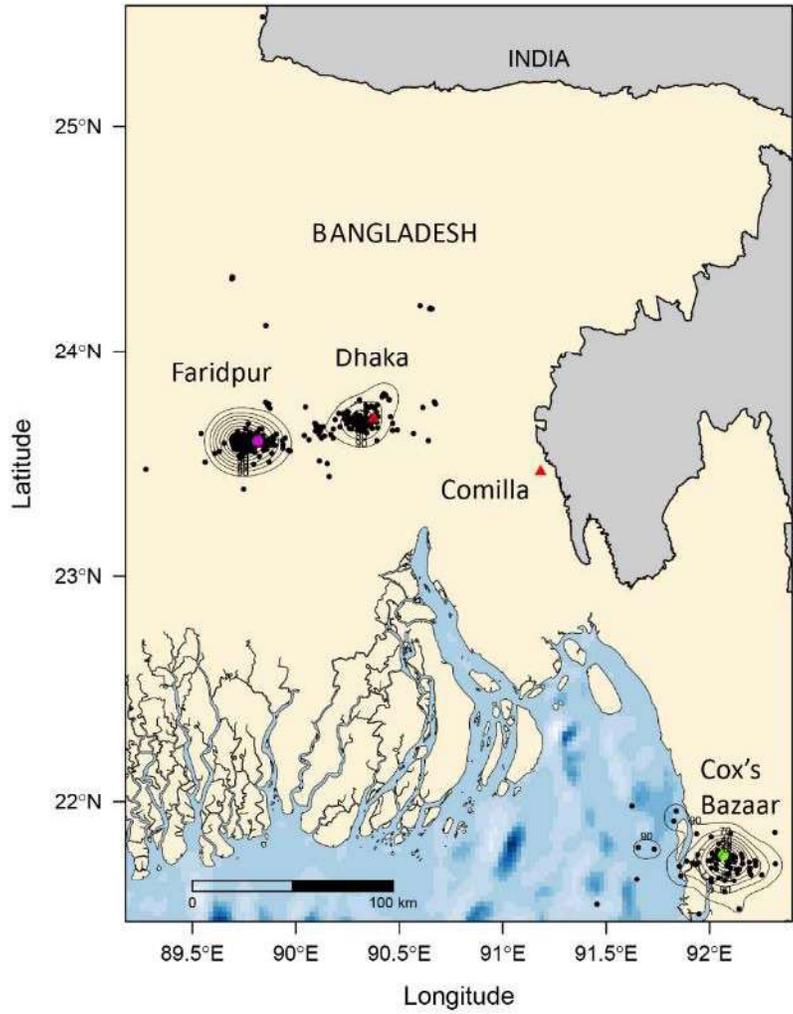

812

813 **Figure 4. NiV serological dynamics in adult and juvenile bats.** The observed data (red and black points  $\pm 1$  SE) and  
814 model fit (solid lines; thick lines show the trajectory for the model with maximum likelihood parameter estimates;  
815 thin lines show realizations for parameter estimates drawn from the estimated distributions) for the fraction of  
816 adults and juveniles seropositive for NiV (left axis), and the model estimated density of infected adult and juvenile  
817 bats (bottom panel and right axis). See Methods for details of model structure.

**Figure 5.** Satellite telemetry and homerange analysis. Location data from satellite collars (n=14) placed on 11 bats from Faridpur and 3 bats from Cox's Bazaar, Chittagong collected between 2009 and 2011, were used to calculate local and long-range movement patterns and home range for these two groups.

**Figure 6. Nipah Virus N gene phylogenetic tree (224nt):** Tree created in Geneious Prime 2019 using a Neighbor-joining Tamura-Nei model with 1,000 replicates (105). The percentage of trees in which the associated taxa clustered together is shown next to the branches. The tree is drawn to scale, with branch lengths measured in the number of substitutions per site. Hendra virus was used as an outgroup. Sample collection date, location and Genbank accession numbers are included in the label for each sequence except *P. medius* sequences which are accession Nos MK995284 – MK995302. Blue labels indicate bat sequences from Faridpur and Bhanga (an outbreak response in Faridpur). Purple sequences are from *P. medius* from other roosts sampled during the longitudinal study. Red sequences are from *P. medius* in Comilla. Green sequences are human NiV sequences from Bangladesh and India.

876 **Table 1.** PCR detection of NiV RNA in *Pteropus medius* 2006-2012.

Nice work Jon.

Attached are a few minor comments.

Good luck with submission.

Steve

Hi Jon,

It's reading pretty well! See my suggested revisions and comments on the main doc and supplemental material. Let me know if you have questions!

Jon Epstein

Wednesday, December 18, 2019 2:00 PM

All,

I hope this email finds you well. Attached is a draft of our manuscript entitled Nipah virus dynamics in bats and implications for spillover to humans. After multiple protracted periods of review in Science Advances, and ultimately a rejection, I've prepared this draft for submission to PNAS. I've revised the manuscript and updated figures and supplemental data in response to the last round of review (comments below, if you're interested).

I have an editor at PNAS willing to send this for review, so please send me any input you may have by December 28th so that I can submit by the 31st. Unless I hear otherwise, I will assume you still consent to co-authorship.

Thank you for your patience, and happy holidays!

Cheers,  
Jon

Reviewer: 1

Epstein et al aim to better understand the distribution and drivers of Nipah virus infection dynamics in *Pteropus medius* in Bangladesh by analysing a large set of serological, virological and movement data over a commendable spatial and temporal scale. Overall, this is a highly exciting study with valuable results that are well-deserving of publication. I have a number of minor comments regarding the addition of detail for clarity (and to ensure transparency in the interpretation of results). I think that the conclusions are mostly justified, however, my major criticism is that the integration and interpretation of the results (particularly those presented in the first paragraph of the discussion) requires a little further thought and explanation. The assumptions surrounding the serological implications of within-host persistence and recrudescence needs to be clearly stated. This is likely to become a 'classic' paper, and there are so few studies in this area supported by data that it is important to ensure that the results are not over-interpreted.

Specific comments:

Abstract:

Line 32- 33: The wording here is too strong regarding recrudescence. Suggest inserting "model results indicated that" prior to "local transmission dynamics."

Line 33-34: Similarly - this is too strong. Suggest "likely due to "

Results:

Figure 1 - presumably the first three bats in the Comilla represent 2008 and the second three represent 2011, but this is not clear. This should be annotated on the plot  
Figure 1 - "Adult bats had equal or greater seroprevalence than juveniles in each location."  
- except Tangail?

Line 129: "detected NiV RNA in 11 individuals, 3 pooled" - insert 'from' before 3

Line 131: - describe "pooled samples" - pooled under-roost urine samples?

Line 132 and 137: This 'figure 2' seems to be missing? Figure 2 refers to serological analyses

Line 145: I suggest that the reference to Figure 2 in line 146 should go in the sentence ending on line 145

Line 149: the significant negative association with body condition warrants mentioning in these results.

Line 154-155 and Figure 3: Additional clarity here regarding juvenile vs. yearling terms. Suggest saying "Juveniles in their first year of life (yearlings)" at first mentioning in the text,  
as well in the figure legend.

Line 159 - incomplete sentence

Lines 160-164: Fascinating results!

Lines 170-171: This information would be helpful to include earlier, with the serological results

Figure 3 and Figure S1 - It would be helpful to have a "total population" size from this roost

complex included on Figures 3 and 4. Understanding more about the bat ecology and the size and stability of these populations over time would be a tremendous help to aid interpretation of these results by researchers working in other systems.

Lines 175-176: "Serodynamics in juveniles were strongly driven by inheritance and loss of maternal antibodies". Supported by what result? This should be explained further, and/or it would be helpful to include the serology (fig 3), model output (fig 4) and population size (Figure s1) together as a series of vertical panels in the one figure to aid interpretation

Lines 178-180: I can't see this information in the supplementary information

Line 182 - this paragraph (and ideally also table S2) should provide information on the duration of tracking for each bat. This would be very helpful in assessing the home range information

Line 195 - should the 'of' be 'if'?

Figure 6 - the utility of this figure would be greatly improved with some annotation and colouring to help identify the new sequences from this study, and their source location, and the 'groups' that are referred to in the text

Lines 238 - 240 - So, your data has found cyclical serodynamics, but no clear links between those dynamics and detection of NiV in bats or in people. Based on experimental studies, it is still a bit unclear exactly what seropositivity in flying foxes represents. If there is within-host persistence of infection, a cycle of infection > seroconversion (in the absence of clearance) > seroreversion > then recrudescence with seroconversion may occur in the absence of ongoing transmission. Additionally, this does not take into account drivers of recrudescence - if this is stress related, then transmission at the population level will also be affected by these broader drivers. Given all the uncertainty around this topic, I think that the wording here needs to be precise. e.g the first sentence should first state the assumption "Assuming that seroconversion results only from new infections, then ...". This could be followed up with a sentence along the lines of "If however, seroconversion can result from recrudescence in the absence of transmission, then broader drivers of recrudescence would also need to be assessed". More clarity here would also help to assess the claims being made in the paragraph beginning 315.

Lines 240 onwards - consider restructuring this paragraph to more clearly step through each stage of the viral dynamics that you are proposing and your assumptions and evidence along the way. For example, you assume infection results in seroconversion, and that antibodies then wane after ~4 years. Are you assuming that all individuals are persistently infected, and it is only when Ab wane that recrudescence can occur? And following that, the individual seroconverts again?

Lines 243 - 245: Not correct - See Brooks et al 2019 JAE Figure S5. That study also involved modelling and has implications for this study more broadly

Lines 245-247: "via recrudescence FROM bats that have previously been infected"? It's also not clear how this links to lines 238-240

Lines 257-259: Consider also cite Peel et al (2018). Scientific Reports, 8(1), e0004796. This study examines waning maternal immunity and waning acquired immunity against henipaviruses in African fruit bats, finding a similar duration of immunity for both  
Line 267 - insert "in our study area" after 'Pteropus medius' as you cannot infer whether these patterns hold true for the species across its range. It may be highly dependent on available food resources - as you go on to discuss

Line 277 - replace 'be' with 'result in'

Lines 295-296 - this links with the SILI hypotheses in Plowright et al (2016) PLoS NTD (see Figure 3)

Line 321- suggest "three periods of transmission (significant at the population level) occurred"

Line 315 See my comments re: paragraph beginning Line 238. The sporadic nature of detections is challenging to draw conclusions and much of the paragraph here (starting line 315) seems over-stated. However, that may become clearer if the comments for the earlier paragraph are addressed.

Methods:

Line 364: I can't see reference to the Faripur colony in the list of colonies in lines 358-359. What are its characteristics? Also, I presume it should be "Faridpur"? Also, it would be

helpful if the "Faridpur roost complex:" could be described in more detail in the methods as to the structure of this population and what this term means.

Line 366: Delete the first 'between'

Lines 388-390 - check the placement of parentheses here

Line 417: what cutoff was used for the Luminex assay and how was it determined?

Line 425 - fix formatting of second Ct

Line 493- 504: More information on the underlying population dynamic model is required e.g. Were births seasonal or continuous in your model? I can't see where this is stated.

If not seasonal, then the effect of this on model output should be addressed. How was the death rate modelled? Was the total population size kept stable inter annually? The latter, in particular, may have implications for interpretation of the density-dependent vs frequency dependent results. The population size is touched on in the discussion in lines 288-291 but never really explained.

Table S1 - there is extra text below Table S1 that looks like it's not supposed to be there

Table S2 - Include what serostatus 0/1 refers to in the table caption

Reviewer: 2

Dear editor, I have reviewed the manuscript entitled "Nipah virus dynamics in bats and implications for zoonotic spillover to humans". The manuscript describes a longitudinal surveillance in Pteropid spp. Bats from 2006 until 2012. Biometric data was collected, sera and swabs/urine were analyzed, and inferences were made largely based on serological data. The manuscript is a compendium of relatively loosely compiled data, ranging from seroprevalence in a variety of different sampling sites, but the majority of the samples stem from Faridpur. The problem is that most of the claims by the authors within the paper are not directly supported by the data. The direct problem of the data is the limited amount of detected virus shedding, out of 2789 animals sampled only 11 were found to be shedding the virus. >>From this only 8 were from the larger study cohort from Faridpur.

This

directly hampers some of the conclusion of potential spillover dynamics as this cannot be directly inferred from serological data alone. In addition, it does not provide any answers on the occurrence of Nipah spillover in the Nipah belt vs the other regions. Moreover, the significant spillover events in Kerala, India from the last two years, are not discussed. Most emphasis has been put on analyzing the serological results from the *Pteropus medius* bats. The authors show variation in the seroprevalence within the population based on timing and age status of the animal. The results have been reported before in other natural reservoir-pathogen systems like avian influenza, however even within these systems inferences on spillover can rarely be made. It is interesting that the authors did not correlate the positive individual bats in Faridpur and Rajbari with their respective serostatus? Is this data not available? It is unclear to me why the authors have not put more effort in trying to perform full genome analyses on the positive samples obtained throughout this study. Currently there are only 27 full genomes available from Nipah virus and relatively limited amount are from the natural reservoir. Performing phylogenetic analyses on a 224 nucleotide fragment of a 19kb virus is really not up to standard. Where it might be suitable for identification of the lineage no additional data can be inferred from this. Interestingly, there appears to be full genome sequencing performed but only N is shown in the supplemental data.

Although I do understand the logistics involved with this kind of work, unfortunately some of the claims, especially regarding spillover, need to be supported by more additional data rather than just serology.

Minor points:

Line 65: pandemic potential, given the limited amount of h-to-h transmission the pandemic potential of this particular virus appears to relatively limited.

Line 143: n=844 or n=883? Why do the numbers not match-up?

Line 410, include level of biosecurity involved in sample analyses. In addition, heatinactivation

is typically to inactivate complement and not inactivation of the pathogen.

From the current wording it is unclear what the authors mean by this? Complement

inactivation or pathogen inactivation?

Line 428, is this data missing? Where is the NSG data? Why not data on the full genomes? I only was able to find the full N gene data in the supplemental figures.

Line 509, given that actual recrudescence in the context of virus shedding in the natural reservoir has never been shown it would be good to treat this a little bit more carefully.

Somehow I mis-spelled "transmission" and left way too many significant digits. I also had left the small table with the coefs in the word doc. I've corrected these three things.

$\Delta$	Recrudescence	2.30E-07	1.41E-08	7.10E-07
$(1-\mu)^{52}$	Adult annual survival	0.75	0.718554	0.80
$\lambda$	Rate of maternal antibody loss	0.057	0.040	0.073
$\tau$	Rate of adult antibody loss	0.0034	0.0021	0.0041

Although obviously a good hook, the data we present are only weakly useful for this since we find no correlation b/w bat dynamics and human cases. If the editor will already send it out for review I'd cut this. Overselling what the paper is about is why the paper was rejected at Science Advances.

24 **Abstract**

25 Nipah virus (NiV) is an emerging bat-borne zoonotic virus with pandemic potential that causes near-  
26 annual outbreaks of fatal encephalitis in South Asia – one of the most populous regions on Earth. In  
27 Bangladesh, infection occurs when people drink date palm sap contaminated with bat excreta, but a  
28 recent outbreak in India involved a different, but yet unknown, route of spillover. Outbreaks are  
29 sporadic and the influence of viral dynamics in bats on their temporal and spatial distribution is poorly  
30 understood. We analyzed data on host ecology, molecular epidemiology, serological dynamics, and viral  
31 genetics to characterize spatio-temporal patterns of NiV dynamics in its wildlife reservoir, *Pteropus*  
32 *medius* bats, in Bangladesh. We found that NiV transmission occurred throughout the country and  
33 throughout the year. Model results indicated that local transmission dynamics were driven by density-  
34 dependent transmission, acquired immunity which is lost over time, and recrudescence. Increased  
35 transmission followed multi-year periods of declining seroprevalence due to bat population turnover  
36 and individual loss of humoral immunity. Individual bats had smaller host ranges than other *Pteropus*  
37 spp., although movement data and the discovery of a Malaysia-clade NiV strain in eastern Bangladesh  
38 suggest connectivity with bats east of Bangladesh. These data suggest that discrete multi-annual local  
39 epidemics in bat populations contribute to the sporadic nature of Nipah virus outbreaks in South Asia. At  
40 the same time, the broad spatial and temporal extent of NiV transmission, including the recent outbreak  
41 in Kerala, India, highlights the continued risk of spillover to humans wherever they may interact with  
42 pteropid bats, and the importance of improving Nipah virus surveillance throughout *Pteropus's* range.

This is interesting but isn't relevant to this paper and we have no data to address it so I'd remove this, especially in the abstract. The mention of it below doesn't require this text. Mentioning it here makes the reader expect us to address it and we can't.

47 **Introduction.**

48 Outbreaks of zoonotic diseases are often sporadic, rare events that are inherently difficult to predict,  
49 but can have devastating consequences (1). Several emerging viral zoonoses with wildlife reservoirs  
50 have become pandemics, including HIV/AIDS, SARS coronavirus, and 1918 Pandemic Influenza H1N1 (2-  
51 4). Bats are important hosts for many zoonotic viruses (5) including Ebola virus, SARS-CoV, and Nipah  
52 virus, but the ecological drivers and transmission dynamics of these viruses in their reservoir hosts are  
53 poorly understood (6-10). A better understanding of the transmission dynamics of zoonotic pathogens in  
54 their natural reservoirs may help anticipate and prevent outbreaks (9, 11).

55 Nipah virus (NiV) is an emerging zoonotic paramyxovirus (genus *Henipavirus*) that has  
56 repeatedly spilled over from bats to cause outbreaks in people and livestock with high case fatality rates  
57 across a broad geographic range, making it a significant threat to global health. It has caused repeated  
58 outbreaks in Bangladesh and India, with a mean case fatality rate greater than 70% (12-14). A single  
59 genus of frugivorous bats (*Pteropus*) appears to be the main reservoir for henipaviruses throughout Asia  
60 and Australia (15-19), including *Pteropus medius* (formerly *Pteropus giganteus* (20)) in Bangladesh and  
61 India (21-24). Nipah virus has several characteristics that make it a significant threat to human and  
62 animal health (25-27): 1) its bat reservoir hosts are widely distributed throughout Asia, overlapping  
63 dense human and livestock populations, providing broad opportunity to cause outbreaks; 2) it can be  
64 transmitted directly to humans by bats or via domestic animals; 3) it can be transmitted from person to  
65 person; 4) spillover has repeatedly occurred in highly populous and internationally connected regions,  
66 giving it pandemic potential; 5) it is associated with high mortality rates in people; and 6) there are  
67 currently no commercially available vaccines or therapeutics. As a result, the World Health Organization  
68 has listed Nipah virus among the ten most significant threats to global health (28). To date, human  
69 Nipah virus infections have been identified in India, Bangladesh, Malaysia, Singapore, and the  
70 Philippines (12, 22, 29-31). In May 2018, an outbreak of Nipah virus encephalitis associated with a 91%  
71 mortality rate occurred in a new location - Kerala, India - more than 1,200 km southwest of previous  
72 Indian and Bangladeshi outbreaks (32). A single case was subsequently reported in Kerala in 2019, and  
73 while local *P. medius* populations have been implicated as the local source of infection, the route of  
74 spillover in both instances remains unknown (32, 33).

75 In Malaysia and Bangladesh, consumption of cultivated food resources contaminated with bat  
76 excreta such as mangoes in Malaysia and date palm sap in Bangladesh and northeastern India have been  
77 identified as the predominant cause of spillover to pigs and people respectively (34). Human outbreaks

---

Number: 1      Author: Author      Date: Indeterminate

I'd put the refs after the statements (even if you cite the same ref multiple times), because otherwise it's hard to know which paper to find the info.

78 occur almost annually in Bangladesh and the seasonal timing (November-April) and spatial distribution  
79 of outbreaks coincide with patterns of raw date palm sap consumption in a region termed the “Nipah  
80 belt” (35). However, the <sup>1</sup> is variability in the number of spillover events and magnitude of the  
81 outbreaks that occur each year (36), and spillover has occasionally occurred outside the predominant  
82 season and region of date-palm sap consumption (37). Further, date palm sap harvesting and  
83 consumption also occurs in eastern Bangladesh, yet no human outbreaks have been reported, while  
84 date palm sap is not cultivated in Kerala, India at all, suggesting an alternate route of spillover (35).  
85 While the full range of mechanisms for zoonotic transmission remain unknown, so too are the  
86 underlying viral infection dynamics in bats and the extent of genetic diversity within the virus – each of  
87 which may influence the timing, location and epidemiology of human outbreaks (35).

88           Previous research on the transmission dynamics of Nipah and Hendra viruses in *Pteropus* spp.  
89 bats have produced mixed and sometimes contradictory findings. Nipah virus, like Ebola, Marburg,  
90 Hendra and some bat coronaviruses, has been hypothesized to have seasonal spikes in infection that  
91 coincide with annual or semi-annual synchronous birth pulses (15, 38-44). Seasonal periods of Nipah  
92 virus shedding were observed in *P. lylei* in Thailand and seasonal spikes in NiV (or a related henipavirus)  
93 seroprevalence coinciding with pregnancy periods were observed in *Eidolon dupreanum* in Madagascar  
94 (45, 46), but not in *P. vampyrus* or *P. hypomelanus* in Peninsular Malaysia (19). Hendra virus prevalence  
95 in Australian pteropid bats has shown multi-year inter-epidemic periods where very little virus can be  
96 detected, followed by periods of increased viral shedding, suggesting that viral dynamics are not annual  
97 (47-49). It has been hypothesized that multi-year periodicity in henipavirus infection dynamics could  
98 arise from a build-up and waning of herd immunity in the reservoir host, with re-introduction of virus via  
99 immigration or recrudescence or viral persistence (10, 50-52). Some pteropid bat species are migratory  
100 and interconnected colonies form a metapopulation which could allow for viral re-introductions (9, 19,  
101 53, 54). In addition, NiV recrudescence has been observed in wild-caught *P. vampyrus* and *Eidolon*  
102 *helvum* and either of these phenomena could allow it to persist regionally during periods of high local  
103 immunity (55). However, no study has yet shown evidence in open, free-ranging bat populations that  
104 favors one or the other hypothesis in driving NiV transmission dynamics.

105           The goal of the current study was to determine the distribution and drivers of NiV infection  
106 dynamics and NiV diversity in *Pteropus medius* in Bangladesh to try to understand patterns of human  
107 outbreaks. We examined spatial, temporal and demographic variation in serological dynamics and viral  
108 shedding in bats over a six-year period to determine the spatio-temporal drivers and dynamics of virus

---

Number: 1      Author: Author      Date: Indeterminate

Isn't there also variation in exactly where there are cases even if there are cases in most years? In short, I think we want to make the pattern of cases in a given place (I'm not sure what scale, but the approximate scale of a bat colony would be useful) as clear as possible. I think the strongest thing we found from the model-fitting analysis is that large epidemics in bats don't occur every year, and thus we wouldn't expect many spill over events in the same communities in consecutive years (although we don't predict zero either, because of recrudescence)). If the human spillover data are consistent with that pattern, it would be suggestive that the bat data and fitted model are telling us something useful.

109 transmission. We also studied movement patterns of individual bats and analyzed NiV phylogenetics to  
110 understand patterns of spatial mixing and virus strain diversity.

111

## 112 **Results**

113 *Comparative Nipah virus prevalence study in bats inside and outside the Nipah Belt and concurrent*  
114 *longitudinal bat study inside the Nipah Belt (2006-2012)*

115 We caught and tested 883 *P. medius* (~100 per district) from eight different districts across  
116 Bangladesh. We detected anti-Nipah IgG antibodies in all colonies (**Figure 1**). Seroprevalence varied by  
117 location ( $\chi^2 = 55.61$ ,  $p < .001$ ), but there was no statistical difference between seroprevalence in bats  
118 inside the Nipah Belt and outside. In all locations except Tangail, adult seroprevalence exceeded juvenile  
119 seroprevalence. Viral detection<sup>1</sup> in individuals was rare; overall, we detected NiV RNA in 11/XXX  
120 individuals as well as 3 pooled oropharyngeal samples (representing 5 bats, but which could not be<sup>2</sup>  
121 resolved to an individual) and 21 or XXX pooled urine samples ("roost urine") collected from tarps  
122 underneath the roost (**Table 1**). We detected<sup>3</sup> viral RNA in individual bats in Faridpur and Rajbari and  
123 from pooled samples from Thakurgaon and roost urine samples from Comilla. Of the 10 PCR positive  
124 individuals, three had detectable IgG antibodies (**Table S1**). We also detected virus in pooled<sup>4</sup> urine  
125 collected from tarps placed below bats at roosts associated with human outbreaks in Bhanga and  
126 Joypurhat. The viral prevalence in Rajbari in January 2006 was 3.8% (95% CI: 0% -11%; n=78). In  
127 Faridpur, where we also conducted an intensive longitudinal study (see below), viral prevalence  
128 estimates ranged from 0% to 3% (95% CI: 0%-10%; n=100 at each of 18 sampling times) (**Table 1**). Nipah  
129 virus RNA was detected in individual bats from inside (Rajbari, Thakurgaon, and Faridpur) and outside  
130 (Comilla) the Nipah Belt. We detected viral RNA in bats both with and without detectable IgG antibodies  
131 (**Table S1**). Urine samples provided<sup>5</sup> the highest NiV detection rate. Detection rates in individual bats by  
132 sample type were: urine/urogenital swab = 4% (n=2,126); oropharyngeal swab 3% (n=2,088); and rectal  
133 swab = 1.3% (n=79). The estimated detection rate from pooled urine samples across the entire study  
134 was 2.7% (+/- 1.6%; n=829).

135

136 *Factors associated with NiV IgG serostatus in P. medius*

137 Among adult and juvenile bats sampled in the aforementioned cross-sectional study from which  
138 we got blood samples (844 of 883), seropositivity was 2.4 times more likely among adults than juveniles,  
139 and 1.6 times more likely among males than females<sup>7</sup> (**Figure 2**). Among females, seropositivity was  
140 higher in pup-carrying<sup>8</sup> (4 times) and pregnant (1.5 times) individuals. Weight or forearm length did not

This is a key result and we need statistics to support this claim. I did these stats a while back and they are probably in a previous version of the paper.
- 
- Number: 2 Author: Author Date: Indeterminate  
Out of how many? We should give a denominator and the percent.
- 
- Number: 3 Author: Author Date: Indeterminate  
Same comment.
- 
- Number: 4 Author: Author Date: Indeterminate  
It says 11 above.
- 
- Number: 5 Author: Author Date: Indeterminate  
This is already clear from the sentence above. I'd delete this.
- 
- Number: 6 Author: Author Date: Indeterminate  
This needs a statistical test to support it. I think I did the stats for this a while back.
- 
- Number: 7 Author: Author Date: Indeterminate  
Odds ratios don't actually mean the prob of seropositivity (unless the prob of seropositivity is very small in which case they are approximately similar). See this page:  
[https://en.wikipedia.org/wiki/Odds\\_ratio](https://en.wikipedia.org/wiki/Odds_ratio)  
You can predict the actual seroprevalence values using the fitted models and then report these actual ratios of seropositivity, but the odds ratios can't be described this way.
- 
- Number: 8 Author: Author Date: Indeterminate  
Same for all of these.
-

141 consistently correlate with seropositivity, however, body condition (an assessment of pectoral muscle  
142 mass by palpation) was significantly negatively correlated (Poor/Fair body condition OR = 0.69) with  
143 serostatus. Finally, serostatus was strongly correlated in mother-pup pairs, with 71/80 pairs (89%)  
144 having matching status.

145

#### 146 *NiV serodynamics over time in a population of P. medius, Faridpur district (2006-2012)*

147 We conducted an intensive longitudinal study of NiV serology in a population of bats in the  
148 Faridpur district and used flexible generalized additive models (GAMs) to characterize changes over  
149 time. There were significant fluctuations in adult (>24 mo.) and juvenile (6 – 24 mo.) seroprevalence  
150 over the six-year study period (**Figure 3A**). Juvenile seroprevalence ranged from 0% to 44% (95%CI 37%-  
151 51%), and decreased over the first year of life for bats born in each year (“yearlings”), consistent with  
152 loss of maternal antibodies in juveniles. A more pronounced decrease occurred from mid-October to  
153 mid-December. However, the GAM indicating this had only marginal better fit ( $\Delta AIC < 1$ ), than one with  
154 a linear decrease over the whole year (**Figure 3B**). The effect of birth cohort was significant on overall  
155 seroprevalence. <sup>1</sup>

156 Adult seroprevalence ranged from 31% (95% CI: 20%-46%) to 82% (95% CI: 77%-87%) and went  
157 through three periods of significant decrease then increase over the course of the study (**Figure 3A**). We  
158 found no evidence of regular seasonal fluctuations; a GAM with annual cyclic terms fit worse than one  
159 without ( $\Delta AIC > 10$ ). Viral RNA detections occurred in periods of increasing, decreasing, and stable  
160 seroprevalence.

161 We fitted a series of age-stratified mechanistic models to examine different biological processes  
162 influencing serodynamics, including density- vs. frequency-dependent transmission, recrudescence vs.  
163 immigration of infected individuals, and seroreversion (loss of antibodies) in both juveniles and adults  
164 (**Figure 4**). We included annual, synchronous birthing, which occurred between March and April. We  
165 assumed that pups weaned from their dams at 3 months, and became independent flyers, and that  
166 maternal antibodies waned after 6 months at which point we had pups transition into the “juvenile”  
167 class (56, 57). We assumed that juveniles became sexually mature at 24 mo., and entered the “adult”  
168 class based on other pteropid species(43, 56, 58). Density-dependent models were a far better fit to the  
169 data than frequency-dependent models (difference in log-likelihood 10.0;  $\Delta AIC = 20.0$ ), suggesting that  
170 movements of bats and fluctuations in colony size alter spatio-temporal variation in the risk of NiV  
171 epidemic spillover to humans. In this colony (Domrakhandi/Khaderdi) <sup>2</sup> during the period of sampling, the  
172 roost population declined from approximately 300 bats to 185, which decreased transmission potential

## Page: 6

---

Number: 1      Author: Author      Date: Indeterminate  
What does this mean?

---

Number: 2      Author: Author      Date: Indeterminate  
Given that you already show a nice figure with these values, I'd just report the factors that are positively and negatively correlated with seropositivity and their relative strength but you don't need to give all the individual values.

173 in the fitted model:  $R_0$  in adult bats was estimated to decrease from 3.5 to 2.1 as the number of bats in  
174 the colony decreased. As a result, over the six-year study period, the fitted model predicted that the  
175 number of infected bats increased when the seroprevalence of adults fell below 72% (when bat counts  
176 were highest - in 2006) and 52% (when bat counts were lowest). The fitted model suggested that  
177 serodynamics in juveniles were strongly driven by inheritance and loss of maternal antibodies. The rate  
178 of loss of maternal antibodies was 17.6 weeks (95% CI: 13.7-25.0), which was much quicker than the loss  
179 of antibodies in adults (290.8 weeks, 95% CI: 245.0-476.4) (**Table S2**). Finally, models with recrudescence  
180 fit the data better than models without recrudescence (**Table S2**; difference in log-likelihood 32.6;  $\Delta$ AIC  
181 = 65.1), and models with recrudescence fit the data better than models with immigration ( $\Delta$ AIC = 3.76).

182

### 183 *Mark-recapture and seroconversion/seroreversion*

184 A total of 2,345 bats from the Faridpur/Rajbari region were sampled and microchipped between  
185 2007 and 2012. There were 56 recapture events (**Table S3**). Thirty-one bats were recaptured at a roost  
186 other than the original capture location. This network of roosts or “roost complex” formed a polygon  
187 covering approximately 80 Km<sup>2</sup> and included 15 roosts sampled during the longitudinal study (**Figure**  
188 **S2A and S2B**). Ten instances of seroconversion (change from IgG negative to IgG positive) and nine  
189 instances of seroreversion (positive to negative) were observed (**Table S3**). The mean time between  
190 positive and negative tests in *adults* (excluding juveniles with maternal antibodies) was 588 days (n=6)  
191 (range: 124-1,082 days).

192

### 193 *Home range and inter-colony connectivity analysis*

194 Home range analysis of satellite telemetry data from 14 bats (**Table S4**) showed that the  
195 majority of bats roosted within 10 km of where the bats were originally collared, in the Faridpur (Nipah  
196 belt) colony, and within 7 km from where the bats in the Cox’s Bazaar colony were originally collared  
197 (315km east of Faridpur). The average foraging radius was 18.7 km (s.d. 21.5 km) for the Faridpur bats  
198 and 10.8 km (s.d. 11.9 km) for the Cox’s Bazaar bats (**Figure S2**). Homerange analysis suggests that bats  
199 in Faridpur and Cox’s Bazar would have a <5% probability of intermingling (**Figure 5**). Homerange size  
200 was significantly larger during the wet season than the dry season (2,746 km<sup>2</sup> vs. 618 km<sup>2</sup>) (**Figures S3 &**  
201 **S4**).

202

### 203 *NiV phylogenetic analysis.*

---

 Number: 1      Author: Author      Date: Indeterminate  
I think this is 2 words. If so, I'd change it throughout.

204 Phylogenetic analysis of NiV sequences from a 224nt section of the N gene (nt position 1290-  
205 1509 [position ref [gb|FJ513078.1](#) India]) suggests that strains from both India and Malaysia clades are  
206 present in Bangladesh bats (**Figure 6**). This finding is supported by an analysis of near-whole N gene  
207 sequences (~1720 nt) from bats, pigs, and humans, including those from a subset of *P. medius* from this  
208 and a more recent study by our group (**Figure S5**) (59). Eleven 224nt N gene sequences obtained from  
209 bats between 2006 and 2012 (all from the Faridpur population) were identical. Overall, the N gene  
210 sequences identified from the Faridpur, Rajbari and Bhanga colonies between 2006 and 2011 had  
211 98.21%-100% shared nucleotide identity. Sequences from Rajbari district obtained five years apart  
212 (January 2006 and January 2011) had only a single nucleotide difference resulting in a synonymous  
213 substitution (G to A) at position 1304, which was found in four other bat NiV sequences from this study,  
214 as well as in the NiV isolate from *P. vampyrus* in Malaysia. Five Human NiV N gene sequences from  
215 various locations within the Nipah belt over the same time period as our bat study show more  
216 nucleotide diversity than those from the Faridpur *P. medius* population. Human sequences throughout  
217 Bangladesh and from Kerala, India, all nested within the diversity found in *P. medius* (**Figure 6**). By  
218 contrast, the sequences found in *P. medius* from Comilla, a location 150Km to the east of Faridpur,  
219 showed 80.8%-82.59% shared nucleotide identity with sequences from *P. medius* in Faridpur and  
220 clustered within the Malaysia group of NiV sequences. The two Comilla sequences were identical to  
221 each other, and had up to 87.95% shared nucleotide identity to sequences from *P. lylei* in Thailand.  
222 *Pteropus lylei* bats in Thailand were also found to carry NiV strains from both Malaysia and Bangladesh  
223 groups.

224

## 225 Discussion

226 Our study provides new insights into Nipah virus transmission dynamics, genetics and host ecology.  
227 Previous studies from Bangladesh suggested that human NiV outbreaks occur only within a defined  
228 region in western Bangladesh, termed the “Nipah belt,” and during a defined season (Nov-Apr), which  
229 raised the question of whether that observation was entirely due to date palm sap consumption, or  
230 whether ecological factors such as the distribution and timing of bat viral infection also influenced the  
231 timing and location of human cases (13, 35, 60). We undertook the most geographically extensive survey  
232 of *Pteropus medius* in Bangladesh to date to understand Nipah virus infection patterns in its putative  
233 reservoir, *Pteropus medius*, which is common in Bangladesh and throughout the Indian subcontinent  
234 (21, 22, 56).

235 Overall, our findings suggest viral circulation is not limited to the Nipah belt, but that NiV  
236 transmission occurs in bat populations throughout the country. We observed that virus can be shed at  
237 any time of year, and that viral dynamics are not annual or seasonal, but driven by demographic and  
238 immunological factors. Analysis of serological data from our longitudinal study suggests that the  
239 underlying mechanism driving the timing of NiV transmission in bats is the waning of herd immunity in  
240 bat populations allowing heightened viral transmission, but recrudescence can result in sporadic  
241 shedding at any time.

242 A number of mechanisms have been proposed for the maintenance of acute viral infections in  
243 bat metapopulations, including synchronous birthing and subsequent loss of maternal antibodies (10,  
244 39, 41), lowered immunity within pregnant females due to stress, nutritional stress and other factors  
245 (43) immigration of infected individuals from other colonies (53, 61, 62), and recrudescence within  
246 previously-infected individuals (10, 55, 63). Our modeling indicates that NiV is primarily driven by  
247 density-dependent transmission dynamics among adult bats, with cycles of higher seroprevalence that  
248 would dampen intra-colony transmission followed by waning of antibody titers within individuals and at  
249 a population level. Waning humoral immunity against Nipah virus is a consistent feature of henipavirus  
250 studies in African pteropodid bats (52, 64). Our recapture data provided the first reported evidence of  
251 the loss of detectable NiV IgG antibodies in recaptured individual free-ranging bats, which supports our  
252 observation of population level waning immunity. The consistently lower and decreasing seroprevalence  
253 that we observed in juveniles suggests that they lose maternal antibodies over their first year, and likely  
254 in the first 6-7 months, consistent with other studies of maternal antibodies against henipaviruses in  
255 pteropodid bats (43, 52, 57, 65). However, our analysis does not support the hypothesis that seasonal  
256 pulses of these new seronegative individuals are the primary driver of new outbreaks in adults (41).

257 Our model outputs suggest that spikes in viral transmission occur after virus is reintroduced into  
258 colonies after immunity has waned. The model fitting suggests that serodynamics are more consistent  
259 with recrudescence, but immigration of infected individuals could also reintroduce the virus.

260 Recrudescence would presumably occur in individuals with antibody titers that have waned below a  
261 neutralizing titer, if loss of humoral immunity following a primary infection is sufficient to allow a second  
262 infection. Recrudescence of henipavirus infection has been observed for NiV in captive *P. vampyrus* (55),  
263 for henipavirus in captive *E. helvum* (52, 66), and has also been observed in humans infected by NiV (67)  
264 and Hendra virus (68). It is difficult to know from serology alone whether wild-caught seronegative bats  
265 had been previously infected. Experimental infection of naïve and previously infected *Pteropus medius*  
266 that have sero-reverted would provide a better understanding of how humoral immunity influences

This is a bit less aggressive. If the paper goes to one of the authors of ref 41 it'd be better to be more gentle.

267 individual susceptibility to infection, and inform dynamics models attempting to explain viral  
268 maintenance within bat populations (64).

269 Our longitudinal study is limited in that it may not necessarily reflect temporal infection  
270 dynamics in all bat populations across Bangladesh. Our roost count data and recapture data from  
271 microchipped bats showed how roost sizes can fluctuate, and local roost shifting can occur. The  
272 observation of individual bats using multiple roost sites suggests that changes in roost count, which our  
273 models suggest impacts transmission dynamics, could reflect local shifts in densities rather than  
274 fluctuations in regional populations.

275 Understanding how bat populations connect across landscapes is important for understanding  
276 viral maintenance, and studying local and migratory bat movements can provide important ecological  
277 information related to viral transmission, including how bats move between different colonies (53). Our  
278 satellite telemetry data suggest that *P. medius* exists as a metapopulation, like other pteropid species  
279 (10, 62). However, *Pteropus*<sup>1</sup>*medius* appear to travel shorter distances and remain within a smaller  
280 home range (321.46km<sup>2</sup> and 2,865.27km<sup>2</sup> for two groups) compared to *P. vampyrus* in Malaysia (64,000  
281 km<sup>2</sup> and 128,000 km<sup>2</sup>) and *Acerodon jubatus* in the Philippines which are similarly sized fruit bats (53,  
282 69). Pteropodid bat migration is primarily driven by seasonal food resource availability (54, 70-72). In  
283 Bangladesh, *P. medius* prefer to roost in human-dominated environments in highly fragmented forests  
284 (73). The anthropogenic colonization and conversion of land over recent human history has likely led to  
285 increased food availability for *P. medius* and reduced necessity for long-distance migration (34). This  
286 may reflect a similar adaptation to anthropogenic food resources as observed over the last few decades  
287 in Australian *Pteropus* species (62). Genetic analysis of *P. medius* across Bangladesh has shown that the  
288 population is panmictic – that historically, there has been interbreeding among populations across  
289 Bangladesh(74). If movements are generally more localized, as suggested by telemetry, then less  
290 connectivity among flying fox populations may influence Nipah transmission by creating longer inter-  
291 epidemic periods and larger amplitude fluctuations in population level immunity compared to more  
292 migratory species (62).

293 Bat movement and population connectivity may also influence the genetic diversity of Nipah  
294 virus found in different locations, and genotypic variation has been associated with different clinical  
295 outcomes in people. While the overall strain diversity among Nipah virus has not been well  
296 characterized due to a dearth of isolates, two distinct NiV clades have been described: A Bangladesh  
297 clade, which includes sequences identified in India and Bangladesh; and a Malaysian clade, which  
298 comprises sequences from Malaysia, Cambodia, The Philippines and Thailand (31, 59, 75). Strains of NiV

---

Number: 1      Author: Author      Date: Indeterminate

It's not a limitation in model parameterization – it was a limitation in the data. If we had seroprevalence data in many individual roosts we could examine the importance of local vs regional population processes. But that would be a ton of work!

299 from these two clades are associated with differences in pathogenesis, epidemiological and clinical  
300 profiles in humans and animal models and observed shedding patterns in bats (45, 76-80). Phenotypic  
301 variation in Nipah virus could influence observed human outbreak patterns by altering transmission to,  
302 or pathogenesis in, humans, and the likelihood of smaller outbreaks being identified or reported (81).  
303 Human-to-human NiV transmission via contact with respiratory and other secretions has been regularly  
304 observed in Bangladesh and India, including the recent 2018 outbreak in Kerala (12, 82, 83), whereas  
305 transmission among people was not a common feature of the Malaysia outbreak, despite close contact  
306 between cases and health care providers (84, 85). Nipah virus cases in Bangladesh have shown more  
307 strain diversity than in the Malaysia outbreak (86),.

308         Until now, there have been very few Nipah sequences obtained from *P. medius*. We found that  
309 Nipah N-gene sequence from bats from the Faridpur population were nearly identical over time,  
310 compared to variation in N-gene sequences from bats and humans from other locations observed over  
311 the same time period (2006-2010). This suggests that there may be locally prevalent and stable NiV  
312 genotypes that persist within bat colonies. Human NiV genotype diversity is likely a reflection of the  
313 relative diversity of the NiV strains in the local bats that seed outbreaks (9). This is also supported by  
314 viral sequences obtained from human and bats associated with the 2018 NiV outbreak in Kerala, India,  
315 where human NiV sequences were most closely related to local *P. medius* sequences (87). We found a  
316 significantly divergent NiV strain in Comilla, which clustered within the Malaysia NiV clade, suggesting  
317 that strains from both clades are circulating in bats in Bangladesh.

318         Connectivity of pteropid bats in Bangladesh with those in Southeast Asia could explain the  
319 observed strain diversity in our study. Historical interbreeding of *P. medius* with pteropid species found  
320 in Myanmar, Thailand, and Malaysia and our telemetry findings showing bats are capable of flying  
321 hundreds of kilometers, could explain our discovery of a Malaysia clade NiV sequence in bats from  
322 Comilla (74). NiV Bangladesh strains have also been found in *P. lylei* in Thailand (88). The N gene of the  
323 Comilla NiV strain differs from those reported from bats in the Nipah belt by 20%, whereas NiV Malaysia  
324 and NiV Bangladesh differ by only 6-9% and are associated with different clinical profiles. Whole  
325 genome sequence (which could not be obtained) would have allowed for better characterization of the  
326 Comilla strain, but the N gene is generally conserved relative to other genes, and suggests the rest of the  
327 genome may also be highly divergent. It is therefore plausible that the clinical profile of a 20% divergent  
328 NiV strain differs significantly from known strains. Further studies linking viral genotype to clinical  
329 phenotype would provide insight into the implications of strain diversity in bats for human outbreaks.

330 Finally, our study sheds light on the sporadic nature of NiV outbreaks with multi-year inter-  
331 epidemic periods in South Asia. First, PCR results show that overall NiV incidence in *P. medius* is low,  
332 consistent with previous studies of Hendra and Nipah virus (43, 48, 89, 90). The data and our modeling  
333 suggests that PCR-positive samples are more likely to be identified during viral transmission spikes after  
334 periodic reintroduction into populations that have become susceptible through waning population-level  
335 immunity (10). Viral detection in bats has also coincided with human outbreaks (59, 87). This is likely a  
336 rare or at least sporadic event. In the current study, observed seroprevalence patterns and the fitted  
337 model suggest that three periods of transmission occurred over the 6 years of sampling, each of which  
338 followed periods of low adult seroprevalence, though not all measurements of low seroprevalence were  
339 followed by outbreaks. We detected NiV RNA during periods of both increasing and decreasing  
340 seroprevalence, supporting the fitted model which suggested that shedding can occur through  
341 recrudescence at low levels in bats even in periods without sustained transmission. Our observation that  
342 not every instance of rising seroprevalence resulted in detectable viral shedding suggests that not all  
343 episodes of viral circulation in bats are of equal magnitude, and that other factors (e.g. variation in  
344 human-bat contact and exposure) may affect likelihood of spillover. Together, this evidence suggests  
345 that outbreaks can occur in bats when the population falls below a protective threshold of immunity in  
346 any season, but variability in how many bats become infected may impact the likelihood of spillover to  
347 humans, assuming a route of transmission is available. This could explain variation in the number of  
348 human outbreaks (e.g. spillover events) from year-to year in Bangladesh. Thus, the timing of multiple  
349 factors involved in driving transmission dynamics needs to align for intra-colony NiV transmission events  
350 and further align with human behavior and availability of a route of spillover for human outbreaks to  
351 occur, as previously hypothesized (91). This, and the seasonality and specific geography of date palm sap  
352 consumption in Bangladesh likely explains the somewhat sporadic nature of human outbreaks in the  
353 region, albeit that when spillover occurs, it is within the well-defined date palm sap collection season  
354 and geographic zone (35).

355 These findings suggest that Nipah virus outbreaks in other regions of Bangladesh where  
356 *Pteropus* spp. bats occur, are also likely to be sporadic and rare, leading to under-reporting or a lack of  
357 reporting, particularly given that human neurologic symptoms are similar to other common infections,  
358 such as Japanese encephalitis, malaria, and measles (92). Understanding whether some NiV strains are  
359 capable of causing mild or asymptomatic cases will provide important insights about why outbreaks may  
360 not have been detected in areas such as eastern Bangladesh or other parts of Asia, where host, virus,  
361 and potential routes of spillover exist. Mild or asymptomatic cases would be unlikely to be detected by

362 current surveillance systems and it's possible that cryptic spillovers have occurred in Bangladesh, where  
363 about half of all outbreaks between 2007 and 2014 were unreported (93). Our work and other reports  
364 suggest that Nipah virus transmission is possible wherever *Pteropus* spp. bats and humans live in close  
365 association and at any time of year, provided there is an available route of transmission. The 2018 and  
366 2019 spillover events in Kerala, India, which were linked to local *P. medius* colonies and which occurred  
367 in an area that does not cultivate date palm sap, further emphasize this point.

368           Identifying areas where high risk interfaces exist between pteropid bats and people, throughout  
369 their range, will be important for monitoring Nipah spillover events and quickly responding to  
370 outbreaks, as well as establishing interventions to prevent spillover. Raising awareness of the potential  
371 for contaminated food to be a route of Nipah virus transmission and in protecting food resources to  
372 limit human or livestock exposure, may be effective in reducing the risk of a more transmissible strain of  
373 Nipah virus from emerging and causing an epidemic with significant human and animal mortality.

374

375 **Methods**

376 The study period was between January 2006 and November 2012. The study was conducted under Tufts  
377 University IACUC protocol #G929-07. Locations were selected based on whether the district had any  
378 previously recorded human NiV encephalitis clusters at the time of this study and was therefore inside  
379 the Nipah Belt (e.g. Rajbari, Tangail, Thakurgaon, and Kushtia) or whether they had not and were  
380 outside the Nipah Belt (e.g. Comilla, Khulna, Sylhet, and Chittagong). The Thakurgaon study was  
381 conducted as part of an NiV outbreak investigation, and coincided with ongoing human transmission  
382 (94). Between 2006-2012, three different studies of *Pteropus medius*, with similar bat sampling  
383 protocols were performed: 1) a cross-sectional spatial study with a single sampling event in each of the  
384 eight locations listed above; 2) a longitudinal study of a Faripur bat colony with repeated sampling  
385 approximately every 3 months from July 2007 to November 2012; and 3) a longitudinal study of the  
386 Rajbari colony with repeated sampling at a monthly interval between 12 month period between April  
387 2010 and May 2011. Opportunistic sampling of *Pteropus medius* was also performed during this time  
388 period during NiV outbreak investigations [Bangha, Faridpur (Feb 2010), Joypurhat (Jan 2012), Rajbari  
389 (Dec 2009), West Algi, Faridpur (Jan 2010)]. Bats were captured using mist nets at locations within eight  
390 different districts across Bangladesh between January 2006 and December 2012 (**Figure 1**).

391

392 *Capture and sample collection*

393 For the country-wide cross-sectional and Faridpur longitudinal study, on average, 100 bats were  
394 sampled at each sampling event, which lasted 7-10 days. This sample size allowed us to detect at least  
395 one exposed bat (IgG antibody-positive) given a seroprevalence of 10% with 95% confidence. Bats were  
396 captured using a custom-made mist net of approximately 10 m x 15 m suspended between bamboo  
397 poles which were mounted atop trees close to the target bat roost. Catching occurred between 11 pm  
398 and 5 am as bats returned from foraging. To minimize bat stress and chance of injury, nets were  
399 continuously monitored and each bat was extracted from the net immediately after entanglement.  
400 Personal protective equipment was worn during capture and sampling, which included dedicated long-  
401 sleeve outerwear or Tyvek suits, P100 respirators (3M, USA), safety glasses, nitrile gloves, and leather  
402 welding gloves for bat restraint. Bats were placed into cotton pillowcases and held for a maximum of 6  
403 hours before being released at the site of capture. Bats were sampled at the site of capture using a field  
404 lab setup. Bats were anesthetized using isoflurane gas (95) and blood, urine, oropharyngeal swabs, and  
405 wing membrane biopsies (for genetic studies) were collected. For some sampling periods, rectal swabs  
406 were collected but due to resource constraints, these samples were deemed to likely be lower yield than

407 saliva and urine for NiV, and were discontinued during the study. For each bat sampled we recorded  
408 age, weight, sex, physiologic and reproductive status, and morphometric measurements as described  
409 previously (21). Bats were classified as either juveniles (approximately four to six months - the age by  
410 which most pups are weaned) to two years old (the age when most *Pteropus* species reach sexual  
411 maturity) or adults (sexually mature) based on body size and the presence of secondary sexual  
412 characteristics, pregnancy, or lactation - indicating reproductive maturity (21, 96).

413 Up to 3.0 mL of blood were collected from the brachial vein and placed into serum tubes with  
414 serum clot activator (Vacutainer, USA). Blood tubes were stored vertically on ice packs in a cold box  
415 and serum was allowed to separate overnight. Serum was drawn from the tube after 24 hours and  
416 placed in a screw-top cryovial (Corning, USA) and stored in a liquid nitrogen dewar (Princeton  
417 Cryogenics, NJ, USA). Sterile pediatric swabs with polyester tips and aluminum shafts were used to  
418 collect urogenital and rectal samples, and larger polyester swabs with plastic shafts (Fisher, USA) were  
419 used to collect oropharyngeal samples. All swabs were collected in duplicate, with one set being placed  
420 individually in cryotubes containing lysis buffer (either tri-reagent or NucliSENS Lysis buffer,  
421 BIOMERIEUX, France) and the second set in viral transport medium. All tubes were stored in liquid  
422 nitrogen in the field then transferred to a -80C freezer.

423 During each sampling event, pooled urine samples were collected beneath bat roosts using  
424 polyethylene sheets (2' x 3') distributed evenly under the colony between 3 am and 6 am. Urine was  
425 collected from each sheet either using a sterile swab to soak up droplets, or a sterile disposable pipette.  
426 Swabs or syringed urine from a single sheet were combined to represent a pooled sample. Each urine  
427 sample was divided in half and aliquoted into lysis buffer or VTM at an approximate ratio of one part  
428 sample to two parts preservative.

429

#### 430 *Serological and molecular assays*

431 Sera from the cross-sectional survey were heat inactivated at 56°C for 30 minutes, as described  
432 (97) prior to shipment to the Center for Infection and Immunity at Columbia University (New York, USA)  
433 for analysis. Samples were screened for anti-NiV IgG antibodies using an enzyme linked immunosorbent  
434 assay (ELISA) as described in (21). Sera from the longitudinal studies were sent to the Australian Animal  
435 Health Laboratory and were gamma irradiated upon receipt. Because of the large sample size and  
436 development of a high throughput multiplex assay of comparable specificity and sensitivity, for these  
437 samples we used a Luminex-based assay to detect anti-Nipah G IgG antibodies reactive to a purified NiV  
438 soluble G protein reagent (98, 99). 1

---

Number: 1      Author: Author      Date: Indeterminate

Jen Barr – please insert language about MFI cutoff that was used for each protein. We used the NiVsG value to decide positive or negative status, but should we discuss NiVsF status, or just focus on G?

439 Total nucleic acids from swabs and urine samples were extracted and cDNA synthesized using  
440 Superscript III (Invitrogen) according to manufacturer's instructions. A nested RT-PCR and a real-time  
441 assay targeting the N gene were used to detect NiV RNA in samples (100). A RT-qPCR designed to detect  
442 the nucleocapsid gene of all known NiV isolates was also utilized (101). Oligonucleotide primers and  
443 probe were as described (101). Assays were performed using AgPath-ID One-StepRT-PCR Reagents  
444 (ThermoFisher) with 250 nM probe, 50 nM forward and 900 nM reverse primers. Thermal cycling was  
445 45°C for 10 min, followed by 45 cycles of 95°C for 15 s and 60°C for 45 s. Cut-off values were cycle  
446 threshold ( $C_T$ )  $\leq 40$  for positive and  $C_T \geq 45$  for negative. Results with  $C_T$  values between 40 and 45 were  
447 deemed indeterminate, i.e. not conclusively positive or negative. Samples with NiV RNA detected by real  
448 time PCR were confirmed by gel electrophoresis and product sequencing.

449 A subset of NiV-positive samples was processed by high-throughput sequencing (HTS) on the Ion  
450 Torrent PGM platform in order to obtain additional NiV genomic sequence. Libraries were prepared  
451 according to the manufacturer's instructions, and 1 million reads allocated per sample. HTS reads were  
452 aligned against host reference databases to remove host background using bowtie2 mapper, and host-  
453 subtracted reads primer trimmed and filtered based on quality, GC content and sequence complexity.  
454 The remaining reads were de novo assembled using Newbler (v2.6) and mapped to the full length NiV  
455 genome. Contigs and unique singletons were also subjected to homology search using MegaBlast  
456 against the GenBank nucleotide database, in case variance in parts of the genome precluded efficient  
457 mapping. From these data, N gene consensus sequences were constructed using Geneious v 7.1, and  
458 used for phylogenetic analyses.

459

#### 460 *Phylogenetic analysis*

461 All *P. medius* NiV sequences have been submitted to Genbank and accession numbers are  
462 included in **Figure 6**. Sequence alignments were constructed using ClustalW in Geneious Prime software  
463 (102). Phylogenetic trees of NiV N-gene sequences were constructed using Neighbor-Joining, Maximum-  
464 Likelihood algorithms and figures constructed in FigTree 1.4.2.

465

#### 466 *Satellite telemetry and homerange analysis*

467 We developed a collar system to attach 12g solar-powered Platform Terminal Transmitters (PTT)  
468 (Microwave Telemetry, Columbia, MD, USA) to adult bats using commercial nylon feline collars with the  
469 buckle removed and 0-gauge nylon suture to attach the PTT to the collar and to fasten the collar around  
470 the bat's neck. Collars were fitted to the bat such that there was enough space to allow for normal neck

471 movement and swallowing, but so that the collar would not slip over the head of the animal (**Figure S6**).  
472 PTTs were programmed with a duty cycle of 10 hours on and 48 hours off. Data was accessed via the  
473 Argos online data service (argos-system.org; France). A total of 14 collars were deployed as follows: Feb  
474 2009: 3 males, 3 females from a colony in Shuvarampur, Faridpur district; Feb 2011: 3 males, 2 females  
475 from the same colony; and April 2011 Cox's Bazaar, 3 bats from a colony in Cox's Bazaar, Chittagong  
476 district. Bats were selected based on size such that the total weight of the collar (~21g) was less than 3%  
477 of the bat's body mass (Table S3).

478 The individual telemetry dataset was combined for each region and its aggregate utilization  
479 distributions (UD) computed in R using package 'adehabitatHR' (103). Population-specific home range is  
480 represented by the \*95% area enclosure of its UD's volume. The volume of intersection between the  
481 colonies quantifies the extent of home range overlap. To evaluate the potential for contact with the  
482 Sylhet colony, we calculated the most likely distance moved ('mldm') for each sampled bat at Faridpur  
483 where the population was more intensively monitored. Movement distance was measured in kilometers  
484 with respect to a centroid location ( $\omega$ ) shared by the whole colony; assuming random spatial distribution  
485 in tracking rate, we estimated its kernel density function per individual and defined mldm as the mode.

486

#### 487 *Statistical approach – cross-sectional study*

488 We fit a Bayesian generalized linear model with a logit link and a Bernoulli distribution to  
489 identify potential predictors which influenced a bat's serostatus. We included age, sex, age- and sex-  
490 normalized mass and forearm length, mass:forearm ratio, body condition, and whether the bat was  
491 pregnant, lactating, or carrying a pup. We included location of sampling as a group effect (similar to a  
492 random effect in a frequentist context) nested within Nipah Belt or non-Nipah Belt regions. We fit the  
493 models and performed posterior predictive checks in R 3.4.3, using the **brms** and **rstan** packages.

494

#### 495 *Statistical approach – longitudinal study*

496 We fit binomial general additive models (GAMs) (104) to the time series of adult and juvenile  
497 seroprevalence in the longitudinal study. For juveniles, we modeled the birth cohort of bats as separate  
498 random effects in a pooled model of juveniles' dynamics starting from June of their birth year, June  
499 being the earliest month we sampled free-flying juveniles in any cohort. We determined the cohort year  
500 of juveniles by using cluster analysis to group individuals by weight, assuming those in the smallest  
501 group were born in the current year and those in the larger group were born the previous year. 92% of

---

Number: 1      Author: Author      Date: Indeterminate

If you used a Bayesian approach you need to specify what priors you used for each coefficient and whether the predictors were standardized, since this determines how informative those priors are.

502 juveniles captured were yearlings. For adults, we modeled dynamics of adults as a single pool over the  
 503 entire course of the study. We tested models with and without annual cyclic effects.

504 Where time series had significant temporal autocorrelation (adults only), we aggregated data by  
 505 week. We determined periods of significant increase in decrease as those where the 95% confidence  
 506 interval of the GAM prediction's derivative did not overlap zero. We fit the models and performed  
 507 checks in R 3.4.3, using the **mgcv** package.

508 To examine the importance of different biological mechanisms in transmission, we fit an age-  
 509 structured (adult and juvenile) maternally immune (M)-susceptible (S)-infected (I)-recovered (R) model  
 510 with recrudescence (R to I) and loss of immunity (R to S) to the seroprevalence data on a weekly  
 511 timescale:

512

$$\frac{dS_J}{dt} = -S_J(\beta_{JJ}I_J + \beta_{AJ}I_A) - \mu_J S_J + bN_A(t-5)\frac{S_A}{N_A} - bN_A(t-52)\frac{S_J}{N_J}(1-\mu_J)^{52} + \lambda M_J$$

$$\frac{dI_J}{dt} = S_J(\beta_{JJ}I_J + \beta_{AJ}I_A) - \gamma I_J - bN_A(t-52)\frac{I_J}{N_J}(1-\mu_J)^{52}$$

$$\frac{dR_J}{dt} = \gamma I_J - \mu_J S_J - \mu_J R_J - bN_A(t-52)\frac{R_J}{N_J}(1-\mu_J)^{52}$$

513 
$$\frac{dM_J}{dt} = bA(t-5)\frac{R_A}{N_A} - \lambda M_J - \mu_J M_J - bN_A(t-52)\frac{R_A}{N_A}(1-\mu_J)^{52} \lambda^{52}$$

$$\frac{dS_A}{dt} = -S_A(\beta_{AA}I_A + \beta_{JA}I_J) - \mu_A S_A + \tau R_A + bN_A(t-52)\frac{S_J}{N_J}(1-\mu_J)^{52}$$

$$\frac{dI_A}{dt} = S_A(\beta_{AA}I_A + \beta_{JA}I_J) - \gamma I_A - \mu_A I_A + bN_A(t-52)\frac{I_J}{N_J}(1-\mu_J)^{52} + \Delta R_A$$

$$\frac{dR_A}{dt} = \gamma I_A - \mu_A R_A + bN_A(t-52)\frac{R_J}{N_J}(1-\mu_J)^{52} - \tau R_A - \Delta R_A$$

514 We included a class M for the density of juvenile bats with maternal antibodies to allow for the biological  
 515 possibility that maternal antibodies are lost at a much higher rate than antibodies acquired following  
 516 infection. The subscripts J refer to juveniles and A to adults,  $\beta$  is the transmission rate,  $\gamma$  is the recovery  
 517 rate,  $\mu$  is the mortality rate,  $\tau$  is the rate of loss of adult immunity,  $\lambda$  is the rate of loss of maternal  
 518 antibodies(57),  $\Delta$  is the adult recrudescence rate (R to I), b is the birth rate (pups join the juvenile  
 519 population after 5 weeks). Juveniles transition to adults after 52 weeks. We included terms for loss of  
 520 antibody in adults ( $\tau$ , S to R), and viral recrudescence ( $\Delta$ , R to I) based on previous studies on captive bats  
 521 that demonstrated the existence of these processes without providing enough data to characterize them  
 522 precisely (55, 65). We fit this deterministic model to the seroprevalence data by maximum likelihood,

523 which assumes that deviations from the model are due to observation error. We estimated the confidence  
524 intervals around maximum likelihood parameter estimates using likelihood profiles using the *profile*  
525 function in package *bbmle* in R v3.2.2.

526 We used model fitting and model comparison to examine the need for several of the biological  
527 processes in the model above that could influence NiV dynamics. First, we examined both density and  
528 frequency-dependent transmission by comparing the fit of the model above to one with transmission  
529 terms that have population size ( $N_A$  or  $N_j$ ) in the denominator. Second, we examined the confidence  
530 intervals of the parameters describing viral recrudescence, loss of antibodies in adult bats, and loss of  
531 antibodies in juvenile bats. If the confidence bounds for these parameters included zero, then these  
532 biological processes are not needed to explain the serological dynamics. Finally, we examined the  
533 confidence bounds for parameters describing the loss of maternal and non-maternal antibodies ( $\tau$  and  
534  $\lambda$ ), to determine if the rate of loss of these two types of immunity were different. We note that this  
535 model structure has similarities to a susceptible-infected-latently infected(L)-infected (SILI) model (if  
536 latently infected individuals are seropositive), but the model above differs in allowing for the possibility  
537 of individuals to transition from the R class back to the S class.

#### 538 *Code availability*

539 SIR model code written in R is available upon request.

540

#### 541 *Data availability*

542 All molecular sequences are available via Genbank. The datasets generated during and/or analyzed  
543 during the current study are available from the corresponding author on reasonable request.

544

545 **Acknowledgements:** We thank Pitu Biswas, Md. Sheikh Gofur, Abdul Hai, and Craig Smith for assistance  
546 in the field, Christopher Allen, and Parvize Hosseini for technical input, Eliza Choi; Yan-Ru Feng and  
547 Lianying Yan for preparing recombinant viral glycoproteins; Jennifer Barr, Vishal Kapoor, Neil Renwick,  
548 and Mohammad Ziadur for laboratory diagnostic and technical support, anonymous reviewers for their  
549 useful comments, and the Government of Bangladesh for permits and logistical support that made this  
550 work possible. This study was funded by an NIH NIAID awards to JHE (AI067549) and CCB (AI054715), an  
551 NIH Fogarty International Center Ecology and Evolution of Infectious Diseases (EEID) award to PD (R01  
552 TW005869) a NSF-NIH EEID award to AMK (EF-0914866), a NIH NIAID award to Lipkin (U19 AI109761), a  
553 US Agency for International Development PEER award to MSK (Award 226), and the US Agency for

554 International Development Emerging Pandemic Threats: PREDICT program (PD, JHE, AI, SA, NR, CZT,  
555 KJO). icddr,b is also grateful to the Governments of Bangladesh, Canada, Sweden and the UK for  
556 providing core/unrestricted support. Study development (JHE, SJA, AI, AMK, SUK, EG, MJH, HEF, GC, MR,  
557 SPL, WIL, & PD); Lab and field data collection & analysis (JHE, SJA, AMK, MS, NR, SAK, Aul, IS, CZT, YT,  
558 PLQ, KJO, TB, CCB, LFW & WIL); manuscript writing (JHE, SJA, AI, AMK, NR, CZT, KJO, EG, HEF, MDF, TB,  
559 GC, SPL, WIL & PD). The authors have no competing interests.

782

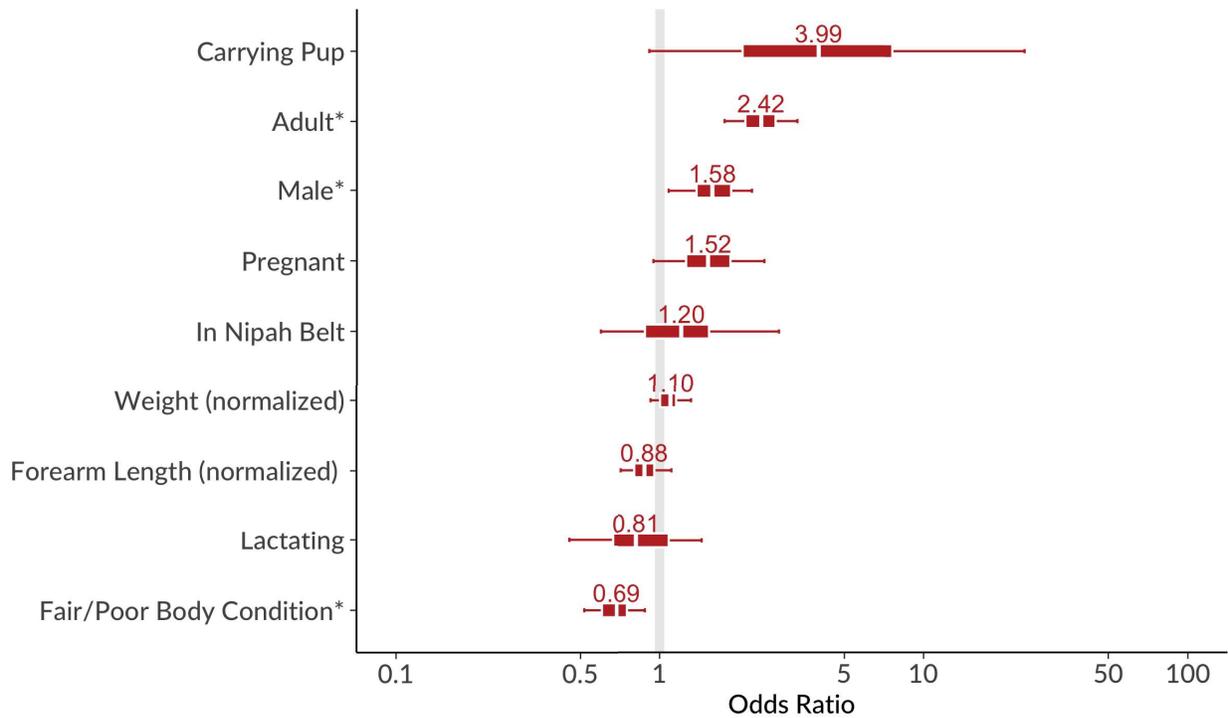

783  
 784 **Figure 1.** Map showing age-stratified seroprevalence in *Pteropus medius* colonies, Bangladesh. Bats from eight  
 785 colonies were sampled and tested for anti-NiV IgG antibodies: four within the “Nipah Belt” (orange shaded) and  
 786 four outside. Seroprevalence of adults (blue, purple), juveniles (red, orange) and total seroprevalence (green, light  
 787 blue) are shown. Number (n) of Adult, Juvenile, and Total bats sampled (clockwise): Tangail [53,41,94], Sylhet [63,  
 788 37, 100], Comilla 2008 [73,27,100], Comilla 2011 [30,20,50], Chittagong [72,24,96], Khulna[85,15,100], Rajbari  
 789 [65,15, 80], Kushtia [64,36,100], Thakurgaon [89,29,118]. The shaded region represents the “Nipah Belt” where  
 790 previous human NiV outbreaks have been reported.  
 791

---

Number: 1      Author: Author      Date: Indeterminate

You only need one legend since it is the same for all panels. This would all you to make the panels a little bigger. I would try to reduce the white-space and zoom in on the map a little and make the graphs bigger. Finally I'd add lines b/w the locations on the map and the graphs.

### GLM Estimates: Factors Affecting Nipah Serostatus

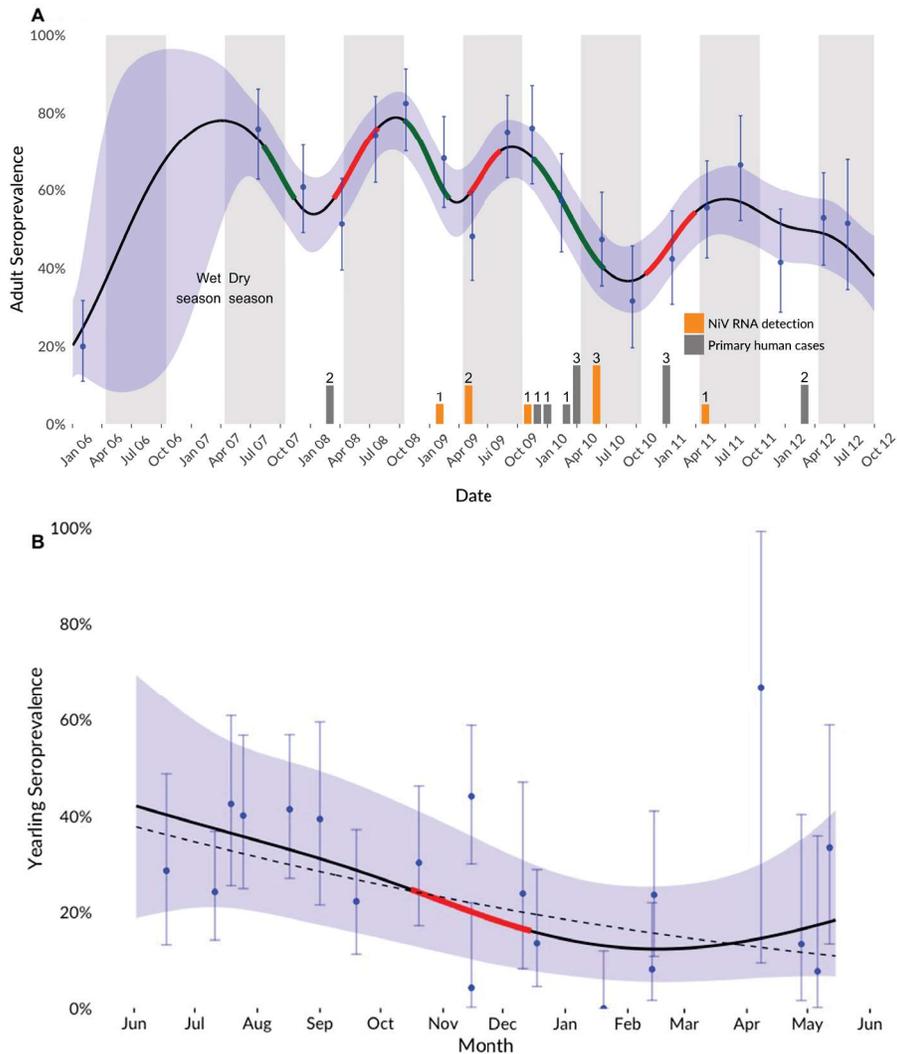

792

793 **Figure 2.** Results of Bayesian GLM of factors affecting Nipah serostatus in bats in cross-sectional study. Bars  
 794 indicate odds ratios and 50% (inner) and 95% (outer) credible intervals for model parameters. Factors with  
 795 asterisks (\*) have 95% CIs that do not overlap 1. Model intercept (predicted probability of seropositivity for a  
 796 juvenile, female, bat outside the Nipah belt of mean size and good body condition) was 0.26, (95% CI 0.12-0.56).  
 797 Random effect of location (not shown) had an estimated SD of 0.63 (95% CI 0.29-1.27)

798

Nipah virus IgG antibody serodynamics in adult and juvenile *Pteropus medius*, Faridpur, Bangladesh 2006-2012

799

800 **Figure 3 A & B.** Serodynamics of the Faridpur bat population. (A) Adult serodynamics, with measured values and  
 801 95% CI in blue, and mean GAM prediction and 95% shown with line and surrounding shaded areas. Periods of  
 802 significant increase (red) and decrease (green) shown where the GAM derivative's 95% CI does not overlap zero.  
 803 Counts of primary human cases from local district (orange, and bat oral detections (dark grey, see Table 1), shown  
 804 on bottom. (B) Juvenile serodynamics during the first year of life ("yearlings"), with all years' measurements  
 805 overlain to show cohort-level dynamics across all study years. Measured values and 95% CI in blue, and mean and  
 806 95% CI for the GAM model pooled across cohorts shown with line and surrounded shaded areas. The period of  
 807 significant decline in the GAM is shown in red. Also shown is the mean prediction of a model with only a linear  
 808 mean term, with similar fit ( $\Delta AIC < 1$ ) as the GAM (dotted line).

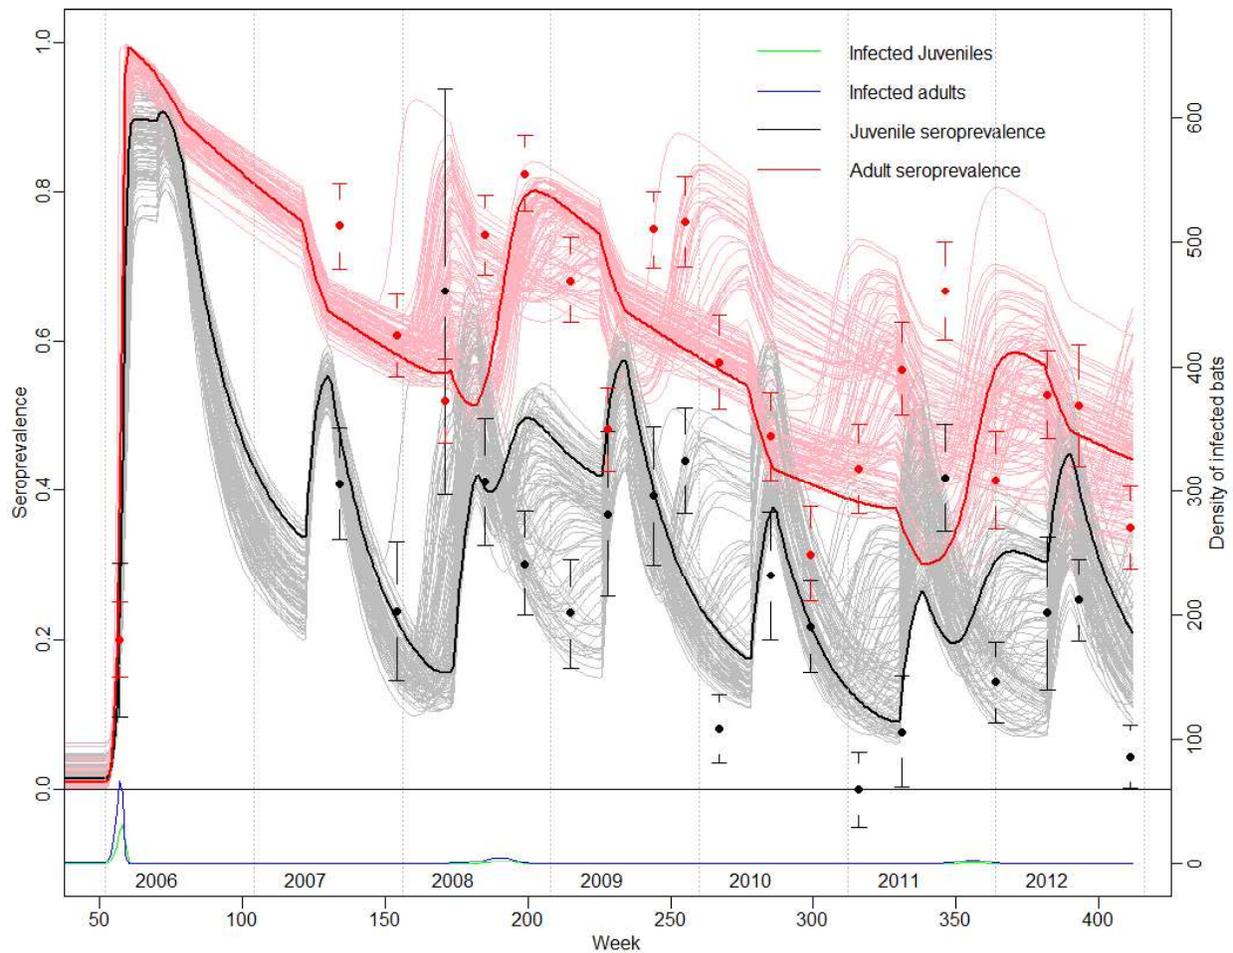

809

---

Number: 1      Author: Author      Date: Indeterminate

I'd show these as a % of samples collected, not the raw #. Otherwise you are confounding prevalence with sampling effort, unless the # of samples was the same for every sample.

810

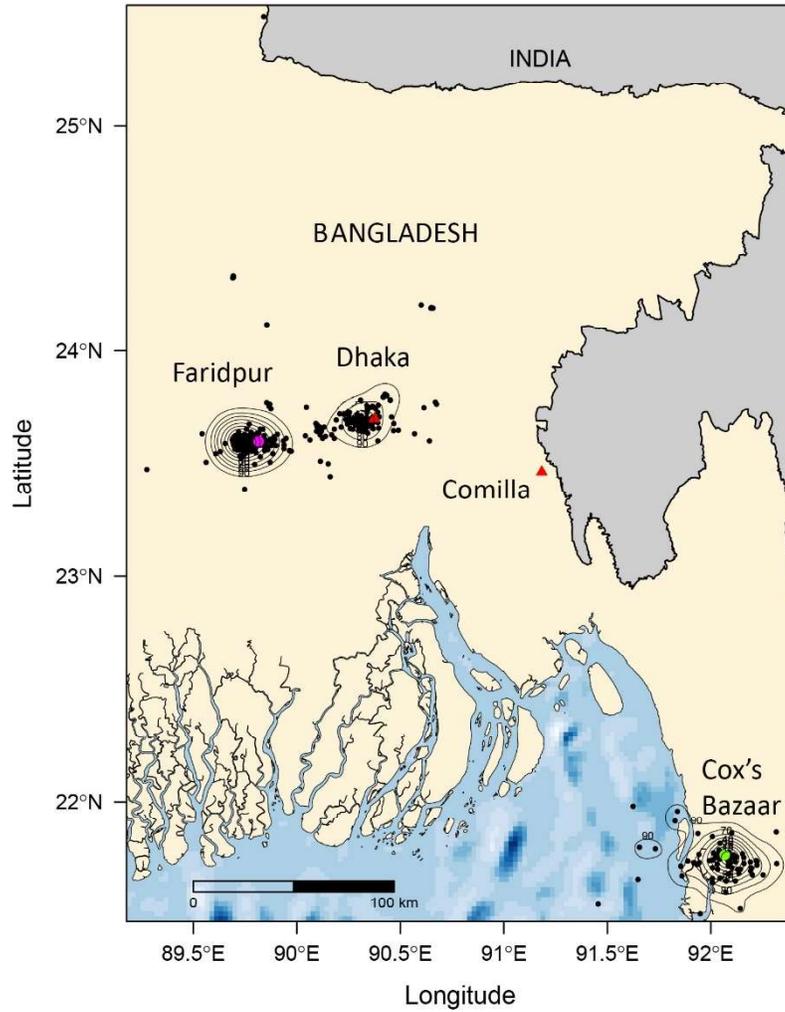

811

812 **Figure 4. NiV serological dynamics in adult and juvenile bats.** The observed data (red and black points  $\pm 1$  SE) and  
813 model fit (solid lines; thick lines show the trajectory for the model with maximum likelihood parameter estimates;  
814 thin lines show realizations for parameter estimates drawn from the estimated distributions) for the fraction of  
815 adults and juveniles seropositive for NiV (left axis), and the model estimated density of infected adult and juvenile  
816 bats (bottom panel and right axis). See Methods for details of model structure.

**Figure 5.** Satellite telemetry and homerange analysis. Location data from satellite collars (n=14) placed on 11 bats from Faridpur and 3 bats from Cox's Bazaar, Chittagong collected between 2009 and 2011, were used to calculate local and long-range movement patterns and home range for these two groups.

866 **Figure 6. Nipah Virus N gene phylogenetic tree (224nt):** Tree created in Geneious Prime 2019 using a Neighbor-  
 867 joining Tamura-Nei model with 1,000 replicates (105). The percentage of trees in which the associated taxa clustered  
 868 together is shown next to the branches. The tree is drawn to scale, with branch lengths measured in the number of  
 869 substitutions per site. Hendra virus was used as an outgroup. Sample collection date, location and Genbank accession  
 870 numbers are included in the label for each sequence except *P. medius* sequences which are accession Nos MK995284  
 871 – MK995302. Blue labels indicate bat sequences from Faridpur and Bhanga (an outbreak response in Faridpur).  
 872 Purple sequences are from *P. medius* from other roosts sampled during the longitudinal study. Red sequences are  
 873 from *P. medius* in Comilla. Green sequences are human NiV sequences from Bangladesh and India.

874

Hi Jon,

It's reading pretty well! See my suggested revisions and comments on the main doc and supplemental material. Let me know if you have questions!

marm

On 12/18/2019 10:00 AM, Jon Epstein wrote:

All,

I hope this email finds you well. Attached is a draft of our manuscript entitled Nipah virus dynamics in bats and implications for spillover to humans. After multiple protracted periods of review in Science Advances, and ultimately a rejection, I've prepared this draft for submission to PNAS. I've revised the manuscript and updated figures and supplemental data in response to the last round of review (comments below, if you're interested).

I have an editor at PNAS willing to send this for review, so please send me any input you may have by December 28th so that I can submit by the 31st. Unless I hear otherwise, I will assume you still consent to co-authorship.

Thank you for your patience, and happy holidays!

Cheers,  
Jon

Epstein et al aim to better understand the distribution and drivers of Nipah virus infection dynamics in *Pteropus medius* in Bangladesh by analysing a large set of serological, virological and movement data over a commendable spatial and temporal scale. Overall, this is a highly exciting study with valuable results that are well-deserving of publication. I have a number of minor comments regarding the addition of detail for clarity (and to ensure transparency in the interpretation of results). I think that the conclusions are mostly justified, however, my major criticism is that the integration and interpretation of the results (particularly those presented in the first paragraph of the discussion) requires a little further thought and explanation. The assumptions surrounding the serological implications of within-host persistence and recrudescence needs to be clearly stated. This is likely to become a 'classic' paper, and there are so few studies in this area supported by data that it is important to ensure that the results are not over-interpreted.

Specific comments:

Abstract:

Line 32- 33: The wording here is too strong regarding recrudescence. Suggest inserting "model results indicated that" prior to "local transmission dynamics.

Line 33-34: Similarly - this is too strong. Suggest "likely due to "

Results:

Figure 1 - presumably the first three bats in the Comilla represent 2008 and the second three represent 2011, but this is not clear. This should be annotated on the plot  
Figure 1 - "Adult bats had equal or greater seroprevalence than juveniles in each location."  
- except Tangail?

Line 129: "detected NiV RNA in 11 individuals, 3 pooled" - insert 'from' before 3

Line 131: - describe "pooled samples" - pooled under-roost urine samples?

Line 132 and 137: This 'figure 2' seems to be missing? Figure 2 refers to serological analyses

Line 145: I suggest that the reference to Figure 2 in line 146 should go in the sentence ending on line 145

Line 149: the significant negative association with body condition warrants mentioning in these results.

Line 154-155 and Figure 3: Additional clarity here regarding juvenile vs. yearling terms. Suggest saying "Juveniles in their first year of life (yearlings)" at first mentioning in the text, as well in the figure legend.

Line 159 - incomplete sentence

Lines 160-164: Fascinating results!

Lines 170-171: This information would be helpful to include earlier, with the serological results

Figure 3 and Figure S1 - It would be helpful to have a "total population" size from this roost complex included on Figures 3 and 4. Understanding more about the bat ecology and the size and stability of these populations over time would be a tremendous help to aid interpretation of these results by researchers working in other systems.

Lines 175-176: "Serodynamics in juveniles were strongly driven by inheritance and loss of maternal antibodies". Supported by what result? This should be explained further, and/or it would be helpful to include the serology (fig 3), model output (fig 4) and population size (Figure s1) together as a series of vertical panels in the one figure to aid interpretation

Lines 178-180: I can't see this information in the supplementary information

Line 182 - this paragraph (and ideally also table S2) should provide information on the duration of tracking for each bat. This would be very helpful in assessing the home range information

Line 195 - should the 'of' be 'if'?

Figure 6 - the utility of this figure would be greatly improved with some annotation and colouring to help identify the new sequences from this study, and their source location, and the 'groups' that are referred to in the text

Lines 238 - 240 - So, your data has found cyclical serodynamics, but no clear links between those dynamics and detection of NiV in bats or in people. Based on experimental studies, it is still a bit unclear exactly what seropositivity in flying foxes represents. If there is within-host persistence of infection, a cycle of infection > seroconversion (in the absence of clearance) > seroreversion > then recrudescence with seroconversion may occur in the absence of ongoing transmission. Additionally, this does not take into account drivers of recrudescence - if this is stress related, then transmission at the population level will also be affected by these broader drivers. Given all the uncertainty around this topic, I think that the wording here needs to be precise. e.g the first sentence should first state the assumption "Assuming that seroconversion results only from new infections, then ...". This could be followed up with a sentence along the lines of "If however, seroconversion can result from recrudescence in the absence of transmission, then broader drivers of recrudescence would also need to be assessed". More clarity here would also help to assess the claims being made in the paragraph beginning 315.

Lines 240 onwards - consider restructuring this paragraph to more clearly step through each stage of the viral dynamics that you are proposing and your assumptions and evidence along the way. For example, you assume infection results in seroconversion, and that antibodies then wane after ~4 years. Are you assuming that all individuals are persistently infected, and it is only when Ab wane that recrudescence can occur? And following that, the individual seroconverts again?

Lines 243 - 245: Not correct - See Brooks et al 2019 JAE Figure S5. That study also involved modelling and has implications for this study more broadly

Lines 245-247: "via recrudescence FROM bats that have previously been infected"? It's also not clear how this links to lines 238-240

Lines 257-259: Consider also cite Peel et al (2018). Scientific Reports, 8(1), e0004796. This study examines waning maternal immunity and waning acquired immunity against henipaviruses in African fruit bats, finding a similar duration of immunity for both

Line 267 - insert "in our study area" after 'Pteropus medius' as you cannot infer whether these patterns hold true for the species across its range. It may be highly dependent on available food resources - as you go on to discuss

Line 277 - replace 'be' with 'result in'

Lines 295-296 - this links with the SILI hypotheses in Plowright et al (2016) PLoS NTD (see Figure 3)

Line 321- suggest "three periods of transmission (significant at the population level) occurred"

Line 315 See my comments re: paragraph beginning Line 238. The sporadic nature of detections is challenging to draw conclusions and much of the paragraph here (starting line 315) seems over-stated. However, that may become clearer if the comments for the earlier paragraph are addressed.

Methods:

Line 364: I can't see reference to the Faripur colony in the list of colonies in lines 358-359. What are its characteristics? Also, I presume it should be "Faridpur"? Also, it would be helpful if the "Faridpur roost complex:" could be described in more detail in the methods as to the structure of this population and what this term means.

Line 366: Delete the first 'between'

Lines 388-390 - check the placement of parentheses here

Line 417: what cutoff was used for the Luminex assay and how was it determined?

Line 425 - fix formatting of second Ct

Line 493- 504: More information on the underlying population dynamic model is required e.g. Were births seasonal or continuous in your model? I can't see where this is stated. If not seasonal, then the effect of this on model output should be addressed. How was the death rate modelled? Was the total population size kept stable inter annually? The latter, in particular, may have implications for interpretation of the density-dependent vs frequency dependent results. The population size is touched on in the discussion in lines 288-291 but never really explained.

Table S1 - there is extra text below Table S1 that looks like it's not supposed to be there

Table S2 - Include what serostatus 0/1 refers to in the table caption

Reviewer: 2

Dear editor, I have reviewed the manuscript entitled "Nipah virus dynamics in bats and implications for zoonotic spillover to humans". The manuscript describes a longitudinal surveillance in Pteropid spp. Bats from 2006 until 2012. Biometric data was collected, sera and swabs/urine were analyzed, and inferences were made largely based on serological data. The manuscript is a compendium of relatively loosely compiled data, ranging from seroprevalence in a variety of different sampling sites, but the majority of the samples stem from Faridpur. The problem is that most of the claims by the authors within the paper are not directly supported by the data. The direct problem of the data is the limited amount of detected virus shedding, out of 2789 animals sampled only 11 were found to be shedding the virus. From this only 8 were from the larger study cohort from Faridpur. This directly hampers some of the conclusion of potential spillover dynamics as this cannot be directly inferred from serological data alone. In addition, it does not provide any answers on the occurrence of Nipah spillover in the Nipah belt vs the other regions. Moreover, the significant spillover events in Kerala, India from the last two years, are not discussed. Most emphasis has been put on analyzing the serological results from the Pteropus medius bats. The authors show variation in the seroprevalence within the population based on timing and age status of the animal. The results have been reported before in other natural reservoir-pathogen systems like avian influenza, however even within

these systems inferences on spillover can rarely be made. It is interesting that the authors did not correlate the positive individual bats in Faridpur and Rajbari with their respective serostatus? Is this data not available? It is unclear to me why the authors have not put more effort in trying to perform full genome analyses on the positive samples obtained throughout this study. Currently there are only 27 full genomes available from Nipah virus and relatively limited amount are from the natural reservoir. Performing phylogenetic analyses on a 224 nucleotide fragment of a 19kb virus is really not up to standard. Where it might be suitable for identification of the lineage no additional data can be inferred from this. Interestingly, there appears to be full genome sequencing performed but only N is shown in the supplemental data.

Although I do understand the logistics involved with this kind of work, unfortunately some of the claims, especially regarding spillover, need to be supported by more additional data rather than just serology.

Minor points:

Line 65: pandemic potential, given the limited amount of h-to-h transmission the pandemic potential of this particular virus appears to be relatively limited.

Line 143: n=844 or n=883? Why do the numbers not match-up?

Line 410, include level of biosecurity involved in sample analyses. In addition, heat inactivation is typically to inactivate complement and not inactivation of the pathogen.

From the current wording it is unclear what the authors mean by this? Complement inactivation or pathogen inactivation?

Line 428, is this data missing? Where is the NSG data? Why not data on the full genomes? I only was able to find the full N gene data in the supplemental figures.

Line 509, given that actual recrudescence in the context of virus shedding in the natural reservoir has never been shown it would be good to treat this a little bit more carefully.

Reviewer: 1

Epstein et al aim to better understand the distribution and drivers of Nipah virus infection dynamics in *Pteropus medius* in Bangladesh by analysing a large set of serological, virological and movement data over a commendable spatial and temporal scale. Overall, this is a highly exciting study with valuable results that are well-deserving of publication. I have a number of minor comments regarding the addition of detail for clarity (and to ensure transparency in the interpretation of results). I think that the conclusions are mostly justified, however, my major criticism is that the integration and interpretation of the results (particularly those presented in the first paragraph of the discussion) requires a little further thought and explanation. The assumptions surrounding the serological implications of within-host persistence and recrudescence needs to be clearly stated. This is likely to become a 'classic' paper, and there are so few studies in this area supported by data that it is important to ensure that the results are not over-interpreted.

Specific comments:

Abstract:

Line 32- 33: The wording here is too strong regarding recrudescence. Suggest inserting "model results indicated that" prior to "local transmission dynamics.

Line 33-34: Similarly - this is too strong. Suggest "likely due to "

Results:

Figure 1 - presumably the first three bats in the Comilla represent 2008 and the second three represent 2011, but this is not clear. This should be annotated on the plot

Figure 1 - "Adult bats had equal or greater seroprevalence than juveniles in each location." - except Tangail?

Line 129: "detected NiV RNA in 11 individuals, 3 pooled" - insert 'from' before 3

Line 131: - describe "pooled samples" - pooled under-roost urine samples?

Line 132 and 137: This 'figure 2' seems to be missing? Figure 2 refers to serological

analyses

Line 145: I suggest that the reference to Figure 2 in line 146 should go in the sentence ending on line 145

Line 149: the significant negative association with body condition warrants mentioning in these results.

Line 154-155 and Figure 3: Additional clarity here regarding juvenile vs. yearling terms. Suggest saying "Juveniles in their first year of life (yearlings)" at first mentioning in the text, as well in the figure legend.

Line 159 - incomplete sentence

Lines 160-164: Fascinating results!

Lines 170-171: This information would be helpful to include earlier, with the serological results

Figure 3 and Figure S1 - It would be helpful to have a "total population" size from this roost complex included on Figures 3 and 4. Understanding more about the bat ecology and the size and stability of these populations over time would be a tremendous help to aid interpretation of these results by researchers working in other systems.

Lines 175-176: "Serodynamics in juveniles were strongly driven by inheritance and loss of maternal antibodies". Supported by what result? This should be explained further, and/or it would be helpful to include the serology (fig 3), model output (fig 4) and population size (Figure s1) together as a series of vertical panels in the one figure to aid interpretation

Lines 178-180: I can't see this information in the supplementary information

Line 182 - this paragraph (and ideally also table S2) should provide information on the duration of tracking for each bat. This would be very helpful in assessing the home range information

Line 195 - should the 'of' be 'if'?

Figure 6 - the utility of this figure would be greatly improved with some annotation and colouring to help identify the new sequences from this study, and their source location, and the 'groups' that are referred to in the text

Lines 238 - 240 - So, your data has found cyclical serodynamics, but no clear links between those dynamics and detection of NiV in bats or in people. Based on experimental studies, it is still a bit unclear exactly what seropositivity in flying foxes represents. If there is within-host persistence of infection, a cycle of infection > seroconversion (in the absence of clearance) > seroreversion > then recrudescence with seroconversion may occur in the absence of ongoing transmission. Additionally, this does not take into account drivers of recrudescence - if this is stress related, then transmission at the population level will also be affected by these broader drivers. Given all the uncertainty around this topic, I think that the wording here needs to be precise. e.g the first sentence should first state the assumption "Assuming that seroconversion results only from new infections, then ...". This could be followed up with a sentence along the lines of "If however, seroconversion can result from recrudescence in the absence of transmission, then broader drivers of recrudescence would also need to be assessed". More clarity here would also help to assess the claims being made in the paragraph beginning 315.

Lines 240 onwards - consider restructuring this paragraph to more clearly step through each stage of the viral dynamics that you are proposing and your assumptions and evidence along the way. For example, you assume infection results in seroconversion, and that antibodies then wane after ~4 years. Are you assuming that all individuals are persistently infected, and it is only when Ab wane that recrudescence can occur? And following that, the individual seroconverts again?

Lines 243 - 245: Not correct - See Brooks et al 2019 JAE Figure S5. That study also involved modelling and has implications for this study more broadly

Lines 245-247: "via recrudescence FROM bats that have previously been infected"? It's also not clear how this links to lines 238-240

Lines 257-259: Consider also cite Peel et al (2018). Scientific Reports, 8(1), e0004796. This study examines waning maternal immunity and waning acquired immunity against henipaviruses in African fruit bats, finding a similar duration of immunity for both

Line 267 - insert "in our study area" after 'Pteropus medius' as you cannot infer whether these patterns hold true for the species across its range. It may be highly dependent on

available food resources - as you go on to discuss

Line 277 - replace 'be' with 'result in'

Lines 295-296 - this links with the SILI hypotheses in Plowright et al (2016) PLoS NTD (see Figure 3)

Line 321- suggest "three periods of transmission (significant at the population level) occurred"

Line 315 See my comments re: paragraph beginning Line 238. The sporadic nature of detections is challenging to draw conclusions and much of the paragraph here (starting line 315) seems over-stated. However, that may become clearer if the comments for the earlier paragraph are addressed.

Methods:

Line 364: I can't see reference to the Faripur colony in the list of colonies in lines 358-359. What are its characteristics? Also, I presume it should be "Faridpur"? Also, it would be helpful if the "Faridpur roost complex:" could be described in more detail in the methods as to the structure of this population and what this term means.

Line 366: Delete the first 'between'

Lines 388-390 - check the placement of parentheses here

Line 417: what cutoff was used for the Luminex assay and how was it determined?

Line 425 - fix formatting of second Ct

Line 493- 504: More information on the underlying population dynamic model is required e.g. Were births seasonal or continuous in your model? I can't see where this is stated. If not seasonal, then the effect of this on model output should be addressed. How was the death rate modelled? Was the total population size kept stable inter annually? The latter, in particular, may have implications for interpretation of the density-dependent vs frequency dependent results. The population size is touched on in the discussion in lines 288-291 but never really explained.

Table S1 - there is extra text below Table S1 that looks like it's not supposed to be there

Table S2 - Include what serostatus 0/1 refers to in the table caption

Where it might be suitable for identification of the lineage no additional data can be inferred from this. Interestingly, there appears to be full genome sequencing performed but only N is shown in the supplemental data.

Although I do understand the logistics involved with this kind of work, unfortunately some of the claims, especially regarding spillover, need to be supported by more additional data rather than just serology.

Minor points:

Line 65: pandemic potential, given the limited amount of h-to-h transmission the pandemic potential of this particular virus appears to relatively limited.

Line 143: n=844 or n=883? Why do the numbers not match-up?

Line 410, include level of biosecurity involved in sample analyses. In addition, heatinactivation

is typically to inactivate complement and not inactivation of the pathogen.

From the current wording it is unclear what the authors mean by this? Complement inactivation or pathogen inactivation?

Line 428, is this data missing? Where is the NSG data? Why not data on the full genomes? I only was able to find the full N gene data in the supplemental figures.

Line 509, given that actual recrudescence in the context of virus shedding in the natural reservoir has never been shown it would be good to treat this a little bit more carefully.

--

DASZAK, P

**1U01AI151797-01 Daszak, P****FOREIGN INSTITUTION  
SCIENTIFIC REVIEW OFFICER'S ADMINISTRATIVE NOTES  
SELECT AGENTS**

**RESUME AND SUMMARY OF DISCUSSION:** This excellent new Research Project Cooperative Agreement application entitled "Understanding Risk of Zoonotic Virus Emergence in EID Hotspots of Southeast Asia" was submitted in response to AI19-028: Emerging Infectious Diseases Research Centers (U01) by the Ecohealth Alliance, Inc., New York, New York with Dr. Peter Daszak as Principal Investigator (PI).

The application has many strengths. The study proposed is adequately focused on the identification of new emerging virus in Southeast Asia, which is a hotspot of viral activity with significant threat to human health. The approach is based on the identification of viral spillovers by studying the pathogen in wild animals and performing surveillance of high-risk communities. There is a strong emphasis to identify and characterize viral etiology of 'cryptic' outbreaks in clinical cohorts by using surveys to look for causal links between syndromes and the viruses detected. The PI, Dr. Daszak, is a well-recognized expert with strong track record in working with zoonotic diseases and researching spillover events. The team of investigators have significance experience working in the SE and includes accomplished scientists such as Dr. Baric, who is a well-recognized coronavirus expert. They have built a network of local collaborators with access to regional clinics in Thailand, Singapore, and Malaysia. Adequate analytic and laboratory techniques are in place for conducting human and animal surveillance to complete the proposed studies. The feasibility of the strategy proposed is supported by the availability of samples from previous studies and the preliminary data presented. The data management plan and statistical plan are well described. The environment and resources are excellent at the established participating institutions. Data management plan and statistical plan are well described.

The application has some weaknesses. There is an overemphasis in the results obtained in previous work. The virus families targeted are somewhat restricted to those previously identified by the team. The roles and responsibilities of the Executive Committee are not clearly described. Some of the key personnel listed does not appear to have appropriate expertise for the tasks proposed. The sample sites for the wildlife studies are not clearly identified. There will be challenges to find new human pathogens by using serological-based field studies. The team does not include a veterinary pathologist nor an expert in entomology/vectors approach. No emphasis is made of efforts to build in-country infrastructure. There is no planned integration or clear leveraging with NIAID resources. The potential role of the movement of animals, people and products within the region and with neighboring countries such as China is not mentioned. The lack of their own lab facilities by the applicant organization is seen also as a weakness as well as the absence from the team of a US-based clinical scientist.

Based upon the evaluation of scientific and technical merit, this application received an Impact/Priority score of 32.

**DESCRIPTION (provided by applicant):** Southeast Asia is one of the world's highest-risk EID hotspots, the origin of the SARS pandemic, Nipah virus, and repeated outbreaks of influenza. This is driven by high diversity of wildlife and rapidly expanding demography that brings human and wildlife populations closer. This proposal will launch the Emerging Infectious Diseases - South East Asia Research Collaboration Hub (EID-SEARCH), a collaboration among leaders in emerging disease research in the USA, Thailand, Singapore and the 3 major Malaysian administrative regions. These researchers have

DASZAK, P

networks that span >50 clinics, laboratories and research institutions across almost all SE Asian countries and will use the EID-SEARCH as an early warning system for outbreaks involving exchange of information, reagents, samples and technology, and a collaborative power-house for fundamental and translational research. The EID-SEARCH will also act as a significant asset to scale-up and deploy resources in the case of an outbreak in the region. This EIDRC will conduct research to: 1) Identify, characterize and rank spillover risk of high zoonotic potential viruses from wildlife, by analyzing previously-archived wildlife samples, conducting targeted wildlife surveillance, and using serology & PCR assays to identify novel viruses. These will be characterized to assess risk of spillover to people, and a series of in vitro (receptor binding, cell culture) and in vivo (humanized mouse and collaborative cross models) assays used to assess their potential to infect people and cause disease; 2) Collect samples and questionnaire data from human communities that live in EID hotspots and have high cultural and behavioral risk of animal exposure (e.g. wildlife hunting, bat guano collection). These will be tested with serological assays to identify evidence of novel virus spillover and analyzed against metadata to identify key risk pathways for transmission; 3) Identify and characterize viral etiology of 'cryptic' outbreaks in clinical cohorts. We will conduct syndromic surveillance at clinics serving the populations in Aim 2, enroll patients with undiagnosed illness and symptoms consistent with emerging viral pathogens, and test samples with molecular and follow-up serological assays to identify causal links between these syndromes and novel viruses. This research will advance our understanding of the risk of novel viral emergence in a uniquely important region. It will also strengthen in-country research capacity by linking local infectious disease scientists with an international collaborative network that has proven capacity to conduct this work and produce significant findings. The large body of high impact collaborative research from this EIDRC leadership team provides proof-of-concept that EID-SEARCH has the background, collaborative network, experience, and skillset to act as a unique early warning system for novel EIDs of any etiology threatening to emerge in this hottest of the EID hotspots.

**PUBLIC HEALTH RELEVANCE:** This proposed EID Research Center (EID-SEARCH) brings leaders in emerging disease research from the US, Thailand, Singapore and the 3 major Malaysian administrative regions together to build an early warning system to safeguard against pandemic disease threats. This team will identify novel viruses from Southeast Asian wildlife, characterize their capacity to infect and cause illness in people, and use serological assays of samples from people in rural communities with high wildlife contact to identify the background rate of exposure, and risk factors that drive this. They will conduct in-depth surveillance of clinical cohorts at hospitals serving these communities to examine if 'cryptic' outbreaks are caused by these novel agents, and to build significant capacity to rapidly detect and respond should there be a major outbreak of a virus in the region.

**CRITIQUE:** The comments in the CRITIQUE section were prepared by the reviewers assigned to this application and are provided without significant modification or editing by staff. They are included to indicate the range of comments made during the discussion and may not reflect the outcome. The RESUME AND SUMMARY OF DISCUSSION section summarizes the final opinion of the committee after the discussion and is the basis for the assigned Overall Impact/Priority score.

### CRITIQUE 1

Significance:	3
Investigator(s):	3
Innovation:	2
Approach:	4
Environment:	2

DASZAK, P

**Overall Impact:** The focus of this application is to identify new pathogens from wild animals and monitor their spillover in high-risk communities. The countries of interest include Thailand and Malaysia. Some of the research team members have excellent expertise relevant to the proposed studies. The availability of samples from previous studies is a strength. The PI has the experience to handle this type of application. This application has a few minor weaknesses and the proposed studies are overly ambitious.

## 1. Significance:

### Strengths

- The identification spillovers of new pathogens from wild animals (bats, rodents, and nonhuman primates) to humans will be significant.
- Surveillance of high-risk communities for new pathogens could be useful to prevent potential pandemic event/s.

### Weaknesses

- They seem to be constrained in their efforts since they are thinking more about coronaviruses (CoVs), paramyxoviruses (PMVs, e.g., henipaviruses) and filoviruses (FVs).
- Outcomes will be hard to evaluate due to complex experimental design.

## 2. Investigators:

### Strengths

- The PI has the relevant expertise and experience to lead this type of multi-national research initiative.
- The research team includes scientists from EcoHealth Alliance, University of North Carolina, Duke-NUS Medical School, Chulalongkorn University Hospital, Gleneagles Hospital, Hospital University Malaysia Sabah, Queen Elizabeth State Hospital, Lintang Clinic of Kuala Kangsar District Health Office, University Malaysia Sarawak, Bario Clinic of Rural Area Service under Ministry of Health Malaysia, Conservation Medicine Ltd., Uniformed Services University, BU NEIDL, University of North Carolina at Chapel Hill, and Hospital Miri.
- Most research team members have the needed expertise for the proposed studies.

### Weaknesses

- It seems that Hongying Li joined a PhD program at Kingston University, UK in 2018, therefore, it is unclear how this person will serve as a China Coordinator.
- Some of the key personnel do not seem to have expertise in the area of proposed research.
- It is unclear who will collect samples and perform various assays at Chulalongkorn Hospital.
- Roles of some of team players could have been explained better.
- A veterinary pathologist is needed in their team.

## 3. Innovation:

### Strengths

- The concept of investigating new pathogen spillovers by studying the pathogen in the wild animals and humans is innovative.

### Weaknesses

DASZAK, P

- None significant.

#### 4. Approach:

##### Strengths

- Preliminary results provide support to some of the proposed studies. The availability of samples from previous studies is a plus.
- Identify, characterize and evaluate spillover risk of high zoonotic potential viruses from wildlife (bats, rodents, primates).
- Surveillance of high-risk communities will be pursued to find evidence of viral spillovers.
- Efforts will be made to identify and characterize viral etiology of 'cryptic' outbreaks in clinical cohorts.
- Administrative plan seems fine.
- Data management plan and statistical plan are well described.

##### Weaknesses

- It is unclear what else they anticipate finding in addition to their earlier findings. They are also focusing their efforts on pathogens already identified by their team.
- The application is overly ambitious.
- In vitro and in vivo characterization of new viral pathogens to evaluate their potential for human infections may lead to misleading results.
- They have not yet identified the wildlife sampling sites.
- Antibody cross-reactivity may sometime be misleading.
- They do not plan to collect samples from NHPs.
- Reverse genetic approach to generate new viruses is doable but will distract from their focus.
- It is difficult to find new pathogens by sero-surveillance.

#### 5. Environment:

##### Strengths

- The research team has all the necessary facilities and resources for the proposed studies.

##### Weaknesses

- The lead organization, EcoHealth Alliance, has limited wet lab research facilities.
- Limited capacity building at the partner sites.

#### CRITIQUE 2

Significance:	1
Investigator(s):	1
Innovation:	1
Approach:	2
Environment:	1

DASZAK, P

**Overall Impact:** This application is highly focused on the identification of emerging zoonotic viruses. The work will be carried out by a highly experienced and accomplished investigative team that has already had substantial success in this area. The strategies for sampling and for prioritization of testing resources is detailed and well planned. Modeling has been incorporated into the plan in a way that increases the likelihood that surveillance and testing will result in the identification of emergent viruses, which then will be efficiently characterized and followed by detection in high risk human cohorts.

### 1. Significance:

#### Strengths

- The application incorporates surveillance data spanning wildlife, human and livestock populations.
- The use of clinical surveys to look for causal links between syndromes and the viruses detected in Aim 1 is an integrated and elegant strategy.
- The work is very focused around the goal of identifying emergent zoonotic viruses. The team has extensively worked in this area with several examples of key discoveries from this group of viruses in the families around which the application is based.

#### Weaknesses

- Given the reliance on geographic-based prediction and targeting in Aim 1, it could be possible for the Aim 1-identified viruses to be in a region or in a type of animal-human interface that is not relevant to the established cohorts in use in Aim 3. This would require Aim 3 work to focus on a different, non-integrated, set of viruses.

### 2. Investigators:

#### Strengths

- The PI and the applicant institution have a long track record in working with zoonotic diseases and researching spillover events.
- The investigator team includes established experts and there is a pre-existing history of collaboration between the partners including a history of joint publications and grant implementation with Dr. Daszak and Dr. Baric.
- The investigator team includes experience with working in SE Asia, conducting human and animal surveillance, and analytic and laboratory techniques necessary to complete the proposed objectives.

#### Weaknesses

- None noted.

### 3. Innovation:

#### Strengths

- The use of combined geographic hotspot and reservoir-specific targeting is innovative and is an improvement on surveillance efforts driven by convenience sampling.
- While not innovative in its individual components, the integration of the components of the project is such that this is a refinement on existing early warning and investigative strategies for zoonotic emergencies.

#### Weaknesses

DASZAK, P

- None noted.

#### 4. Approach:

##### Strengths

- The approach is detailed and integrated across each aim, with a logical progression from zoonotic discovery, to basic science work, to clinical surveillance. Preliminary data is presented to support likelihood of success at each stage.
- While the application is primarily focused on a limited number of virus families, the expertise and capacity are available to expand this further into other viruses if needed. The application demonstrates examples of the team's ability to conduct rapid response.
- Targeted, systematic sampling strategies are used for prioritization of viruses.
- The sampling infrastructure needed for Aim 1 appears to already be in place.
- Preliminary testing in one of the proposed sample sets has already been conducted and several novel viruses have already been identified.
- Statistical approaches are listed in detail and are appropriate for the scientific questions (including the use of LASSO).
- This proposal will collect a very large number of specimens, only a subset will be used for the intensive laboratory analysis proposed in Aim 2. Testing in Aim 2 is informed by the findings in Aim 1 following a detailed plan for prioritization of resources.
- For studies in human specimens, the investigators have access to established population surveillance efforts in communities that are likely to be most impacted by the spillover mechanism that is hypothesized in this application. Serosurvey efforts are augmented by the appropriate epidemiologic data needed to integrate Aim 2 with Aim 3.
- Meetings with the community are included in the specimen collection plans.

##### Weaknesses

- The application mentions processing of PBMCs after serologic testing confirms exposure. Given issues of timing in processing PBMCs, it is uncertain to what degree systematic PBMC collection is feasible.

#### 5. Environment:

##### Strengths

- Serology testing capabilities are available at individual sites.
- The environment is excellent with strength both in established clinical sites and in superb laboratory infrastructure.

##### Weaknesses

- There is no planned integration with NIAID resources, however there is integration with USAID programs and the investigator team has extensive experience working with NIAID.

#### CRITIQUE 3

Significance: 2

DASZAK, P

Investigator(s):	3
Innovation:	2
Approach:	3
Environment:	2

**Overall Impact:** The application by Daszak and colleagues plans to build off their collective work under PREDICT and several R01s to conduct research to identify, characterize, assess potential for human infection and risk factors of zoonotic viruses in South East Asia. The team will be led by the EcoHealth Alliance, an NGO based in New York that has experience with similar projects and working with the consortium members. The application contains three aims to identify and characterize zoonotic viruses utilizing a large biorepository of animal and clinical specimens, determining the risk of spill-over into the human and other animal populations in the region linking to their large network in the three countries (Malaysia, Thailand and Singapore, and characterize cryptic outbreaks of viral EIDs in the region. The proposal has many strengths, including the use of the humanized mouse model to determine infectivity of novel viruses, efficient use of banked specimens, multidisciplinary team able to respond to potential and actual outbreaks in the three countries including neighboring regions, local capacity building, access to BSL3+ facilities and bioinformatic and other analytical expertise. I have identified several mild weaknesses in the proposal including: no clear veterinary or entomological expertise, limited clinical expertise amongst the US collaborating institutions which might be important for future diagnostic and treatment protocols, no clear expertise to identify and characterize non-zoonotic viruses, including bacteria, and lack of clear responsibilities for the Executive Committee to manage this complex project. Overall, I believe the project has significant strengths with several mild weaknesses.

### 1. Significance:

#### Strengths

- Zoonoses are common in SE Asia and have led to significant human and domestic animal outbreaks, with evidence that viruses are circulating in animals in the region
- Team will use an early warning approach to identify EIDs

#### Weaknesses

- While the team is taking a regional approach, there is no mention of the movement of animals, people and products within the region, as well as with neighboring countries such as China

### 2. Investigators:

#### Strengths

- Dr. Daszak is an internationally recognized leader in emerging viral zoonosis, with the administrative experience to direct this project
- The team is multidisciplinary, albeit with a bias towards ID ecologist, microbiologists, etc.

#### Weaknesses

- No clear expertise in veterinary medicine nor entomology to address new EIDs
- Little clinical research expertise from US-based investigators which could be required for advancing therapeutic and diagnostic studies

### 3. Innovation:

DASZAK, P

### Strengths

- Evaluation of infectivity of novel viruses using the humanized mouse model

### Weaknesses

- Unclear how team will identify previously uncharacterized EID viruses, and if needed non-viral EIDs in the region as needed during the project time period

## 4. Approach:

### Strengths

- The focus on zoonotic viral EIDs is relevant to SE Asia and the US
- Use of banked specimens will ensure success of Aim 1
- In order to determine the impact to human health, the team will use transgenic mice to test infectivity of humanized cells
- Use of validated instruments to test for associations with risk exposure in human populations
- Use of case-control cross-sectional studies to determine risk of infection

### Weaknesses

- The responsibilities of the Executive Committee are not clearly laid out

## 5. Environment:

### Strengths

- The EcoHealth Alliance is an NGO that will serve to coordinate this project in the field and with its US partners. The Alliance has managed related projects including the USAID-PREDICT as a partner
- The Partner institutions have BSL3+ facilities
- Access to many banked specimens for screening of human and animals throughout the region—this will be a very efficient aspect of this project

### Weaknesses

- No clear leveraging of existing networks, other than the recently completed PREDICT

**THE FOLLOWING RESUME SECTIONS WERE PREPARED BY THE SCIENTIFIC REVIEW OFFICER TO SUMMARIZE THE OUTCOME OF DISCUSSIONS OF THE REVIEW COMMITTEE ON THE FOLLOWING ISSUES:**

**PROTECTION OF HUMAN SUBJECTS: ACCEPTABLE (CODE 30).** This application is a study of human spillover and exposure to animal coronaviruses, henipaviruses, and filoviruses in Southeast Asia, with active sample collection in Thailand and Malaysia and testing of archived samples in Singapore.

Study participants will be recruited for this project within the study sites in Thailand, Malaysia, and Singapore. The protection of Human Subjects is adequately described.

DASZAK, P

**INCLUSION OF WOMEN PLAN:** Male and female subjects are anticipated (G1A)  
The inclusion plan is appropriate for the scientific goals of the research.

**INCLUSION OF MINORITIES PLAN: ACCEPTABLE (Code M5A).** The study population will be selected from the hotspot regions of Ratchaburi (Thailand), Chonburi (Thailand), Peninsular Malaysia, Sabah Malaysia, and Sarawak. The inclusion plan is appropriate for the scientific goals of the research.

**INCLUSION OF INDIVIDUALS ACROSS THE LIFESPAN: ACCEPTABLE (C1A).** All individuals across the lifespan will be enrolled with no exclusion based on age or gender. The inclusion plan is appropriate for the scientific goals of the research.

**VERTEBRATE ANIMAL: ACCEPTABLE. (CODE 30).** This application involves working with vertebrate animals in Thailand and Malaysia for field sampling and the University of North Carolina, Chapel Hill, and the National Emerging Infectious Diseases Laboratory (NEIDL), Boston, USA for mouse model experimental infections. Wild animals capture includes bats, rodents and non-human primates. The protection of Vertebrate Animal welfare is adequately described.

**BIOHAZARD COMMENT: ACCEPTABLE.** The plan to prevent risks during handling of biohazard materials or samples is adequate. The proposed research requires higher biosafety level containment (BSL3/4) for the selected select agents that are available at the University of North Carolina at Chapel Hill (UNC) and the National Emerging Infectious Diseases Laboratories (NEIDL), who will conduct select agent research. All biohazards that are shipped or received for the planned projects will meet the standards of the High Hazard Materials Management policy.

**SELECT AGENTS: ACCEPTABLE.** The pathogen surveillance activities proposed will result in the identification of the following select agents SARS-CoV (coronaviruses); wildtype Nipah, Hendra and related bat viruses (Henipaviruses); and wildtype Ebola viruses (Filoviruses).

#### **RESOURCE SHARING PLANS**

**DATA SHARING PLAN: ACCEPTABLE.** Data will be shared in accordance with NIH guidelines. Plan will need to be improved by Data Coordination Center

**MODEL ORGANISM SHARING PLAN: ACCEPTABLE.**  
There is an adequate plan for sharing of model organisms that may be generated in the project.

**GENOMIC DATA SHARING PLAN:** Applicant will ensure compliance with NIH's Genomic Data Sharing plans for all viral sequence data generated in this project.

**FOREIGN INSTITUTION: JUSTIFIED.** The involvement of foreign organizations in Southeast Asia in this application is properly justified.

**AUTHENTICATION OF KEY BIOLOGICAL AND/OR CHEMICAL RESOURCES: ACCEPTABLE**  
Adequate plans for authentication of key resources are outlined in the application.

**BUDGETARY OVERLAP: NON-APPLICABLE.**

**SCIENTIFIC REVIEW OFFICER'S ADMINISTRATIVE NOTES:**

DASZAK, P

During the review of this application, reviewers and/or NIH staff noted that one or more biosketches did not comply with the required format ([NOT-OD-15-032](#)). NIH has the authority to withdraw such applications from review or consideration for funding.

**COMMITTEE BUDGET RECOMMENDATIONS: The budget is recommended as requested in all years.**

---

Footnotes for 1 U01 AI151797-01; PI Name: DASZAK, PETER

NIH has modified its policy regarding the receipt of resubmissions (amended applications). See Guide Notice NOT-OD-14-074 at <http://grants.nih.gov/grants/guide/notice-files/NOT-OD-14-074.html>. The impact/priority score is calculated after discussion of an application by averaging the overall scores (1-9) given by all voting reviewers on the committee and multiplying by 10. The criterion scores are submitted prior to the meeting by the individual reviewers assigned to an application, and are not discussed specifically at the review meeting or calculated into the overall impact score. Some applications also receive a percentile ranking. For details on the review process, see [http://grants.nih.gov/grants/peer\\_review\\_process.htm#scoring](http://grants.nih.gov/grants/peer_review_process.htm#scoring).

# MEETING ROSTER

**Subject:** RE: EIDRC Summary Statement from NIAID  
**Date:** Friday, December 6, 2019 7:08:35 PM  
**Attachments:** [Summary Statement - EIDRC Grant.pdf](#)  
**Importance:** High

---

Dear All,

Attached is the summary statement from our EIDRC review. We didn't do badly at all – 3 reviewers, two of whom gave us 2's and 3's, and the second reviewer who loved it (mainly 1's).

The good news is that the summary statement starts with “in this excellent ...proposal”, which is a good sign, although there were some negatives of course.

In my opinion, we're touch and go on whether we'll get funded on this, so I quickly wanted to check in with who of you will be at the Singapore Nipah meeting over the next few days? I'll be there, as will Jon Epstein (cc'd here so he can help). Linfa and Danielle, obviously. **Supaporn, Chris, Ralph – will you be there in Singapore?**

The reason I'm asking is that Cristina Casseti, and possibly others from NIH/NIAID/DMID will be there as well, and they're in a key position to decide whether to push this forwards for funding. The council meeting is on January 27<sup>th</sup>.

Linfa or Danielle – can you email me a list of who's registered for the meeting from NIAID or NIH please? Jean Patterson is the Program Officer and Eun-Chung Park will be part of the process also.

For those of you going – we can't lobby NIH directly, but it will be good for us to be seen as a cohesive team at that meeting, and talk very positively about our work together over the past few years, including on PREDICT and the samples that have been collected that could be also used in this project. Also, if you have chance, please re-read some of the proposal in case we do get chance to talk with them about it (attached in a previous email).

Fingers crossed on this one!

Cheers,

Peter

**Subject:** EIDRC impact scores from NIH

**Importance:** High

Dear All,

Just to let you know that we've got the results back from NIH. EHA submitted two EIDRC proposals, and we were linked to a third one as a subcontract. Out of these, the only one to get a score was the Southeast Asia EIDRC (EID-SEARCH) which you are all collaborators on. I also know of another good group that wasn't scored, so just to get a score is actually a good result...

**Our 'impact score' was 32**, which normally would put us right on the edge of being funded. I've already contacted the NIAID program officer (Jean Patterson) to ask about the likelihood of being funded. She told me that NIH staff are currently working out the structure of the network and a funding plan. She felt our proposal was well-received and scored well enough to be considered, and she asked me to hold off for a week or two and then they'd know more.

My take on this is that they're now deciding what the geography and scope of the network should be, how many EIDRC centers they can afford to fund, and then they'll decide priorities for funding. With this being strongly driven by NIAID's internal concerns about their reach into different geographies, it's really going to be a decision driven by their own considerations of who else is in the mix and what strengths/weaknesses different proposals have. That means we're in with a chance, but we don't really know the factors driving a decision.

I'll contact NIAID again in a few days, but in the meantime, please do the following: 1) try not to share this information with colleagues because we don't want to have a situation where they scored better than us and we got funded, leading to a bad feeling (or worse, the other way round!); 2) if you meet people from NIAID, tell them how keen and enthusiastic you are about the proposal and the work we're conducting (I've attached the final text again as a reminder) – you never know how this might help. Key people at NIAID who will be making this decision are: Tony Fauci (head of NIAID),

Cristina Cassetti (Deputy Head, and in charge of this line of work), Jean Patterson (Program Officer directly in charge of the EIDRCs), Eun-Chung Park (also directly in charge of this work), Pat Repik (I think she's involved).

Finally – I've attached the Review Committee Roster for you to look at who the people are who either liked or disliked our proposal! I know a few of them, and I'm sure you know the others...

Will be in touch as soon as I hear more.

Cheers,

Peter

**Subject:** EIDRC grant submitted

**Importance:** High

Dear All,

Just to let you all know that the grant was successfully submitted today with time to spare, and no errors. It's in the system, and it's all down to the reviewers now! Thanks to all of you for your help and support in getting this finalized and completed. Please pass on my personal thanks to the Co-Investigators, Key Personnel and Consultants who you also brought into the team.

I've attached a pdf of the final proposal text and will send the Word version in a few minutes. It's actually a good read, and I'm especially grateful to Hongying who generated all the cool graphics, based largely on Ralph's previous NIH grant proposals.

As you read the text, please remember that the wording is very carefully targeted to a typical US-based NIH reviewer, and to the Program Officers, with the sole purpose of trying to win the grant. If I've exaggerated or made mistakes, or used language that isn't quite right, I apologize, but I did it for the key goal of getting funded.

In the meantime, please don't share this proposal beyond our group on this email chain, so we don't give our competitors an edge!

Good luck, and I'll be keeping my fingers crossed all summer in the hope that we win this...

Cheers,

Peter

Dear All,

Here's version 4. Apologies for the delay. It's in better shape now, but there are still lots of areas that need your attention. Please put in time today, and tomorrow to edit and firm up the text. I've put your names in some of the comment boxes where I need specific help but I also need you to read this critically now and edit and tighten it up. We have 30 pages of space, and our research plan is now 21 pages, so we need to lose maybe 3 or 4 pages. There are also some weak points, specifically on Filoviruses, on the details of where we'll do our clinical work, and on what we'll do with the animal models for henipias and filis.

Please get comments back with me before Wednesday 26<sup>th</sup> 4pm New York time, so that I have Wednesday evening and all day Thursday to incorporate them. In the meantime, I'll be working with folks here on better figures, and all the extra sections that come after the research plan. I'll need you all to help with those on Thursday while I'm finishing off the draft.

Thanks to all of you in advance and look forward to the next round.

Cheers,

Peter

**Subject:** EIDRC-SEA v.3

**Importance:** High

Dear all,

Thanks to everyone for comments and text for the earlier draft at the beginning of the week. Kevin's spent the last couple of days pulling all the comments together into one draft and inserting his changes, and I've now attached a v3 of the draft. It's still rough, and now too long, but it's getting there. I wanted you to look at this rough version because I'm stuck in Liberia in meetings Friday, then flying back home Saturday. I'll continue editing this draft on the plane and will be working solely on this grant from home on Sunday, Monday, Tues, Wed, Thurs.

Please work on this rapidly if possible. If you can all push your comments through, using track changes, and get them back to me **by Sunday evening New York Time**, I will turn round a polished draft by Tuesday, giving us time for significant last go-over on Wed, Thurs. It's tight, but unfortunately, it is what it is, so please commit the time if you can!! As well as general edits (using track changes, with references in comment boxes), please do the following...

Linfa/Danielle – We especially need your input in section 1.1, 1.3, 1.4 and 2.5

Ralph/Amy - Please work your magic on this draft, inserting text, editing and reducing text, and making sure the technical details of the characterization are correct and fit the proposed work on CoVs, PMVs and Henipaviruses

Chris/Eric – Eric – congratulations on your (b) (6) and thanks for working on it at this time!  
Chris – please help and edit/finesse the language in the relevant sections for you

Tom – Your edits crossed over with Kevin's changes, so please insert all the bits that were new in the last version you sent to me, into this version. I think these are mainly the sections and comments from the other Malaysian colleagues, but please check and re-insert all key text. We especially need to be specific about which partner in Malaysia is doing what cohorts, and where, and about who's doing the testing

Thanks again all, and I'm looking forward to non-stop work on this as soon as I get on my flight in 24 hours...

Cheers,

Peter

## II. Research Strategy:

**1. Significance:** Southeast Asia is a critical hotspot for emerging diseases due to its high biodiversity of wildlife and their viruses, and the presence of key ecological and socioeconomic drivers of emergence (**Fig. 1**) (1). These include dense human populations living in networks of rural and urban communities, with strong cultural and occupational connection to wildlife and livestock farming and trading, and intimate connection to global travel networks (2). The region is undergoing rapid environmental and demographic change, both of which increase the risk of disease emergence and spread. Pathogens that emerge in this region often spread and sometimes enter the USA (e.g. prior influenza pandemics, SARS) and threaten global health security.

**Fig. 1:** Southeast Asia, and in particular, parts of Thailand and Malaysia are hotspots of risk for disease emergence (**left**), and predicted high diversity of 'missing' or as-yet undiscovered viruses, yellow = highest diversity (**left**). From (1-3).

Not surprisingly novel viruses, including near-neighbors of known agents, have emerged in the region leading to often unusual clinical

presentations (**Table 1**). This adds to a significant background burden of repeated Dengue virus outbreaks in the region (20), and over 30 known *Flavivirus* species circulating throughout S. and SE Asia (21). The events in Table 1 are dominated by three viral families: coronaviruses (CoVs), paramyxoviruses (PMVs - particularly henipaviruses) and filoviruses (FVs), which are initial examples of our team's research focus and capabilities. These viral groups have led to globally important emerging zoonoses (4, 5, 22-31), causing tens of thousands of deaths, and costing billions of dollars (32-34). Furthermore, near-neighbors of known pathogens in these families have been reported throughout the region, including by members of our consortium: henipaviruses in bats in Thailand, Cambodia, Philippines, Laos, Indonesia, China, Malaysia, Bangladesh and India (35-41); a novel henipavirus, Mòjiāng virus, in wild rats in Yunnan (14); serological evidence of FVs in bats in Bangladesh (42) and Singapore (43); Nipah- and Ebola-like viruses in *Hipposideros*, *Cynopterus* and *Rhinolophus* species in Malaysia (Hughes *et al.*, in prep.); evidence of novel FVs in bats in China (44-46), including Měnglà virus

Viral agent	Site, date	Impact	Novelty of event	Ref.
Nipah virus	Malaysia, Singapore 1998-9	~246 human cases, ~40% fatal	2 <sup>nd</sup> emergence of a zoonotic henipavirus, 1 <sup>st</sup> large outbreak	(4-6)
Melaka & Kampar virus	Malaysia 2006	SARI in family group, individual	1 <sup>st</sup> disease due to bat-origin reoviruses, also Singapore, Vietnam etc.	(7-10)
Reston filovirus	Philippines 2008	Seropositive people killed pigs,	No prior FVs in pigs	(11)
Thrombocytopenia Syndrome virus	E. Asia 2009	100s of deaths in people	Novel tick-borne zoonosis with large caseload	(12)
Reston filovirus	Shanghai 2011	PCR positive pigs	Further evidence of pig RESTV infection	(13)
Mòjiāng virus	Yunnan 2012	Death of 3 mineworkers	1 <sup>st</sup> evidence of rodent origin henipavirus in people	(14)
Nipah-like virus	Philippines 2015	Killed horses	No prior horse infection for NiV, known for HeV	(15)
SARSr-CoV & HKU10-CoV	S. China 2015	Seropositive people	1 <sup>st</sup> evidence human infection HKU10 & SARSr-CoV	(16)
SADS-CoV	China 2017	>25,000 pig deaths seronegative people	Novel emergence of bat-origin CoV	(17)
Nipah virus	Kerala 2018, 2019	Killed 17/19 people 2018, 1 infected 2019	1 <sup>st</sup> outbreak of NiV outside Bangladesh, W. Bengal focus	(18, 19)

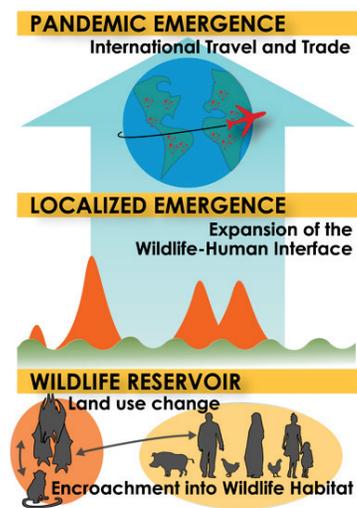

that appears capable of infecting human cells (47); novel PMVs in bats and rodents consumed as bushmeat in Vietnam (48); a lineage C  $\beta$ -CoV in bats in China using the same cell receptor as MERS-CoV to infect human cells *in vitro* (49); MERSr-CoVs in bat guano harvested as fertilizer in Thailand (50), and directly in bats (Wacharapluesadee *et al.*, in prep.); 172

**Table 1:** Recent emergence events in SE Asia indicating potential for novel pathways of emergence, or unusual presentations for known or

related viruses.

novel  $\beta$ -CoVs (52 novel SARSr-CoVs) and a new  $\beta$ -CoV clade (“lineage E”) in bats in S. China that occur throughout the region (24, 49, 51, 52); 9 novel wildlife-origin CoVs and 27 PMVs in Thailand, and 9 novel CoVs in Malaysia reported by us from USAID-PREDICT funding (51, 53). These discoveries underscore the clear and present danger of zoonotic events in the region. The wide diversity of potentially pathogenic viral strains also has significant potential use in broadly active vaccine, immunotherapeutic and drug development (49).

Most high-impact zoonotic viruses originate in wildlife reservoirs, sometimes spilling over first into livestock ‘amplifier’ hosts, or directly into localized human populations with high levels of animal contact (**Fig. 2**). Efforts to prevent emerging zoonoses have targeted these high-risk populations in regions prone to disease emergence (31, 54). However, these regions tend to be in the developing world, where nations often lack the resources to investigate novel zoonotic events, or wildlife reservoirs of zoonoses, and prioritize more immediate public health concerns such as Dengue virus or NTDs (20). Zoonotic disease surveillance and control is also hampered by inadequate information on basic disease ecology (e.g. range of wildlife reservoirs, risk factors for spillover) and pathogen biology (viral diversity, pathogenesis), and by logistical challenges sharing novel diagnostics, animal models, samples and reagents at sites where outbreaks begin (55). Countermeasure and vaccine development is challenged by the small number of isolates available, and the presence of closely-related strains, some with evidence of transmission to people but with unknown pathogenicity. For example, using NIH and other funding, we found serological evidence of exposure to African henipaviruses in 3-4% of a sample of people in Cameroon, with a significant risk factor being butchering of bats; and serological responses to bat SARSr-CoVs in 6/209 (2.87%) and bat HKU10-CoV in 2/412 (0.5%) people living close to a bat cave in Yunnan, all novel viruses with unknown clinical impact (16, 56). We discovered two novel bat-borne reoviruses, Melaka and Pulau viruses, and showed that 14/109 (13%) of people living in close proximity to bat roosts on Tioman Island, Malaysia were exposed to these viruses (7) as well as 12/856 (1.4%) of a random sample screened in Singapore (8). Previous studies in the Philippines found farmers and butchers who had contact with sick pigs tested positive for Reston ebolavirus antibodies but had not experienced illness (11), and it was our team that discovered Philippine bats as natural reservoir hosts for Reston virus (57). In preliminary screening in Malaysia with funding from DTRA we found serological evidence of exposure to henipaviruses (Hendra, Nipah and Cedar) in 14 bats and 6 human samples, and Ebola (Zaire and Sudan)-related viruses in 11 bats, 2 non-human primates (NHP) and 3 human samples (Hughes, in prep.).

Even when spillover leads to outbreaks of illness and mortality, they are often unreported, undiagnosed or misdiagnosed. We initiated targeted syndromic surveillance of encephalitis patients in Bangladesh clinics and showed that Nipah virus (NiV) causes repeated annual outbreaks with an overall mortality rate of ~70% (58). NiV has been reported in people in West Bengal, India, which borders Bangladesh (28), in bats in Central North India (59), and now in people in Kerala, South India in 2018 and 2019, raising the specter of future spillover at other sites in the region (18, 60).

**Fig. 2: Our Early Warning Approach:** Most zoonotic viruses emerge from wildlife hosts, sometimes via livestock (**lower panel**), to cause small scale outbreaks (green) or larger chains (red) of human-to-human transmission (**middle**). In some cases, these spread more widely via air travel (**upper**). Our EIDRC proposal targets each stage: SA1 examines the diversity and spillover potential of viral threats in targeted SE Asian wildlife; **SA2** seeks evidence of their spillover into focused high-risk human populations; **SA3** identifies their capacity to cause illness and to spread more widely. Figure from (54).

Under a current NIAID R01, we have shown that we can use analytical approaches to target surveillance of wildlife and people and identify likely sites of spillover. We used phylogenetic analysis of bat hosts and their CoVs to identify a key cave complex in SW Yunnan Province that harbors all the genetic elements of SARS-CoV (61), as well as a series of SARSr-CoVs that can infect human cells *in vitro*, cause SARS-like clinical signs in humanized mice, and evade vaccine treatment and therapeutics (24, 49, 51, 52, 62-64). We conducted risk factor surveys and biological sampling of human populations living close to this cave and found serological evidence of spillover in people highly exposed to wildlife (16). **This work provides proof-of-**

**concept for an early warning approach that we will expand in this EIDRC to target other viral groups in one of the world's most high-risk EID hotspots.**

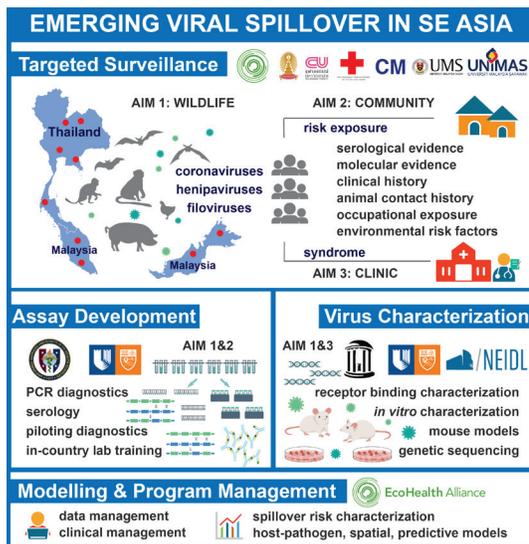

The overall premise of this EIDRC proposal is that there is substantial evidence that: 1) diverse CoVs, henipaviruses and FVs related to known human pathogens are circulating in wildlife reservoirs in Southeast Asia; 2) these viruses likely spillover regularly to people, are often unreported or misdiagnosed, and their clinical manifestations and potential to cause pandemics are unknown and underestimated; and 3) our strategy for targeted surveillance and detection of spillover and illness in at-risk human populations can be used as an 'early warning system' to conduct public health interventions and disrupt disease emergence. To scale-up this approach, we propose to launch EID-SEARCH (the **E**merging **I**nfectious **D**iseases - **S**outh **E**ast **A**sia **R**esearch **C**ollaboration **H**ub), to better understand, and respond to, the risk of zoonotic viral emergence in Southeast Asia. We will initially focus on the diversity of known and novel CoVs, henipaviruses, and FVs in wildlife reservoirs. We will use this work to build our center's interactive network throughout the region, bridge barriers, provide early focal point for basic and translational studies, develop sample handling and storage routines, communication networks, cohort management, infrastructure development, and cross-training in surveillance and novel diagnostic platforms. We will develop and transfer technology to test these viruses' capacity to infect human cells and mouse models, develop new specific and sensitive serological and molecular diagnostic tools, conduct surveillance of human communities with high risk of exposure to wildlife, and clinical cohorts to identify evidence of spillover of viruses causing previously 'cryptic' clinical syndromes in people. We will test the capacity of novel viruses to infect human cells and/or mouse models, and thus assess potential for spillover and spread which will feed into our risk models. Our group also has extensive experience in other viruses, including vector-borne flaviviruses, and alphaviruses, and will use this experience to provide robust long-term surveillance, diagnostics, and basic science opportunities. While the current proposal focuses its basic and applied research agendas on this group of viral EID, we note that the EID-SEARCH is poised to rapidly respond to any outbreak. **Thus, FVs, henipaviruses and CoVs are examples of sentinel surveillance systems in place that illustrate EID-SEARCH's capacity to identify and initiate a rapid response targeting any novel microbial pathogen that emerges in this region.**

**2. Innovation:** Previous work by our consortium has developed strategies to target surveillance in wildlife and people to better anticipate and identify early spillover events and pre-empt outbreaks of emerging viruses. In the EID-SEARCH we scale up this approach in a central research "hub" made up of leading laboratories, clinics and surveillance sites in three critically high-risk EID hotspot countries in SE Asia. EID-SEARCH's reach is expanded through its regional network of collaborators that covers nearly all of the greater SE Asia region. The innovation of the EID-SEARCH is in: 1) Its multidisciplinary approach that combines modeling to target geographic and taxonomic sampling targets with on-the-ground zoonotic disease surveillance in human and wildlife populations; 2) the biological characterization approach that identifies how likely viruses are to be able to infect people, and enables evaluation of existing countermeasure technologies; an approach that is grounded in our successful work on SARSr-CoVs; and 3) the strategic sampling of both high-risk communities with extensive animal contact at the front-lines of viral spillover and syndromic clinical cohorts that present with signs of novel viral emergence, to identify risk of viral spillover in an early warning system approach (**Fig. 2**). **In Aim 1, we will target viruses in archived and newly collected wildlife samples, and characterize their risk of spillover to people.** We will use spatial and phylogeographic analyses to identify the geography and species of wildlife to test samples from, and to further characterize viruses we have recently discovered. We will use *in silico* methods (novel ecological-phylogenetic risk ranking and mapping of receptor binding domains), cell culture, and animal models to assess their potential for spillover into high-risk human populations. **In Aim 2, we will conduct targeted cross-sectional serological surveys of human communities with high levels of animal contact to find evidence of viral spillover, and identify occupational and other risk factors for zoonotic virus transmission.** We will use serological tests targeting viruses identified in Aim 1 to identify the baseline spillover of known or novel CoVs, henipaviruses and FVs in these populations. Serological findings will be analyzed together with subject metadata (including a simple animal-contact survey, location data, viral sequence/isolates etc.) to identify zoonotic risk factors and routes of exposure from specific wildlife or vector species. **In Aim 3, we will use syndromic surveillance of clinical human cohorts to identify evidence of viral etiology for otherwise 'cryptic' outbreaks.** We will enroll and

collect biological samples from patients in local clinics and hospitals who present with syndromes previously linked to known viral agents and live within communities at high risk for disease emergence. We will conduct molecular and follow-up serological diagnostic assays to identify likely viral etiology of syndromes that may represent otherwise cryptic events. Where viruses are identified, we will attempt to isolate or molecularly re-derive them, and use survey data, ecological and phylogenetic analysis to identify likely reservoir hosts and inform intervention programs. Our US partner BSL-4 laboratory, NEIDL, will attempt isolation and characterization of viruses requiring BSL-4 of containment (e.g. novel filoviruses, close relatives of Hev/NiV).

**3. Approach: 3.1. Research team:** The EID-SEARCH builds on long-term collaboration among world leaders in emerging virus research with proven experience collaborating internationally on field, lab and human surveillance research (**Fig. 3**). Over the past two decades, our consortium partners have conducted high profile research on EIDs within the region and globally, including identifying the wildlife reservoirs for NiV and Hendra virus (HeV), MERS- and SARS-CoVs (24, 27, 59, 61, 65-67), discovering SADS-CoV (17), and developing an array of serological, molecular, *in vitro* and *in vivo* approaches to characterizing high-risk CoVs, henipaviruses, and FVs (62-64, 68-81). Our team has substantial experience conducting human surveillance in the community and during outbreaks (Sections 2.2.a., 2.2.b., 2.2.c, 3.2.a, 3.2.b), including: USAID-PREDICT, and DTRA-funded viral surveillance of indigenous communities in Peninsular Malaysia and syndromic surveillance of hospital patients in Sabah (Co-I Hughes); collection of >2,000 serum samples from healthy blood donors and sanitation workers, febrile and influenza like illness (ILI), and diarrheal stool samples from children under 5 years of age across Borneo Malaysia (Co-I Kamruddin); collaboration on the MONKEYBAR project with the

London School of Hygiene and Tropical Medicine to analyze risk and prevalence of the zoonotic malaria *Plasmodium knowlesi* through case control and cross-sectional studies in Sabah villagers (n=~800, 10,000 resp.) and clinical observational studies to determine the etiology of central nervous system infections and acute undifferentiated febrile illness in Sabah. (Co-Is William, Rajahram, Yeo); and community-based surveillance of hundreds of bat-exposed villagers in Thailand (Co-Is Wacharapluesedee, Hemachudha). As a proof-of-concept of how our team can rapidly scale up resources for diagnostics and surveillance in the face of a new EID, in 2016, we discovered a novel bat-origin HKU-2 CoV (82, 83) killing >20,000 pigs in S. China, designed PCR and serological assays, surveyed pig farmers for evidence of exposure, and conducted experimental infections, pathogenesis and molecular studies, **all in the span of 3 months** (17, 84).

**Fig. 3:** EID-SEARCH scope, core institutions, and roles.

The administration of this center (**Section 4.1.**) will be centralized at EcoHealth Alliance (EHA) led by PI Daszak, who has >20 years' experience managing international research collaborations on emerging zoonoses, and has collaborated with all partners in the EIDRC consortium for 5-20 yrs on NIAID- and USAID-funded research. He will oversee all activities in this EIDRC, supported by Deputy lead, Dr. Olival – who has managed human and wildlife disease surveillance projects in SE Asia for >10 years, and a **Core Executive Committee (Section 4.1.a)**. Co-Is Olival and Zambrana are leaders infectious disease analytics, and head the modeling and analytics work for USAID-PREDICT. Co-Is Wang, Baric, Broder, Anderson, and Laing have developed a unique array of *in vitro* cell culture, serological and molecular reagents to identify and characterize emerging viruses in people and animals (henipaviruses and other PMVs, CoVs, FVs and many others). Co-Is Wacharapluesedee, Hemachudha, and Hughes and collaborators have coordinated clinical and community surveillance of people, and of wildlife and livestock within Thailand and Malaysia for the past 15 years, in collaboration with Ministries of Health, Agriculture and Environment. Finally, this consortium has extensive external funding from NIH, DoD, USAID, DHS and other USG agencies supporting laboratory, analytical and field studies directly related to the current proposal, and will bring substantial leverage to our EIDRC.

**3.2. Geographical focus:** The three core (hub) countries for this proposed EIDRC are Thailand, Malaysia and Singapore, three contiguous EID hotspot countries that stretch through one of the most significant foci of EID origins globally. Our proposed work includes sampling wildlife and people in Thailand, Peninsular Malaysia, Sarawak and Sabah, and thus contains overlapping wildlife biogeography with India, Bangladesh, Myanmar, SW China, Laos, Cambodia, Vietnam, Philippines, and Indonesia. It encompasses diverse cultural and socioeconomic backgrounds which have correspondingly diverse and intensive interactions with wildlife reservoirs and the global travel network. We have already begun sampling of wildlife hunters, livestock workers, wildlife farmers and market workers, rural villagers living close to high risk wildlife species, people otherwise highly exposed to animals in these countries, and clinical cohorts, as part of current/prior NIH, DTRA, and USAID funding. Our core member's extensive network of collaborators in clinics, research institutes and public health laboratories in almost every other Southeast Asian country positions the EID-SEARCH within a much larger catchment area for emerging zoonoses and will allow us to rapidly scale up to include additional sites in response to an outbreak or shift in research priorities. We will conduct regular meetings with key research, public health and community leaders, including >50 leading laboratories/institutions in 10 countries (**Section 4.2**) to maintain these collaborative relationships with the core members of our consortium (**Fig. 4**).

We will use these, and our annual meetings, to share information on novel research and diagnostic approaches, pathogens that are of key pandemic potential, regions or populations at high risk of spillover, and information from the greater network on likely outbreaks of novel disease. This platform will coordinate sample sharing and diagnostic platforms and help build a rapid response to outbreaks across the region.

**Fig.4 :** Map of Southeast Asia indicating three hub countries for this proposed EIDRC (**Red**: Thailand, Singapore, Malaysia) and countries in which Key Personnel have existing collaborating partners via other funded work (**Green**), indicating that EID-SEARCH provides access to key collaborators and sites throughout the region.

**3.3. Capacity for linkage with other NIAID studies, and scaling up to respond to outbreaks:** EID-SEARCH US-based partners include senior scientists with significant experience on NIAID-funded projects, extensive collaborations with other NIAID-funded scientists, and previous experience working with NIAID leadership through workshops, review of programs (e.g. PI Daszak's role in NIAID CEIRS external review), and work on study sections. These contacts ensure that the EID-SEARCH senior leadership will be ready and able to rapidly set up data, sample and reagent/assay sharing protocols with NIAID researchers, the other EIDRCs, the EIDRC CC and other NIAID research centers. EID-SEARCH in-country partners include senior medical doctors and infectious disease specialists at national and regional hospitals in each country and administrative state in this proposal. On news of potential outbreaks, **EID-SEARCH will rapidly mobilize its core staff and their extensive collaborative network across almost all SE Asian countries (Fig. 4) (Sections 4.1.a, 4.2. 4.3)**. The core analytical approach can be used to rapidly identify sampling sites and targets to harvest vectors, vector borne arboviruses, birds and mammalian species that harbor most other viral threats. Through existing projects such as the USAID PREDICT Project and DTRA-funded biosurveillance projects, EHA is currently partnered with hospitals and researchers across South and Western Asia, West and Central Africa, and Latin America. Our partners already have capacity to conduct human and wildlife sampling and testing for novel viral agents, so expanding in geography or scale is readily achievable given sufficient resources.

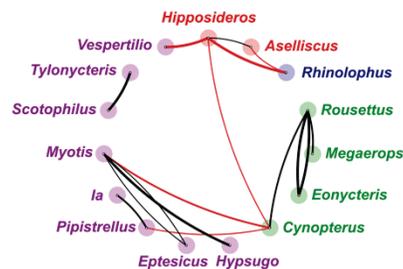

**Aim 1: Identify, characterize and rank spillover risk of high zoonotic potential viruses from wildlife.**

**1.1 Rationale/Innovation:** The vast majority of emerging zoonotic pathogens are linked directly or indirectly to wildlife host, particularly from important mammalian groups like bats, rodents and NHPs (3). Our previous work on wildlife origin viruses demonstrates that zoonotic viral emergence tends to occur in specific regions with high diversity of wildlife that harbor viruses of zoonotic potential, and human populations that have close contact to these wildlife (**Fig. 1**) (2, 3). In Aim 1 (**see Fig. 9 for overview**), we will strategically conduct EID surveillance by applying risk analytics to prioritize the regions, wildlife species, and human populations that

have a particularly high risk of viral spillover. We will target high-risk zoonotic host reservoirs (bats, rodents and NHPs) in these regions and apply novel predictive models to estimate viral diversity and host range to identify wildlife species that have been ignored or under-sampled by previous zoonotic disease surveillance efforts. We will strategically collect specimens from these species and screen them, together with some of the tens of thousands of recently collected samples we have archived, for known and novel agents. We will begin screening using conserved PCR assays to identify known and novel viruses in high risk RNA viral families, *Coronaviridae*, *Paramyxoviridae*, and *Filoviridae*. We will expand to other groups of pathogens, including arboviruses, pending available resources and priorities established with the EIDRC coordinating center (EIDRC-CC) and other regional EIDRCs. Using risk ranking algorithms and a series of ecological and virological risk factors, we will triage the wildlife viruses we discover for further genomic characterization and viral isolation. On this subset of viruses, we will then use *in vitro* and *in vivo* approaches (viral rescue, cell lines, gene edited humanized transgenic mice and the collaborative cross genetic reference mouse population) previously developed and widely used by our team to predict capacity of novel viruses to infect people and spillover (63, 85-88). These high-risk viruses and their close relatives will be targets for human community serosurveys and clinical sampling in Aims 2 and 3, respectively.

**1.2 Preliminary data: 1.2.a. Geographic targeting:** EHA has led the field in analyzing where the highest risk of zoonotic spillover is across the globe, identifying SE Asia as a major EID hotspot (1, 2). These hotspots are sites where high wildlife biodiversity, human population density and rapid ecologic change collide (**Fig 1**). Using host and ICTV viral data for all known mammalian viruses, and generalized additive models to correct for sampling bias, we are able to predict the relative number of yet-to-be-described viruses that a species harbors (3). This demonstrates substantial undiscovered viral diversity in mammals across Southeast Asia, and particularly in regions of Thailand, Singapore and Malaysia (**Fig. 1**). Separately, we found that factors driving spillover (host diversity, climate) differ from those driving spread in human populations (population density, bushmeat hunting, livestock production) (89). We therefore analyze capacity for viral spread as a separate risk factor, using our unique demographic and air travel and flight data modeling software (90, 91). In the current proposed work, we will use all the above approaches to target wildlife sampling (archival and new field collections) in Aim 1, to inform sites for human sampling in Aim 2, and to assess risk of spread in Aim 3.

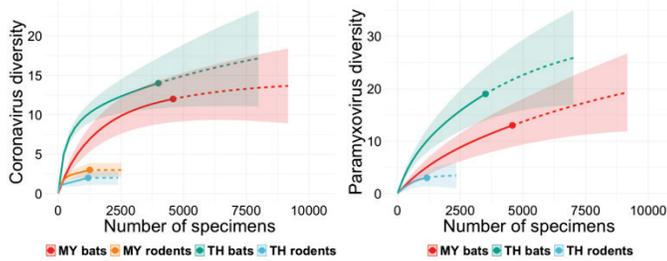

**1.2.b. Reservoir host species targeting:** Our analysis of all known mammalian host-viral associations demonstrates that bats, rodents and NHPs represent the three most important reservoirs for zoonoses, responsible for the highest proportion of known and predicted viral diversity of zoonotic potential (3). Thus, the bulk of our proposed wildlife sampling and testing will consist of these three taxa with a focus on bats, because this group is the known or hypothesized reservoir for the majority of high-impact zoonotic CoVs, PMVs and FVs (50, 92-94). Bats have the highest proportion of predicted zoonotic viruses in any mammalian group (2), and are exceedingly diverse in Southeast Asia (~500 species). To further prioritize taxonomic sampling targets within these diverse geographic hotspots, we used a novel Bayesian phylogeographic algorithm to identify host genera and species that are the most important centers of evolutionary diversity for a given viral group, e.g. bat genera for  $\beta$ -CoVs (**Fig. 5**) (51). This approach will be extended to other mammal taxa and viral families of interest, allowing us to identify the reservoir hosts of specific zoonotic viral groups, where viral diversity is likely highest.

**Fig 5:** Preliminary analysis of sequence data collected under prior NIH funding, identifying SE Asian bat genera with the highest  $\beta$ -CoV evolutionary diversity. We will apply this Bayesian discrete phylogeographic model to identify taxonomic and geographic centers of viral diversification and sharing for relevant PMV, CoV, FV and other virus clades. Line thickness proportional to probability of virus sharing between two genera. Inter-family switches in red.

Finally, we have designed a strategy to estimate sampling gaps, using a viral 'mark-recapture' approach we previously published (95, 96) (**Fig. 6**). Using prior data for bat, rodent and NHP viral discovery vs. sampling rates, we can identify the likely total viral diversity for specific host groups in a region, and use this to estimate sample sizes to discovering the majority of unknown viruses within a specific family or genus. **In the current**

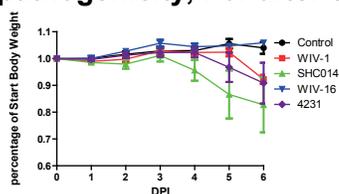

**proposal**, we will use these analyses to estimate geographic and species-specific sampling targets **to more effectively identify new strains to support experimental infection studies and risk assessment.**

**Fig. 6:** Estimated CoV (left) and PMV (right) diversity in bats and rodents from Thailand and Malaysia, using data from PCR screening and RdRp sequences from >10,000 specimens in bats and 4,500 in rodents. Bats have 4X more viral species than rodents, controlling for sampling effort. We estimate that additional collection of 5k-9k bat specimens and testing of our archived bat and rodent specimens alone will identify >80% of remaining CoV and PMV viral species in these key reservoirs, yielding >800 unique viral strains.

**1.2.c. Sample testing to identify known and novel viruses:** We have conducted extensive wildlife surveillance for novel viruses across Southeast Asia in prior NIAID funded work and as part of the USAID PREDICT project. Under the 10-year PREDICT program globally, we identified 912 novel and 210 known viruses, more than the total number of viruses previously recognized in mammals by the ICTV (97). This work included collecting nearly 300,000 individual mammal samples from 14 EHA-led PREDICT countries, and PCR-screening of more than 60,000 individual specimens (53). In southern China alone, we identified 178  $\beta$ -CoVs, of which 172 were novel, discovered a new  $\beta$ -CoV clade, “lineage E” (41), diverse HKU3r-CoVs (179 sequences) within a 'sister' clade to the SARS-CoV lineage, and a new bat-origin SADS-CoV, responsible for killing >25,000 pigs in Guangdong Province (17). We have collected 28,957 samples from bats, rodents and NHPs in Thailand and 47,178 in Malaysia, **but have only tested a minority of these using PCR.** We have identified 100 novel viruses in Thailand and 77 in Malaysia. **Furthermore, we have only sequenced a small segment of one gene for all novel viruses found. We have archived duplicate samples which are now available for use in this project**, including fecal, oral, urogenital, serum samples, and biopsies from bats, rodents, and NHPs. In the current proposed work, we will attempt to sequence, isolate and characterize those viruses that our analyses below suggest are most likely to be able to infect humans.

**1.2.d. In vitro & in vivo characterization of viral potential for human infection:** Using Coronaviridae as an example, we have conducted *in vitro* and *in vivo* experiments to characterize the pathogenic potential of novel SARSr-CoVs from bats. We isolated three SARSr-CoVs from bat feces: WIV1, WIV16 and Rs4874, with Spike (S) protein sequences that diverged from SARS-CoV by 3-7% (24, 61, 98). We conducted full-length genome sequencing of 12 other novel SARSr-CoVs, some highly similar to outbreak SARS-CoV in the most variable genes (61). Using our reverse genetics system we constructed chimeric viruses and rederived full length recombinant SARSr-CoV from in silico sequence. All 3 SARSr-CoV full length isolates and the two chimeric viruses replicated efficiently in Vero E6 cells and in HeLa cells expressing hACE2, civet and bat ACE2, but not in those without ACE2 (24, 61, 98). We used the SARS-CoV reverse genetics system (72) to generate a chimeric virus with a mouse-adapted SARS-CoV backbone expressing SHC014 S protein with 10% sequence divergence from SARS-CoV S. This and the other full length and chimera viruses replicated in primary human airway epithelium, using the human ACE2 receptor to enter into cells (62). Thus, **SARSr-CoVs with diverse variants of SL-CoV S protein without deletions in their RBD can use human ACE2 as receptor for cell entry.** The Baric lab has a well-established hACE2 and DPP4 transgenic mouse model that **we used to assess the capacity of novel SARSr-CoVs and MERS-CoV to infect humans and cause disease (85, 99).** Infection of bat SARSr-SHC014 or WIV1 caused SARS-like clinical signs in the transgenic hACE2 mouse model **that weren't reduced by immune-therapeutic monoclonals that attenuate SARS-CoV pathogenicity, nor after challenge following vaccination against SARS-CoV (62) (Fig. 7).** We repeated

this virus characterization approach with chimeras using HKU3r-CoV S proteins that are ~25% divergent from SARS-CoV S, **and found that they are unable to use the ACE2 receptor.** Additionally, we were unable to culture HKU3r-CoVs in Vero E6, or human cell lines.

**Fig. 7:** Body weight change in hACE2 transgenic mice after SARSr-CoV infection, demonstrating that bat-origin SARSr-CoVs cause similar clinical signs to outbreak SARS-CoV strain (4231) (62, 63).

A similar approach to the above pipeline for CoVs will be applied to novel henipaviruses we discover during our research. The broad mammalian tropism of HeV and NiV (68) is likely mediated by their usage of highly conserved ephrin ligands for cell entry (19, 100). A third isolated henipavirus, Cedar virus does not cause pathogenesis in animal models. **Co-Is Broder and Laing** have developed a reverse genetics system and rescued a recombinant CedV to test ephrin receptor usage/tropism and pathogenicity during henipavirus infections (77). CedV is unable to use the Ephrin-B3 receptor (77, 101) which is found in spinal cord and may underlie NiV encephalitis (102) and that pathogenesis also involves virulence factors V and W proteins. The putative henipaviruses, Ghana virus and Mòjiāng virus, predict V and W protein expression, with GhV able to bind to ephrin-B2, but not -B2 (103), and the receptor for MoJV remains unknown (104) but is likely ephrin-B2 (105). Our group has also used similar methods to test the hypothesis that novel Filoviruses discovered in wildlife are able to infect people. NiV, EBOV and MERS-CoV all infect primary microvascular endothelial cells, which are available at Co-I Baric's lab for EID-SEARCH collaborators (71, 106). Primary human lung endothelial cells are highly susceptible to Ebolavirus infection (107), and Huh7 cells can be used to isolate virus from clinical samples (108) offering advantages for reverse genetic recovery of novel FVs (109). The three filovirus genera, *Ebolavirus*, *Marburgvirus* and *Cuevavirus*, use Niemann–Pick type C1 (NPC1) protein as cell entry receptor (110). For novel filoviruses, cell culture would be carried out under BSL-4, however they can readily be characterized following identification of their encoded GP sequences which can be pseudotyped into recombinant GP-bearing vesicular stomatitis virus (VSV) pseudovirions (111). These pseudovirions can be safely used to characterize the tropism and entry filoviruses mediated by GP without a need for BSL4 containment. **Co-Is Wang and Anderson** used cells originating from various mammalian species to determine spillover and/or zoonotic potential of MLAV, a newly discovered Asian filovirus (47). Despite the low amino acid sequence identity (22–39%) of the glycoprotein with other filoviruses, MLAV is capable of using NPC1 as entry receptor. Cells from humans, monkeys, dogs, hamsters and bats were able to be infected with a MLAV pseudovirus, implying a broad species cell tropism with a high risk of interspecies spillover transmission.

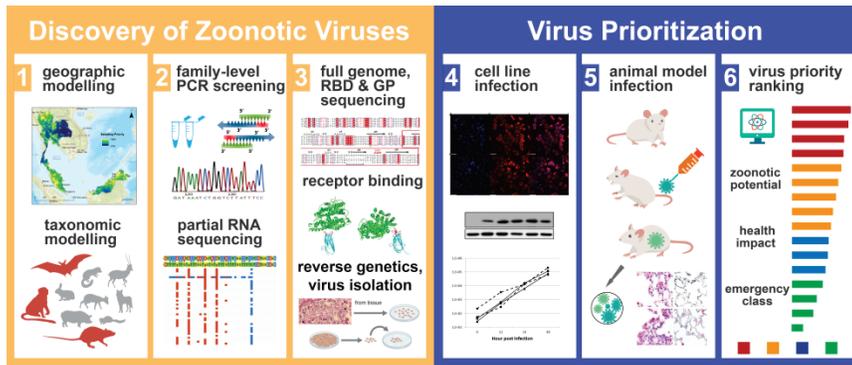

**Mouse models.** For novel viruses across all families, we will use the UNC collaborative cross mouse that captures 90% of the diversity within all mouse groups to assess the most suitable model for further experiments (112). We have used this model for CoV, FV (Ebola), Flaviviruses, and alphaviruses infections. Clinical signs such as weight loss, hemorrhage, encephalitis, and, acute or chronic arthritis were recapitulated in these mice following SARS, EBOV, West Nile virus and Chikungunya infections, respectively (86-88, 113-116). Note that CC OR3015 shows hemorrhagic disease phenotypes after EBOV infection (**Fig. 8**). **Bat Models.** Duke-NUS has developed two models for bat *in vivo* studies: a colony of *Eonycteris spelaea* (cave dwelling small fruit bat) and a bat mouse model, which contains the bat immune system in an immunodeficient mouse (117). In a proof of concept study, **Co-Is Wang and Anderson** infected *E. spelaea* bats with MERS-CoV to demonstrate their susceptibility and suitability for infection with a bat borne virus under BSL3 containment. These bats and the bat mouse model will serve to complement and expand studies from the UNC collaborative cross mouse, pending further funding from EIDRC CC.

Recombinant viruses, transgenic mouse models and experimental recombinant protein constructs described above will be made available to the EID-SEARCH consortium and other EIDRCs following standard procedures (**see Resource Sharing Plan**).

**Fig. 8:** EBOV Infection in Collaborative Cross Mouse. **Panel A/B:** Wt EBOV in two different CC lines demonstrate different disease patterns. **Panel C/D:** Hemorrhagic phenotypes on d. 6 (arrow) in spleen and liver, resp. From (86).

**1.3. General Approach:** We will conduct analyses to geographically- and taxonomically-target testing of samples from wild mammals that are most likely to harbor known high-profile zoonotic pathogens, or close relatives with potential to infect people. This includes selecting from tens of thousands of samples collected on recent projects and stored in freezers in our laboratories, and new sampling of wildlife in high risk locales. We will use viral family level PCR assays to identify and partially characterize viruses, then follow up sequencing of relevant receptor binding proteins to assess homology and predict binding affinity, then attempt to isolate and

biologically characterize viruses that phylogenetic and other data suggest have high spillover and pandemic potential. We will follow this with *in vitro* binding assays and cell culture experiments, and *in vivo* animal model infections to assess their potential to infect people and cause disease (**Fig. 9**). EHA will lead the study design, targeted sampling, and data analysis; Co-Is Hughes and Wacharapluesadee will lead field sampling and in-country testing; Duke-NUS, UNC, USUS will lead the serological and PCR diagnostic development and the *in vitro* and *in vivo* analyses, as well as cross-training and tech transfer to the hub labs in Thailand and Malaysia. This will include via support of one Malaysian Ph.D student, Mei-Ho Lee (CM Ltd.) who has worked with the EID-SEARCH collaborators for 9 years. The focus of her study will be infection potential of novel CoVs and PMVs already found in bats in Malaysia under preliminary data for this proposal.

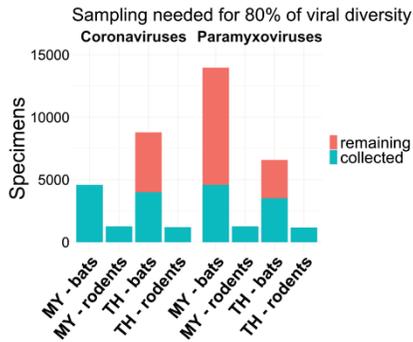

**Fig. 9:** Aim 1 will use analytical tools to target selection of archived and newly collected samples, conduct PCR and sequencing of novel viruses, recover by reverse genetics, and assess zoonotic potential using *in vitro* and *in vivo* models and analyses.

**1.4 Wildlife samples: 1.4.a. Geographic and taxonomic targeting for newly collected wildlife samples:** We will prioritize sites within each country that rank highest for both the risk of zoonotic

disease emergence (2) and the predicted number of 'missing' zoonotic viruses (3). Our preliminary analysis (**Fig. 1**) suggests priority areas include: the Kra Isthmus (S. Thailand) and adjacent forests in N. Peninsular Malaysia, NW Thailand (near the Myanmar-Laos border), and lowland rainforests of Sarawak and Sabah. In each of these 'hottest of the hotspots' regions, we will identify 2-4 distinct sampling sites based on the geographic distribution of key hosts we prioritize for additional wildlife sampling. We will priority rank bat, rodent, and NHP species using host trait-based models (3). We will also identify species predicted to be centers of evolutionary diversity for CoVs, PMVs, and FVs using ancestral host reconstruction of available sequence data and Bayesian discrete phylogeographic models (118-120). We will leverage our strong collaborations with wildlife experts in Malaysia and Thailand, including many of whom are based at our core partner institutions, to ground-truth geographic and taxonomic model outputs with local expert knowledge to ensure the sampling plan is realistic based on current species distributions, population size estimates, seasonality, and accessibility to sites. Most zoonotic viruses are naturally carried by multiple wildlife host species, and there are strong, predictable relations between host phylogeny and viral taxonomy (3). We will use a combined network analysis and phylogeographic model to rapidly predict and prioritize new (unsampled) hosts for important, novel viruses we discover during our research. We have shown this relatively simple model (using just wildlife species range overlap and phylogenetic similarity between host species) is both generalizable to estimate host range for all mammalian and avian viruses *and* robust – accurately predicting hosts 98% of the time when cross-validated using data from known viruses (121).

**1.4.b. Sample size justifications for testing new and archived wildlife specimens:** We calculate initial sample sizes targets using our preliminary data on average PCR prevalence from screening tens of thousands of bat, rodent and NHP specimens for CoV and PMVs based on previous studies in Malaysia and Thailand. We will refine these sample size targets, in real-time, over the course of our project using viral discovery curve analyses (**Fig. 6**) to either scale-up or scale-back new sampling and testing of archived specimens for each species depending on viral capture rates. We will only collect additional specimens projected from each prioritized taxa to achieve statistically robust sample sizes and to complement our archived specimens. For example, *Rousettus* spp. bats, known FV reservoirs, were not adequately sampled under PREDICT research in Thailand. Preliminary analysis indicates that, for all viral target families, we will require ~14,000 new samples to identify 80% of remaining viral species diversity in our study region, ~5,000 samples from Thailand and ~9,000 samples from Malaysia (**Fig. 10**). Viral strain diversity from a sampling effort this size is expected to number in the hundreds of strains. For example, given ~6% prevalence of CoVs in bat species previously sampled under the PREDICT project, a target of 14,000 individuals would yield ~800 PCR positive individuals,

representing, an estimated ~600 novel sequences/strains. Similarly, for PMVs, which have an average PCR detection prevalence of ~1.5%, sampling of 14,000 individuals would yield ~200 positives and an estimated 150 unique strains. Filovirus estimates are not feasible yet due to the small number of positive samples in prior

studies, but will be estimated as the project begins. From each mammal, we will collect serum, whole blood, throat swabs, urine and fecal samples or rectal swab using our previously-validated nondestructive methods. We will sample sites at different time-points throughout each year, and sample an equal number of males and females to account for seasonal or sex-specific differences viral shedding (**See Vertebrate Animals**) (122, 123). Dead or animals euthanized due to injury will be necropsied.

**Fig. 10:** Stacked bar plot showing number of currently-archived specimens (blue) and new specimens required (orange) to discover 80% of predicted number of CoVs and PMV species from high-risk bat and rodent taxa in Malaysia and Thailand.

**1.4.c. Sample collection, testing, viral isolation:** Wildlife will be captured and sampled using previously published techniques, by personnel wearing appropriate personal protective equipment (Tyvek suits or dedicated long external clothing, double nitrile gloves, leather gloves, an N95 or p100 respirator, and safety glasses) (53, 93, 95, 96, 122, 124). All samples will be placed in a vapor phase liquid nitrogen dry shipper immediately upon collection, and then transferred to a -80C freezer once back in the lab, until testing. Viral RNA will be extracted from bat fecal pellets/anal swabs. RNA will be aliquoted, and stored at -80C. PCR screening will be performed with pan-coronavirus (125, 126), filovirus (127) and paramyxovirus primers (128), in addition to virus specific primers where additional sensitivity is warranted in key viral reservoirs, i.e. Nipah virus or MERS virus specific primers (129, 130). PCR products will be gel purified and sequenced. We will attempt isolation on samples that contain viruses of interest (determined in **Aim 1.5 below**), using Vero cells and primary cell culture from the wildlife taxonomic order (bat, rodent and NHP cell lines). Over 70 bat cell lines are maintained at Duke-NUS from five different bat species. These include primary lung, brain, bone marrow, heart, kidney, intestine, liver, lymph node, muscle, spleen, PBMC and ovary/testes from *Eonycteris spelaea*, *Cynopterus bracyhotis*, *Rhinolophus Lepidus*, *Myotis muricola* and *Pteropus alecto* bats. In addition we have 8 immortalized cell lines, including those derived from lungs, therefore suitable for the isolation of respiratory viruses.

**1.4.d. Moving beyond RNA viruses:** To detect pathogens from other families, such as non-RNA viruses, we will combine conserved PCR assays with NGS. We will perform either unbiased NGS, or use a pan-viral enrichment library to sequence full-length genomes (131). We will conduct this work via EID-CC research projects or as part of outbreak detection/investigation in the region from DNA viruses or other agents.

**1.4.e. Sequencing Spike Glycoproteins:** Based on earlier studies, our working hypothesis is that zoonotic CoVs, FVs and henipaviruses encode receptor binding glycoproteins that elicit efficient infection of primary or continuous human cell lines (e.g., lung, liver, etc.) (16, 61, 62). Characterization these for SARSr-CoVs suggest that viruses up to 10%, but not 25%, different in the spike glycoprotein use human and bat ACE2 receptors for docking and entry. Uneven sampling gaps (e.g., no strains were found with 10-25% spike variation) prevent a thorough understanding of the transition point where the most divergent strains lose human ACE2 receptor usage. Our viral discovery curves (**Fig. 6**) suggest further sampling will reveal a rich diversity of as-yet-undiscovered SARSr-CoVs and strains of other viruses that fill in the phylogenetic tree between currently-described viruses. In this aim we will use phylogenetic and viral discovery analysis to specifically target bat species and regions that are under-sampled to allow sufficient power to identify and characterize missing strain diversity for potential zoonoses. We will sequence the S proteins of novel SARSr-CoVs to prioritize viruses for experimental work in Aim 3 to test this hypothesis. Likewise, we will test the hypothesis that phylogenetic related zoonotic receptor binding protein genes of MERS-related, Ebola-related and NiV/HeV-related viruses will also program efficient entry via human and ortholog receptors. For all novel virus strains, we will sequence the complete entry spike genes by amplifying overlapping fragments using degenerate primers as shown previously (24, 61). **Reverse Genetics:** Full-length genomes of selected CoVs, FVs or henipaviruses (representative across subclades) will be sequenced using NEBNext Ultra II DNA Library

Prep Kit for Illumina and sequenced on a MiSeq sequencer. PCR or Minlon sequencing will be performed to fill gaps in the genome. The full length spike gene sequences, including the amount of variation in the receptor binding residues that bind the appropriate human receptor will be used to select strains for Aim 3 experiments. We will sequence full length genomes of high risk strains that are antigenically distinct and escape SARS or MERS-CoV cross neutralization, synthetically reconstruct a small subset (1-2) and evaluate growth in Vero, BHK and Huh7 cells (63, 132). From full length sequences, synthetic clones will be ordered to recover recombinant viruses using reverse genetics as described by our groups (62, 63, 77, 109, 133, 134). Recombinant virus growth will be accessed in Vero, BHK, Huh7 and select bat cells and recovered viruses used for downstream studies. Virus strain prioritization is described below.

**1.5. Assessing risk for spillover. 1.5.a. Capacity to infect human cells:** We will use a series of cell cultures to assess the capacity of target viruses to enter human cells. For CoVs, FVs and henipaviruses, we will use primary human ciliated airway epithelial cells (HAE) and lung endothelial cell cultures derived from the lungs of de-identified transplant recipients. HAE are highly differentiated and grown on an air-liquid interface for several weeks prior to use (62, 63, 132). We will prepare HAE and lung endothelial cultures from three different patient codes in triplicate in collaboration with the tissue procurement facility at the Cystic Fibrosis Center at UNC. Cultures will be inoculated with chimeric bat SARSr-CoVs or novel FVs or henipaviruses to assess efficient replication. At 72 hpi, cultures will be fixed for immunofluorescent staining using antisera to the SARS-CoV conserved nucleocapsid protein (N) or to structural genes of the other viruses (64, 71). SARSr-CoVs that differ significantly in S protein sequence (11-24%) from epidemic SARS-CoV yet replicate *in vitro*, will also be evaluated for sensitivity to neutralization in Vero cells by PRNT50 assays using broadly SARS-CoV cross reactive human mAbs S227.14, S230.15, S215.17, and S109.8 (63, 135) or monoclonal antibodies targeting the Ebola or Marburg E glycoprotein (Available through BEI), or NiV/HeV glycoproteins (136). As controls or if antisera is not available, the S genes of novel SARSr-CoV or spike entry genes of other novel viruses under investigation will be inserted into VEE 3526 replicon vectors (VRP3526-S), packaged and used to vaccinate mice (137). Polyclonal sera against test bat-SARS virus or other spike genes will be harvested and tested for ability to cross neutralize SARS-CoV, GD03, WIV-1, SHC014, WIV-16, other novel SARSr-CoV and HKU3-SRBD by PRNT50 assay (63, 138, 139). Using PRNT50 titers with sera (n=4 each) among these viruses, antigenic cartography (140) will allow comparison of antigenic vs. phylogenetic distance, identifying the transition at which SARSr-CoV strains escape SARS-CoV based vaccines, informing immunotherapeutic and vaccine design strategies (141-143). Similar approaches will be applied to novel MERS-related viruses, other CoV, FVs or henipaviruses. While most wildlife-origin viruses with unknown transmission potential or pathogenicity in people uncategorized, we use BSL-3 for isolation as standard, and cell culture for potentially BSL-4 pathogens will be undertaken at collaborating institute NEIDL. To facilitate this, duplicate samples in culture medium from animals PCR +ve for FVs and very close relatives of NiV or HeV will be shipped to NEIDL (**See letter of support**) for culture, characterization and sharing with other approved agencies including NIH Rocky Mountain Laboratories where PI Daszak and Co-Is Baric have ongoing collaborations. Similarly, some duplicate samples of animals PCR +ve for CoVs will be shipped to UNC for further characterization by Co-I Baric. Where feasible and appropriate, training opportunities at NEIDL and UNC for in-country staff will be given, thereby enriching hands-on collaboration across sites.

**1.5.b. Host ACE2, DPPR, Niemann-Pick C1 (NPC1) and EphrinB2/EphrinB3 receptors:** We will sequence relevant host receptors for select mammalian wildlife species we find positive for strains of high-priority CoV clades, and all new henipaviruses and FVs. Of particular interest is homology across 18 bat and human orthologue ACE2 contact interface residues that engage the SARS RBD as a potential indicator of SARSr-CoV cross species transmission potential and growth in human cells (70). Likewise, variation in the NPC1 receptor has been shown to alter EBOV ability to infect in humans and bats, so this can be structurally mapped for prediction and downselection of strains (144). Signatures of positive selection in bat NPC1 were concentrated at the virus-receptor interface, with the strongest signal at the same residue that controls EBOV infection in *Eidolon helvum* cells. Thus NPC1 is a genetic determinant of FV susceptibility in bats, and some NPC1 variations likely reflect host adaptations to reduce FV replication and virulence (145). NiV and HeV use ephrin B2 or ephrin B3 as a receptor, and variation affects its ability to use human vs bat receptor molecules (103, 146).

**1.5.c. Host-virus evolution and predicting receptor binding:** We will use Bayesian and Maximum Likelihood phylogenetic analyses of RNA-dependent RNA polymerase (RdRp) sequences from PCR screening, receptor binding glycoproteins, and/or full genome sequence data (when available) to reconstruct the evolutionary history of the novel bat SARSr-CoVs, bat MERSr-CoV, FVs and henipaviruses that we identify. We will run co-phylogenetic analyses to map out instances of host-switching (147, 148) and ancestral state reconstruction analyses (Fig. 4) to identify the most important species for shaping evolutionary diversity for these viruses (51, 149), allowing for more targeted future surveillance and spillover mitigation interventions. For receptor binding glycoprotein sequence data from characterized viruses, we will apply codon usage analyses and codon adaptation indices, as used recently on henipaviruses (150), to assess the relative contributions of natural selection and mutation pressure in shaping host adaptation and host range.

**1.5.d. Viral strain prioritization:** Of the expected 100-200 novel SARSr-CoV strains, and approximately 600 total CoV strains, we will down-select to prioritize for further characterization based on S genes that are: i) different from SHC014, WIV1, SARS-CoV with diversity ranges of 10-25%; ii) have virus S RBD that could use human/bat receptors; iii) have recombinant chimeric spikes indicative of gene flow between clade I and II strains; iv) have bat ACE2 or DPP4 receptors that might select for spike RBDs that can use human receptors for entry (15/18 conserved residues in human/bat ACE2 molecules that bind SARSs-CoV S RBD domains are likely more efficient receptors than 3/18 conserved sites). Using structural models based on the SARS S glycoprotein, the extent and location of antigenic variation will be annotated onto the structure, further resolving the locations of highly evolving and conserved structural motifs/epitopes that function in protective immunity (135, 151-153). For novel henipaviruses, we will examine the receptor-binding proteins (e.g. envelope attachment (G) proteins) for sequence and structural homology with particular attention to conservation of amino acids that mediate ephrin receptor binding. We will prioritize strains that are predicted to interact with ephrin-B2 and expression V/W proteins to determine whether these viruses represent zoonotic threats. Using the recombinant Cedar virus (rCedV) platform, we will be able to rescue rCedV that express heterotypic G proteins to explore receptor utilization and tissue dissemination in animal models. We will assess ability to infect human cells using a continuous lung epithelial cell line, Calu3, which our group has previously used to generate data on NiV and HeV growth curves and a variety of host expression changes after infection (154). We will also use primary human airway cultures and microvascular endothelial cells to assess human infection for FVs, henipaviruses and MERSr- and SARSr-CoVs (155) (156). There is some evidence for NiV and HeV replication in mouse lung, low level titers in young animals, 10 fold higher titers in aged mice (157, 158). Thus it is likely these models could be improved in the collaborative cross mouse resource at UNC. We have identified CC lines that are highly vulnerable to wildtype SARS and others that develop hemorrhagic disease following mouse adapted Ebola infections (86-88).

**1.5.e. Animal models:** We will use transgenic mouse models and the UNC Collaborative Cross model to assess spillover potential of viruses. For work on CoVs, we will follow the protocols in the transgenic mouse model used by the Baric lab previously. Briefly, in the BSL3 lab, 10- to 20-week old hACE2 or hDPP4 transgenic mice will be intranasally inoculated with  $5 \times 10^4$  PFU of full length wildtype rbat CoV, or chimeric SARSr-CoV or MERSr-CoV encoding different bat CoV spike proteins respectively, then monitored daily for weight loss, morbidity, and clinical signs of disease. Mice will be euthanized at 2, 4, and 6 dpi (endpoint of 14 dpi), organs harvested and virus quantified by plaque assay or genome (mRNA1) RT-PCR. After 7 days in formalin, tissues for histopathology will be removed from the BSL3 and stained with H&E, and for immunohistochemistry using polyclonal antibodies against the N protein. We will conduct limited evaluation of existing countermeasures using therapeutic monoclonal antibodies *in vitro*. Existing SARSr-CoV or MERS-CoV mAbs (159, 160) will be diluted in DMEM starting at 1:20, and serial dilutions mixed with an equal volume of 50 PFU of chimeric bat SARSr-CoVs encoding different spike proteins and RFP indicator genes, then incubated on Vero E6 cells at 37°C for 1 h. Antibody neutralization titers will be evaluated by plaque quantification at 4-5dpi. In select instances, hACE2 transgenic mice will be injected with SARS-CoV mAbs, and infected with chimeric bat SARSr-CoVs. Clinical signs and morbidity will be assessed and tissue pathology examined and compared with mice without treatment of mAbs to determine the therapeutic effect on SARSr-CoV infection, and protection of SARSr-CoV by wildtype SARS-S based vaccines assessed as described (132, 161). We will sequence full length genomes of high risk strains that are antigenically distinct and escape SARS or MERS-

CoV cross neutralization, synthetically reconstruct a small subset (1-2), recover full length viruses and evaluate the ability of nucleoside analogues to inhibit growth in HAE cultures and/or *in vivo* (63, 132). For the Collaborative Cross model, we will infect six to eight mice from 6-8 Collaborative Cross mouse lines (10 weeks of age) with six test viruses/yr, intranasally or by subcutaneous infection with  $1 \times 10^4$  virus. Animals will be followed for weight loss, morbidity, mortality and other clinical disease symptoms (e.g., hunching, hindleg paralysis). One half the animals will be sacrificed at day 3 and day 7 pi. to evaluate virus growth in various organs, and organ pathology. In highly vulnerable lines, additional experiments will be performed using more animals, evaluating virus growth, clinical disease symptoms, respiratory pathology, tropism and organ pathology through day 28 pi. We anticipate that some CC lines will prove highly vulnerable to select wildtype viruses, because of host susceptibility combinations that promote severe disease outcomes.

**1.6. Potential problems/alternative approaches: Challenges with logistics or obtaining permission for wildlife sampling in sites we select.** We have a >20-year track record of successful field work in Malaysia, and >10 years in Thailand, and have strong established partnerships with local wildlife authorities and communities to ensure access. We have existing permissions in place which will be renewed at the start of this project. Due to the abundance of wildlife habitats in the region, if access to a site is withdrawn, we will rapidly identify a suitable, complementary site with similar bat species composition and abundance. Finally, we have already collected tens of thousands of wildlife samples from the region and will focus on these while waiting for permission. **We may not identify novel viruses in our sample wildlife species due to seasonality of viral shedding or other factors.** We have calculated sample sizes based on realistic detection rates from our extensive preliminary data, and are confident that we will detect and identify large numbers of potentially zoonotic pathogens, particularly for CoVs and PMVs. We acknowledge that FV strain diversity may be harder to capture, given relatively low seroprevalence in bat populations – suggesting lower levels of viral circulation (42, 43). However, our team was the first and only group to sequence FV RNA from Asian wildlife species (46, 47, 57), and we are confident that with our targeted sampling and testing strategy offers the best chance globally to identify additional strains of Ebola and related viruses. The sampling regions we have selected are subtropical, and our previous data, and even published studies in temperate regions (162), do not suggest a strong pattern of seasonality in CoV shedding, and where seasonal patterns do occur, i.e. for henipaviruses in Thailand (163), or can be predicted from wildlife serology data, we will be sure to conduct sampling at different timepoints throughout the year to account for this.

**Aim 2: Identify evidence and analyze risk factors for viral spillover in high-risk communities using novel serological assays.**

**2.1 Rationale/Innovation:** Rapid response requires early detection. Assessing the spillover of rare or novel zoonotic agents will require targeted surveillance of high-risk communities that interface frequently with wildlife that harbor high risk emerging viral strains. To enhance the low statistical probability of identifying these rare events, In Aim 2 we will target rural human communities inhabiting regions identified in Aim 1 as having high viral diversity in wildlife, that also engage in practices that increase the risk of spillover (e.g. hunting and butchering wildlife). We will initially identify 4 subsites in each of Thailand, Peninsular Malaysia, Sarawak, and Sabah for sampling. We will design and deploy human risk factor questionnaires, and specific and sensitive serological assays to identify the baseline frequency, and causes of, spillover of known and related novel viral pathogens in these populations. **We will use the results to test a key hypothesis: that hunting wildlife increases the risk of exposure to novel viruses, compared to the rest of the community.** The alternative hypothesis is that seroprevalence in the general community is not statistically different to those who hunt and butcher wildlife, because exposure to wildlife pathogens is largely through inhabiting a biodiverse landscape where wildlife make indirect contact with people (e.g. via fomites). For participants who report symptoms related to 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; 5) hemorrhagic fever; or 6) unusual presentation of high fever with severe diarrhea; all within the last 10 days, an additional sample type will be collected, two nasal or oropharyngeal swabs. Samples will be marked for additional PCR-based assays to identify presence of known and novel CoVs, henipaviruses and FVs, and for isolation and biological characterization of potential pathogens, using the approach laid out in Aim 1.

**2.2 Preliminary data on high-zoonotic risk human community surveillance: 2.2.a Biological sample collection in SE Asia:** Our long-term collaboration in the region has included qualitative and quantitative survey data, and collecting large archives of banked human sera and other biological samples from high zoonotic-risk populations. For example, under the USAID-PREDICT project, EHA has collected 1,400 and 678 specimens in Malaysia and Thailand respectively from people living in zoonotic disease interfaces, all of which will be available for retrospective serological testing by EID-SEARCH which we have ensured is compliant with our existing IRB. Our core group has collected and tested many thousand additional specimens from other important community cohorts (**Table 2**), and some of these will continue under EID-SEARCH (**Section 2.4**).

Country, site	Lead	# enrolled, focus	Findings
Peninsular Malaysia	Hughes	9,800+ samples, Orang Asli indigenous pop., for PCR/serol.	25+ novel CoVs, influenza, Nipah ab+ve, FV ab+ve
Malaysia Sabah	Kamruddin	1,283 for serology	40% JE, 5% ZIKV ab+ve
Malaysia Sabah	William	10,800 for zoonotic malaria study	High burden of macaque-origin malaria
Malaysia Sabah	Hughes	150 bat cave workers	Ongoing
Malaysia Sarawak	Siang	500 Bidayuh and Iban people	8% PCR prevalence HPV in women
Malaysia PREDICT	Hughes	1,400 high zoonotic-risk communities for viral PCR, serology	Ongoing. Multiple known and novel CoVs, PMVs, others.
Thailand	Wacharaplu-esadee	100s of bat guano harvesters/villagers	Novel HKU1-CoV assoc. clinical findings
Thailand PREDICT	Wacharaplu-esadee	678 high zoonotic-risk communities for viral PCR, serology	Ongoing. Multiple known and novel CoVs, PMVs, others.
Singapore	Wang	856, for Melaka virus	7-11% MELV ab+ve

**Table 2:** Biological sample collection from healthy populations conducted by members of **EID-SEARCH** in our hub countries.

Of particular interest is the access to indigenous communities in Peninsular Malaysia (Orang Asli) and Sarawak (Bidayuh, Iban people), and the bat guano harvesters in Thailand. These communities hunt, butcher and eat wildlife daily, and work in supremely high-risk zoonotic interfaces (e.g. bat caves). One of our indigenous community sites is experiencing an ongoing outbreak of unknown etiology that we are investigating currently (Section 3.2.a).

**2.2.b Human Contact Risk Factors:** EHA is the lead organization across all 27 USAID-PREDICT project countries for collecting data on, and analyzing the human aspects of, zoonotic spillover risk (164, 165). We conducted exploratory studies using standardized one-on-one semi-structured interviews and site observation data with people living in hotspot areas or engaged in high-zoonotic spillover risk activities, using these data to assess local social and cultural norms underlying wildlife contact (165). We then developed a risk factor survey to accompany human biological sampling to evaluate the type and frequency of animal contact, wildlife exposure in daily life, occupational risk in markets and long the wildlife value chain, and unusual illnesses reported over the past 12 months. We conducted cross-sectional studies in high risk populations in 27 countries, and study participants provided biological samples (oral/oropharyngeal swab, nasal/nasopharyngeal swab, urine sample/urogenital swab, fecal sample/rectal swab, whole blood, serum, plasma). For example, survey and biological samples were collected from: 1,585 participants from 7 sites in Yunnan, Guangxi, and Guangdong provinces, China; 1,400 participants from 4 sites in Malaysia; and 678 participants from 4 sites in Thailand. Samples were tested with novel serological assays and results analyzed against risk factors from survey data (16). In China, CoV-seropositive individuals were mostly farmers/peasants (8/9), living in Yunnan province (7/9), 41-60 yrs old (7/9), with domestic contact with rodents (6/9), that are male (6/9). Although these results are preliminary and don't provide detailed information on routes of exposure, they identify key subpopulations to target that would likely increase the opportunity for identifying evidence of spillover for other CoVs, PMVs and FVs. Data from PREDICT surveys have been used to help identify target populations in Aim 2, identify strategies to better target at-risk people, and conduct focused **human risk factor surveys and serosurveys to produce statistically significant findings for henipaviruses, CoVs and FVs.** In Aim 2, we will use combined biological sampling and risk factor surveillance in targeted populations within the community to 1) test the hypothesis that occupational (i.e. wildlife hunting) risk factors correlate with seropositivity to henipaviruses, FVs and CoVs; 2) assess possible health effects of infection in people; and 3) where recent

illness is reported, obtain biological samples for PCR testing and potential viral isolation and characterization. Obtaining this information could be a significant step in understanding the likelihood of recent 'hidden' spillover events and their public health impacts, as well as the risk of future emergence of viral disease.

**2.2.c. Risk factors for illness:** Our preliminary data in Thailand, Malaysia and other SE Asian countries revealed that frequent contact with wild (e.g. bats, rodents, NHPs) and domestic animals (e.g. poultry, swine) among local communities was associated with a high percentage of self-reported severe/acute respiratory illness (SARI/ARI) and Influenza-like illness (ILI) symptoms (**Section 3.2.b**). In addition, people involved in crop production, hunting and butchering of wildlife reported statistically significantly higher SARI and ILI symptoms (Li *et al.*, in prep.). **These preliminary data suggest a target population and sites for current proposal with the correct targets for serological surveillance and risk factor surveys in Aim 2 to produce statistically significant findings.** Coupled with better serological tools from our team (**Section 2.2.d**), we will be able to identify the likely routes of exposure to known or novel coronaviruses, henipaviruses, and FVs in the study region, as well as build data on the illnesses they cause in people.

**2.2.d. Serological platform development:** Most emerging viruses produced a short-lived viremia in people so that large sample sizes are required to provide enough PCR-positive individuals to analyze infection patterns. For Aim 2, we will focus on serological sampling in the community, because antibodies are typically long-lived and can be used to assess prior virus exposure or infection with much smaller sample sizes (123). Most serological assays target a single protein, and for emerging viruses, it's often unclear which viral antigen will be immunodominant during human infection, and therefore which to target in developing serological assays. Co-Is Wang, Anderson (Duke-NUS) and Broder, Laing (USUS) have developed a series of approaches to deal with this problem, and which will be used in testing human biological samples in Aims 2 and 3. Henipaviruses, FV and CoVs express envelope receptor-binding proteins that are the target of protective antibody responses. Co-I Broder has led efforts to express and purify henipavirus native-like virus surface proteins for immunoassay application (166, 167), developing monoclonal antibodies (168, 169) and as subunit vaccines (170, 171), has developed a novel, multiplex microsphere immunoassay (MMIA) allowing serum samples to be simultaneously tested for antibodies reactive with henipaviruses, FVs and CoVs. This MMIA uses a Luminex-based multiplex platform and custom designed virus receptor-binding proteins expressed in a mammalian cell-culture system and purified as native-like oligomeric proteins. These oligomeric antigens retain post-translational modifications and quaternary structures, allowing capture of conformational-dependent antibodies raised during a natural infection, which represent the majority of the protective humoral response. The known diversity of henipaviruses includes five presently described viruses, NiV, HeV, CedV, GhV and MojV and this assay has been expanded to include all described species (**Fig. 11**). In the past, our collaborators have used NiV and HeV G protein antigens in a MMIA assay to identify a serological footprint of NiV-related African henipaviruses and exposure to virus(es) antigenically-related to NiV in livestock sampled in Bangladesh (78, 79). To strengthen serological data interpretation, the G protein from each virus is integrated into the MMIA so that virus-specific vs. henipavirus cross-reactive antibodies can be detected and address specificity of past virus exposure. Extensive cross-reactivity exists among ebolaviruses and between ebolaviruses and marburgviruses (172-174). We are validating the MMIA pan-FV assay for specificity, and as part of this, in collaboration with Duke-NUS, we have found serological evidence of past exposure to a filovirus(es) most antigenically-related to ebolaviruses (e.g. Ebola virus, Bundibugyo virus), but unreactive with Reston virus GP in three under-sampled fruit bat species, suggesting that novel FVs circulate within bat hosts in SE Asia (43). **This platform has now been set up for use in Malaysia and Thailand and will be available for use in this proposed work.** Co-Is Hughes, Broder, Laing have conducted initial screening of human, wildlife and livestock samples at high-risk interfaces in Malaysia, finding serological evidence of past exposure to viruses antigenically-related to NiV and EBOV in humans, bats and non-human primates (NHPs).

**Fig. 11:** Validation of multiplex microsphere immunoassay (MMIA) specificity and identification of immunologically cross-reactive viruses for A) NiV B) EBOV.

Co-Is Wang and Anderson (Duke-NUS) have developed a phage-display method to screen antibodies for all known and related bat-borne viruses, including henipaviruses, FVs and CoVs and have set up a similar Luminex-based assay. Additionally the Duke-NUS team has demonstrated capacity for rapid and cost-effective development of LIPS serological assays against novel viral agents (**Sections 2.6.a, 3.2.a**). These will be used for verification and expanded surveillance. For molecular investigation (Aim 2 & 3), we will combine targeted PCR with a discovery-driven enrichment NGS strategy to not only survey currently known viruses, but also to discover potential novel viruses. Both the phage-display serological and enrichment platforms can be rapidly updated to include new viruses identified.

**2.3 General Approach/Innovation: Our human sampling approach uses two approaches in Aims 1 & 2 (Fig. 12). In Aim 2 we will conduct community-based surveillance using a brief, focused questionnaire to**

identify the prevalence and frequency of risk-factors for viral spillover in tandem with collection of high quality biological samples to determine the seroprevalence of spillover viruses in at-risk human populations. We will use generalized linear models to analyze correlation between biological results and risk-factors for viral spillover. **In Aim 3**, we will conduct clinic-based syndromic surveillance and biological sampling at clinics/hospitals that are the catchment healthcare facilities for the communities sampled in Aim 2. Both community-based and clinic-based syndromic surveillance programs are cross sectional case-control studies designed with the sample sizes necessary to statistically quantify (with a power of 80%) risk factors and health impacts for viral spillover, linked to serological status and PCR prevalence in symptomatic patients. All human sampling conducted under Aims 2 and 3 will adhere to strict criteria for inclusion and recruitment and protection of human subjects from research risk (**see Human Subjects and Clinical Trials Information**).

**Fig. 12:** Human sampling approach. Aim 2 (left) focuses on serology in high-risk communities to identify evidence of population exposure to novel zoonotic viruses. Aim 3 (right) sets up clinical cohorts at hospitals serving these high-risk communities to conduct syndromic surveillance and identify the etiology of new viral syndromes

**2.4 Target population & sample sizes:** We will target populations in the same geographic regions as those identified in Aim 1 that harbor wildlife with high potential zoonotic viral diversity, that are EID hotspots, and that are well-connected through regional travel and trade hubs to the global travel network (**Fig 13**). Within each geographic region we will identify populations at four sub-sites, building on our preliminary data (Table 2). We will target specific communities based on our analysis of previously collected behavioral questionnaire data, and other publicly available data (e.g. wildlife hunting licenses sold in a region, number of guano caves accessed for fertilizer etc.) to identify key at-risk populations and occupations with high exposure to wildlife. We will conduct concurrent sampling trips at visits to sub-sites during which members of the community will be enrolled and wildlife surveillance activities conducted. Individuals living or working around wildlife habitats (e.g. bat caves/roosts), who hunt wildlife, work with wildlife or livestock, or slaughtering wildlife will be considered for enrollment. Participants will complete a consent form and questionnaire in addition to having biological samples collected. During these community trips after data collection the field research staff will conduct community meetings to help inform the public health risk of zoonoses. **Target populations:** Thailand (Co-I Wacharapluesadee): 100 subjects of healthy high-risk community from 2 study sites, Chonburi (NiV, other PMVs and CoVs found by PCR in bats in our previous work), and Ratchaburi (bat guano harvester villages where we found a MERSr-CoV in bat guano (50, 175) and serological evidence of α-CoVs, HKU1-CoV in people (175)). Peninsular Malaysia (Co-I Hughes, CM Ltd.): We will expand our sampling of the Orang Asli indigenous communities to include sub-sites in communities in Districts we have already sampled and

additional Districts in the States of Kelantan Perak, Pahang, and Kelantan all close to bat caves. Samples will be stored and tested at NPHL. Sarawak (Co-I Tan, Fac. Med. Hlth. Sci. UNIMAS): We will expand our sampling of the Bidayuh and Iban indigenous people to include the Dayak and Orang Ulu (“people of the interior”) because this group has a more intimate connection to remote wildlife-rich areas than the other two, albeit all are hunters. Human sampling will be led by UniMAS in collaboration with CM Ltd / EHA. Sabah: We will conduct sampling at the Madai bat and bird cave that has 200 permanent residents who harvest bird’s nests for soup, and >1,000 during the harvesting season and at Gomantong cave – one of the largest bat and cave swiftlet nesting sites in the world. Sabah: (Co-I Hughes): We will conduct sampling at the Madai bat and bird cave that has 200 permanent residents who harvest bird’s nests for soup, and >1,000 during the harvesting season and at Gomantong cave – one of the largest bat and cave swiftlet nesting sites in the world. Protocols follow those for Peninsular Malaysia Singapore: (Co-I Wang, Duke-NUS): Active human surveillance will be not be conducted in Singapore, but archived human specimens e.g. from our Melaka virus serosurvey (8), will be made available to conduct retrospective serosurveys for specific pathogens that are identified as high interest to the EIDRC, NIH, and EID-CC.

**Fig. 13:** Targeting high-risk sites for human zoonotic disease surveillance in Thailand and Malaysia. This map plots areas with high numbers of expected viruses in wildlife (3), greater spillover probability based on EID risk factors (2), and higher levels of connectivity (measured by road density data) that may facilitate person-person spread.

**Sample sizes:** From our previous work we conservatively anticipate that 10-30% of the community population will have had exposure to wildlife allowing us to capture highly exposed and non-exposure individuals at each site. Individuals living or working around wildlife habitats (e.g. bat caves/roosts), who hunt wildlife, work with wildlife or livestock farming, transportation, selling, or slaughtering wildlife in the surveyed areas will be targeted so that they make

up  $\geq 30\%$  of the sampled population in each community. We will stratify sampling to ensure appropriate representation of sex, demographic, and socio-economic factors at each community site. In each of our regions, we will conduct sampling at four sub-sites in populations with high prevalence of high occupational and environmental risk of exposure to wildlife populations, sampling 175 persons at each sub-site. We will target populations with, on average, 30% or higher prevalence of occupational or environmental exposures to wildlife based on data from previous studies. This design will give us >80% power to detect 5 percentage point differences in seroprevalence against any of our viral groups between baseline and high-risk subgroups. We conservatively assume 5% base seroprevalence, as well as assuming high spatio-temporal variance amongst sub-sites, with baseline varying 0-25% amongst sub-sites and the fraction of the population at risk varying from 20-40%. (Power calculation conducted by 500 simulations of a generalized linear mixed model (GLMM)). For community-based surveillance, we will enroll 700 individuals per study region, allowing us to make county/province-level comparisons of differing effects; the total sample will be 3,500 participants over 5 years.

**2.5 Data & sample collection:** Following enrollment, biological specimens (5mL will be drawn for whole blood and serum collection, samples will be aliquoted, at least one max 500  $\mu$ L of whole blood and two 500  $\mu$ L serum samples) will be collected by locally certified healthcare professional proficient in phlebotomy techniques and a short questionnaire will be administered by trained project staff that speak appropriate local language to all participants. Through the serological findings and the survey we will investigate the details of five risk factors related to high risk wildlife exposure, to maximize the power of the analyses, based on continuing analysis of our previous work, and will focus on: 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, in/around house; 3) proximity of residence or work place to environments of increased risks, e.g. nearby bat roosts; 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms in the past 12mo and lifetime. For participants who report the symptoms relating to 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; or 5) hemorrhagic fever within the last 10 days, an additional sample type will be collected, nasal or oropharyngeal swab (2x). Blood of participants whose serum tests positive for emerging viral pathogens will be taken and Peripheral Blood Mononuclear Cells (PBMCs) frozen for future use.

These will be used for future harvesting of polyclonal and monoclonal antibodies as potential therapeutics/diagnostics (**see Letter of Support NEIDL**).

**2.6: Laboratory analysis: 2.6.a Serological testing:** We will screen all human specimens for henipaviruses, FVs and CoVs using our novel, multiplex microsphere immunoassay (MMIA) (**Section 2.2.d**). We will use ELISA and serum neutralization tests (SNT) as confirmatory, where feasible and appropriate for the biocontainment level given sensitivity and specificity variation, and the need for live virus for SNTs (**See Select Agent Research**). Serologic evidence of local spillover will be used to prioritize zoonotic strains for recombinant virus recovery from full length sequences. Preliminary data suggest ELISA will be effective for some viral groups. We previously developed a SARSr-CoV specific ELISA for serosurveillance using the purified NP of a bat SARSr-CoV (Rp3). The specificity of this assay was evaluated using polyclonal antibodies against HKU1, OC43, 229E, NL63, MERS-CoV and EBOV and no significant cross-activity detected (16). **This suggests that if we can expand our NP serology tests to cover other bat CoVs, and that doing so may identify many more seropositive individuals.** For CoVs, we will therefore use two serological testing approaches: 1) testing human sera collected from both community- and clinic- based sampling for a panel of bat CoVs that will include SARS-CoV, MERS-CoV, SADS-CoV and a range of bat SARSr-CoVs (16); 2) testing for antibodies to common human CoVs (HCoV NL63, OC43 – **Section 2.8**). We will test panels of NP and G recombinant proteins to assess if this approach will act as a comparison to MMIA for FVs and PMVs.

**2.6.b RT-PCR testing.** Specimens from individuals in the community who reported being symptomatic within the last 10 days (**Section 2.5**) will be screened using RT-PCR initially for CoVs, PMVs, and FVs following published protocols (**Section 1.4.c**). Positive samples will be subjected to full genome sequencing and RT-PCR amplification of the glycoprotein genes. Samples from the clinic-based syndromic surveillance will also be tested using RT-PCR for Influenza A & B, HCoV NL63, OC43, HKU1, SARS-CoV & 229E, NiV, HeV, Ebola (WHO PCR protocol) based on the symptom as rule-outs.

**2.6.c Biological characterization of viruses identified:** Novel viruses identified in humans will be recovered by cultivation or viruses re-derived from full length genome sequences using reverse genetic approaches. Viruses will be characterized for growth in primary human cell lines and in mouse models, including the Collaborative Cross Mice or humanized mice expressing human receptors from related strains. The approaches are discussed in more detail under Aim 1.

**2.7 Epidemiological analysis:** We will conduct a cross sectional case-control study to identify risk factors for Henipavirus, FVs, and CoVs spillover. “Cases” are defined as participants whose samples tested positive for Henipavirus, FVs, or CoVs by serological tests. “Controls” will be selected from the pool of participants admitted to the studies and whose samples tested negative for Henipavirus, FVs, or CoVs. We will use nearest neighbor matching to pair cases demographically (e.g. age, sex, location) with controls at a 1-to-3 ratio or greater. We will use generalized linear models and least absolute shrinkage and selection operator (LASSO) regression analyses (176) to analyze correlation between biological results, serological/PCR status, and risk factors related to high risk wildlife exposure including: 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, in/around house; 3) home or work proximity to environments of increased risks, e.g. nearby bat roosts; 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms lifetime and past 12mo. Additionally, we will use this procedure to determine how clinical presentation differs between Henipavirus, FVs, or CoVs in exposed and unexposed participants, as well as in the time course of illness, severity of symptoms, and type of symptoms.

**2.8 Potential problems/alternative approaches: Rarity of spillover events** means it may be difficult to identify sufficient seropositives to statistically analyze human risk profiles. First, we will be targeting our community-based surveillance to subpopulations with high-levels of wildlife exposure, at sites selected for diverse and prevalent viruses to increase likelihood of finding positive individuals. Second, our serology testing will include a multi-plex panel of assays for a large diversity of viruses, increasing likelihood of positives. For example, in previous work our overall bat CoV PCR prevalence in the community was, 11.8%;  $\beta$ -CoV, 3.4%;  $\alpha$ -CoV, 9.1%). Thus, using this broad serological panel to screen individuals prone to contact with species of higher zoonotic risk increases the potential for detecting spillover with enough power for statistical analyses,

and will shed light on behaviors that predispose to spillover. Third, we will include common human CoVs, PMVs, and influenza viruses in our panel, so that even if low prevalence of wildlife viruses is found, we will be able to conduct a valuable cross-sectional study of the seroprevalence of more common human viruses. Finally, we will be able to assess relative measures of human-wildlife contact from our survey work. We will analyze intensity of contact with high-risk taxa against other risk factors to provide useful proxy information for spillover risk. **Serological testing may be difficult to interpret in the presence of known and novel viruses.** We will use the three-tiered serological testing system outline in **2.6.a** to try to identify exposure to these ‘novel’ viruses. However, we know exposure to a range of related viruses generates antisera that are cross-reactive with known, related virus antigens - a serious challenge to serological surveillance and diagnostics. Our collaborations have already demonstrated that SE Asia bat sera samples screened with our pan-filovirus MMIA have been exposed to an Ebola-like virus, that is antigenically-distinct from known Asiatic filoviruses, Reston virus and Měnglà virus (43). Using these three serological platforms we will address inherent challenges of indirect virus surveillance through antibody capture by testing multiple binding assay platforms and antigens, using positive control samples to establish serological profiles against known viruses that will aid in our interpretations of cross-reactive antisera responses likely representative of ‘novel’ viruses.

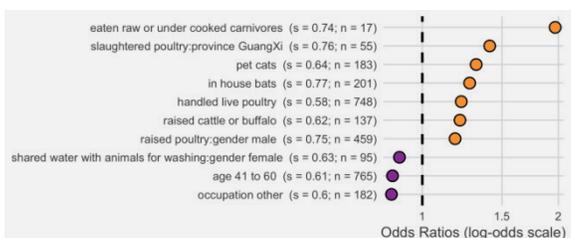

### **Aim 3: Identify and characterize viral etiology of ‘cryptic’ outbreaks in clinical cohorts.**

**3.1 Rationale/Innovation:** Our previous research (**Table 1**) and other data suggests that there are substantial numbers of outbreaks or clinical cases for which the etiologic agent is not diagnosed, e.g. (177, 178). To investigate this in SE. Asia, we have assembled a multi-disciplinary team that includes senior infectious disease doctors and clinicians and will work directly with local clinics and regional hospitals to identify the ‘cryptic’ outbreaks or cases that occur in the region. **In Aim 2, we will conduct serology in high zoonotic-risk communities to find evidence of prior exposure in people**, i.e. evidence of viral spillover into the community. In Aim 3 we identify members of these communities presenting at clinic with undiagnosed illness that may have high-impact zoonotic viral etiology. **Therefore, in Aim 3 we focus on PCR to identify the putative viruses that are replicating in these actively-infected patients (Fig. 12).** We will enroll, and collect high quality biological samples from patients who live in rural communities linked to Aim 2 and who present at regional clinics or hospitals with symptoms typical of high impact zoonotic viruses. We will collect detailed survey data to assess their contact type and frequency with wildlife and livestock and conduct molecular and serological diagnostic assays to test causal links between their syndromes and the known and novel viral agents identified in Aim 1. We will conduct molecular viral discovery assays on patients who present with symptoms indicative of a high-risk zoonotic virus. If novel pathogens are identified by PCR, we will attempt to isolate, obtain full genome sequence and/or biologically characterize the wildtype or molecularly re-derived pathogen, using the *in vitro* and *in vivo* strategy laid out in Aim 1.

**3.2 Preliminary data clinical surveillance: 3.2.a. Clinical surveys and outbreak investigations:** Our longterm collaboration in the region has included the following activities investigating clinical syndromes: **Peninsular Malaysia: At the time of writing, an outbreak of suspected undiagnosed viral illness in the indigenous Batek Orang Asli (“people of the forest”) community living at Gua Musang (“civet cat cave”) district, in Kelantan, Malaysia, close to Taman Negara – a National Park containing the oldest known rainforest. This community is one where we have conducted prior routine surveillance and biological sampling, demonstrating proof-of-concept that our two-pronged high-risk community/clinic approach will work.** Dozens of people are affected and the outbreak is currently being investigated by our group in collaboration with the Malaysian NPHL. The Orang Asli continue to practice traditional subsistence hunting of wild animals (bats, rodents, primates). These communities are remotely located, in heavily forested areas, with limited access to medical services. **This outbreak, and others that will continue to emerge just like it, underscore the critical need for our EIDRC - to improve the technological tools, training, and human capacity for rapid EID surveillance, diagnosis, and response at the frontlines of disease emergence in SE Asia. Investigating this outbreak is a key priority if EID-SEARCH is funded.** **Sabah:** Co-I Kamruddin (BMHRC) is leading an asymptomatic leptospirosis study on sanitation workers, an ILI study in a Kota Kinabalu clinic and diarrheal study in children under 5 yrs. Co-Is William, Tan and others have conducted clinical observational studies to determine the etiology of central nervous system infections and acute undifferentiated febrile illness in Sabah.

Co-Is William and consultant Yeo have collaborated with Co-I Wang to enroll 90 adult and over 100 pediatric participants with central nervous system infections, negative tests for malaria and dengue from 3 district hospitals in Sabah to determine the various etiologies. While a proportion tested positive for rickettsial agents, the majority had no clear diagnosis. Co-Is William, Rajahram, and Yeo have conducted clinical studies of over 200 inpatients with acute febrile illness with negative tests for malaria and dengue from 3 district hospitals in Sabah to determine the various etiologies. While a high proportion tested positive for rickettsial agents, the majority had no clear diagnosis. **Sarawak:** Co-I Siang (UNIMAS) is conducting a survey of high-risk female Kelabit indigenous people and has found 8% with HPV52 as the dominant strain. He is working on clinical cohorts of hand, foot and mouth disease and will recruit patients from that study in the current proposed work. Finally, Co-Is Siang, Kamruddin are conducting a long-term study of rotavirus and other viral etiologies of acute gastroenteritis in Kuching, Sarawak that will include swine herders and farmers. The Baric lab is a global leader in norovirus VLP diagnostic reagents to detect serologic evidence of norovirus gastroenteritis, as well as RT-PCR detection of novel noroviruses in humans, and has identified novel bat noroviruses, suggesting further opportunities for expansion of this work (142, 179-181). This work is particularly relevant in Malaysia because pig farms are shunned by the government and local villagers to they are placed far away from town centers, deep in the forest, and it is this scenario that led to the emergence of Nipah virus in 1998-9 (6, 22). **Thailand:** Co-Is Hemachudha, Wacharapluesdee (TRC-EID, Chulalongkorn Univ. Hosp.) work in coordination with the Thailand Ministry of Health to investigate outbreak etiology, including the first case of imported MERS-CoV in Thailand, **for which we produced sequence confirmation within 24 hours from acquiring the specimen.** Three imported MERS cases have been detected in Thailand since 2015, and all cases were confirmed at the TRC-EID. We worked during the Zika outbreak to identify > 500 PCR-positive Zika patients with sequence confirmation. We have also worked on returning and suspected Ebola travelers, syndromic surveillance for SARI, encephalitis, Hand Foot and Mouth disease in children and viral diarrhea. Consultant Hickey (US CDC, Thailand), screened specimens collected between 1998 and 2002 from a large cohort of children from Kamphaeng Phet Province to examine Dengue virus and JE epidemiology (182, 183). Among the 784/2,574 convalescent sera henipavirus-specific antibodies were detected in 13 serum samples (1.7% seroprevalence), suggesting prior exposure to endemic henipaviruses or a related PMV in rural Thailand. **Singapore:** Duke-NUS has worked with the Ministry of Health to investigate Zika cases (184), and other EIDs. With EHA and others, Duke-NUS has developed novel CoV assays for clinical surveillance, and for expedited analysis during outbreaks. Our pipeline of novel virus detection, reservoir host identification, serological assay development, and serological testing is as rapid as several months, with the development of novel serological assays from sequence data in 7 days (17). **For example, with the discovery of SADS-CoV, we identified and fully sequenced a new virus, screened archived wildlife specimens to identify the natural reservoir host species (*Rhinolophus* spp. bats), developed LIPS serological assays, and tested human and swine samples to assess seroprevalence in less than 3 months (17).**

**3.2.b Analysis of self-reported illness:** We have developed a standardized approach for analyzing data from study participants on self-reported symptoms related to target illnesses: fever with cough and shortness of breath or difficulty breathing (severe acute respiratory illness - SARI); fever with muscle aches (fevers of unknown origin (FUO)); and, cough or sore throat (influenza-like illness - ILI). For all of our prior human clinical surveillance in 20+ countries, including in Malaysia and Thailand, we used a least absolute shrinkage and selection operator (LASSO) regression to identify associations between participants who reported ILI and/or

SARI symptoms and demographics, occupation, and contact with animals in the last year. Results have clear biological relevance. For example, in Yunnan, China, factors strongly associated with prior disease involve animal hunting and consumption (Fig. 14). We will expand this approach for all clinical syndromes in Aim 3, and use targeted questions to assess patient's exposure to wildlife in terms that are relevant to each specific country.

**Fig. 14:** Factors associated with self-reported ILI & SARI in prior 12 months (s = bootstrap support; n = #+ve out of 1,585 respondents). **Orange circles** = odds ratios > 1 (+ve association); **purple** = odds ratios < 1 (-ve association).

**3.3 General Approach:** Our previous research suggests that there are substantial numbers of outbreak cases for which the etiologic agent has not been identified. To capture these, we will expand on our current syndromic surveillance to enroll, and collect high quality biological samples from patients who present at regional clinics and live in rural communities linked to Aim 2. Case definitions and enrollment criteria include: 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; 5) hemorrhagic fever; or 6) high fever/diarrhea with unusual presentation. We will collect survey data to assess contact with wildlife, and occupational and environmental exposures, conduct molecular and serological assays to test causal links between their syndromes and the known and novel viral agents identified in Aim 1. If novel pathogens are identified by PCR, we will attempt to isolate and biologically characterize the pathogen, using the collaborative cross to identify an appropriate animal model to conduct preliminary pathogenesis work. We will then use behavioral survey data, ecological and phylogeographic analyses to assess the likely reservoir hosts to inform intervention programs.

**3.4 Clinical cohorts. 3.4.a Cohort selection:** We will initiate active clinic-based syndromic surveillance at 2 town-level level clinics and 2 provincial-level hospitals in each Thailand, Peninsular Malaysia, Sabah and Sarawak. These serve as the catchment healthcare facilities for people in our community-based surveillance of Aim 2 and are inclusive of wildlife sampling sites in Aim 1. Patients  $\geq 12$  years old presenting at the health facility who meet the syndromic and clinical case definitions above will be recruited into the study after completing a consent form. We will aim to enroll 300 participants per hospital, with that we will have a 95% probability of detecting live virus in patients in each hospital assuming a population prevalence of 1%. This sampling effort will total of 4,800 individuals for clinical syndromic surveillance. We assume up to 40% loss from follow-up, therefore yielding 2880 participants that will be available for follow-up blood sampling (**Section 3.4.b**). While enrollment is limited by the number of patients that come to the healthcare facility presenting with relevant clinical symptoms, in our work in the PREDICT project we enrolled an average of 100 participants per year, so we are confident this is an achievable enrollment target. Study data will be pooled across country regions, as clinical patients are limited by the number of individuals presenting at hospitals. “Cases” will be determined as participants whose samples tested positive for either CoVs, henipavirus, or FVs, PCR tests. “Controls” will be selected from the pool of participants admitted to the studies and whose samples tested negative. We will use nearest neighbor matching to pair cases demographically (e.g. age, sex, location) with controls at a 1-to-3 ratio or greater. Sites: Thailand: We will work with two primary hospital, Phanat Nikhom Hosp., Chonburi district (Key Pers. Dr. P. Hemachudha) & Photharam Hosp., Ratchaburi Province, and a large tertiary hospital, King Chulalongkorn Memorial Hospital, Bangkok Thailand (Co-I Dr. T. Hemachudha). Peninsular Malaysia: **Focusing immediately on the current outbreak in Orang Asli, we will work closely with the Malaysian Ministry of Health to support their investigation, and with 6 Orang Asli clinics which focus solely on this indigenous community.** Co-I Sellaran (Lintang Clinic, Kuala Kangsar) refers patients to Sungai Siput Hospital and Gen. Hospital, Ipoh. Key Pers. I Lotfi (Pos Betau clinic, Kuala Lipis) will continue collaboration with Co-I Hughes in the communities at that site. Sarawak: Key Pers. Diyana (Director, Bario Clinic) refers patients to Miri Hospital (Co-I Utap) and serves people from the Kelabit, and nomadic tribes in the region, as well as populations within a number of large towns. Sabah: We will continue our collaboration with Queen Elizabeth Hospital, QEH (Key Pers. Lee, Rajahram) and Hospital University Malaysia Sabah, HUMS (Co-I Lasimbang, Director). Both clinics include our targeted sites for **Aim 2** in their catchment, and both have ongoing collaboration with the Borneo Medical Health Ctr (Co-I Kamruddin, Director). Singapore: Currently, there are no plans to conduct clinic surveillance based on budget constraints. However, in the event that that is an evolving need for clinic surveillance, enrollment, and sampling, we have close working relationships with all hospitals in the country, and the central infectious disease reference lab (key clinicians at which are aware of our proposal). This would allow us to rapidly on-board a hospital based site.

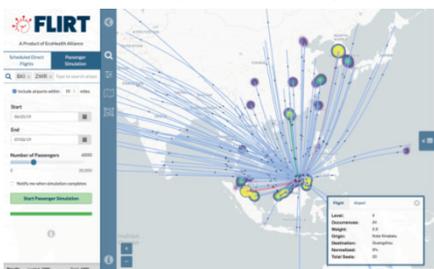

**3.4.b Clinic enrollment and follow-up:** We will recruit inpatients and outpatients to participate in the study after initial screening to determine if they meet our clinical case definitions. Once consented and enrolled, biological samples will be collected by trained and locally certified hospital staff and a questionnaire administered by trained hospital or research staff that speak appropriate local language. Every effort will be made to take samples concurrently when collecting samples for normative diagnostics. For both inpatients and outpatients, samples will be collected no more than 10 days of reported onset of illness to increase the chance

of PCR detection of viruses (185). Where possible, we will follow up 35 days after enrollment to collect an additional two 500  $\mu$ L serum samples conduct a standardized questionnaire supplement to collect additional data on the course of symptoms in the interim period. This gives adequate time for development of IgG, which occurs <28 days after onset of symptoms for SARS patients (186-188). Serum samples will be used to screen panels of high risk human and local zoonotic Filovirus, Henipavirus and Coronavirus strains as described in Aim 2. These samples may prove valuable to collaborators in that the PBMC could be used in production of therapeutic antibodies.

**3.4.c Sampling and clinical interview:** Biological specimens whole blood (5mL will be drawn for whole blood and serum collection, samples will be aliquoted, at least one max. 500  $\mu$ L whole blood; two 500  $\mu$ L serum samples) and two nasal or oropharyngeal swabs will be collected from all participants, and a questionnaire will be administered. We will investigate five risk factors, to maximize the power of the analyses, all related to high risk wildlife exposure, based on continuing analysis of our previous work, and will include: 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, in/around house; 3) proximity of residence or work place to environments of increased risks, e.g. nearby bat roosts; 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms in the past 12mo and lifetime. With additional consent considerations for participants enrolled from clinical settings, we will review clinical records to collect data on medical history, clinical syndromes, and patient etiology. Blood will be taken for future harvesting of Peripheral Blood Mononuclear Cells (PBMCs), as per **Section 2.5**.

**3.5 Sample testing:** The standard syndromic diagnostic PCR assays for common pathogens will be conducted and the results will be shared with the hospital with 48 hours. Specimens will be further tested for 3 viral families; CoV, PMV and filovirus by consensus PCR (**Section 1.4.c**). Necropsy samples from deceased patients will be further characterized by NGS if previous PCRs are negative and unable to identify the cause of infection. Co-Is Wang, Anderson will conduct a VirScan serological assay using paired serum samples at Duke-NUS that identifies antibodies with a four-fold rise in titer in the convalescent sample compared with the acute sample, thereby indicating a possible etiological agent. A PCR test with the specific primer from each virus antibody positive case will be further tested from acute specimens to confirm infection.

**3.6 Viral risk characterization and potential for pandemic spread:** We will use statistical models built from collated biological, ecological, and genetic data to assess the likelihood of pathogenicity for the range of diverse viruses we will characterize. The aim is to quickly identify and assess which viruses pose the most significant risk to human health and thus prioritize additional resources to more fully characterize, better understand pathogenicity, and invest in our animal model pipeline and ultimately therapeutic development for those pathogens. We will combine two independent but related statistical models to predict pathogen spillover risk and pathogenicity. First, we will expand a simple generalized additive modeling approach (3) to assess spillover risk probability to a new virus that is currently not known to infect people, when we have only limited genetic data from initial PCR screening and sequencing. Additional data from receptor binding protein homology and cell line infection experiments will be incorporated into the model framework as available. Second, given high likelihood to spillover and infect humans, or direct evidence of human infection from our clinical surveillance, we will then assess the likelihood of pathogenicity based on traits for phylogenetically related nearest neighbor viruses as a first approximation and incorporating more detailed data from genomic characterization and animal model experiments (Aim 1). Epidemiological trait data for ~300 viral species known to infect people (e.g. case fatality rate, global estimates of number of human cases per year or decade,  $R_0$ , infectious period, and primary symptoms) have been collated by recent studies and will be used as predictor variables (189). Thirdly, we will apply tools already developed, and being refined by EHA under DTRA and DHS supported research, to predict pandemic spread for viruses using global flight models, as well as additional datasets on human movement and connectivity across Southeast Asia (90, 91) (**Fig. 15**).

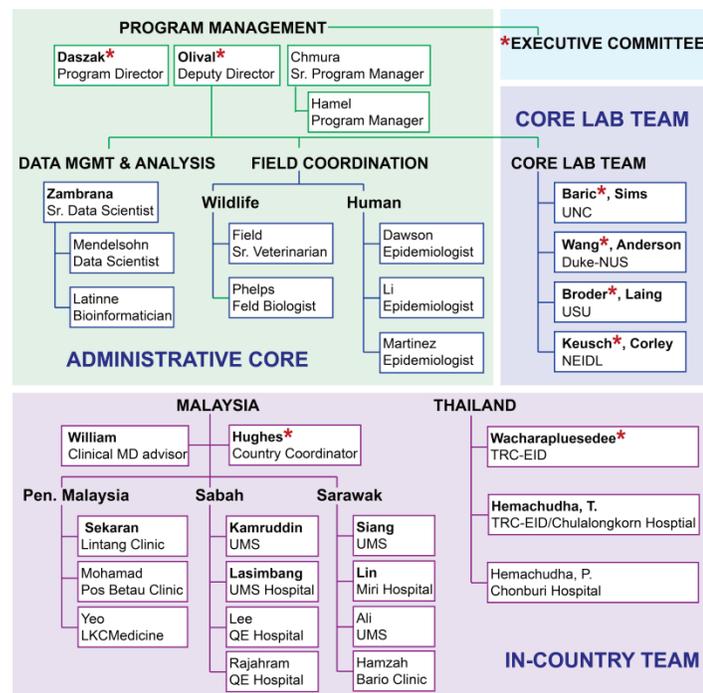

**Fig. 15:** Probability feed from EHA's Flight Risk Tracker tool (FLIRT). This image is of the likely pathways of spread and establishment for a Nipah-like virus emerging from Sabah, based on human movement and airline flight data (90, 91).

**3.7 Potential problems/alternative approaches: Patients visiting clinics may have cleared virus, but not yet developed IgG antibodies, reducing seropositive cases.** Our 35 day follow-up sampling should account for this because the maximum lag time between SARS infection and IgG development is ~28 days and Ebola virus infection and IgG approximately 20 days (185-188, 190). We also expect that patients in rural communities will only visit clinics when symptoms have progressed, likely coinciding with late illness and onset of IgG. We will also have data from our community study that can be analyzed in conjunction with, or in the absence of, clinical data from the hospital data to identify PCR- or seropositives. Finally, the risk of limited detection is outweighed by the potential public health importance of discovering active spillover of new henipaviruses, FVs or CoVs infection.

#### 4. Administrative Plan

**4.1. Project management: 4.1.a. Administrative core:** The EID-SEARCH organizational partner roles are laid out by Specific Aim above (see Fig. 3). EcoHealth Alliance (EHA) will lead the administrative core of the EID-SEARCH, including: coordination and management of all human and animal research; communication with consortium partners, NIH, other EIDRCs, and the EIDRC-CC; data management and quality assurance; modeling and analysis; and compliance with all US, international, and institutional rules and regulations. The administration will be led by PI Daszak, who has >20 years' experience managing international research collaborations on emerging zoonoses, and has collaborated with all partners in the EIDRC consortium for 5-20 yrs on NIAID- and USAID-funded research (Fig. 16). He also has direct experience as one of two external reviewers of one of the CEIRS partners for NIAID (Program officer Diane Post). PI Daszak will be assisted by Deputy Lead, co-I Olival, who has overseen zoonotic disease research in Southeast Asia for >10 years and working directly with our partners in Thailand and Malaysia for 15 years. Senior program manager (Chmura) and full-time program assistant (Hamel) will provide administrative support. The EID-SEARCH data management, epidemiological analysis, and modeling activities will be led by co-Is Olival and Zambrana who have led all modeling and analytics on USAID USAID PREDICT for the last 10 years. They will oversee a programmer/data scientist (Mendelsohn), evolutionary biologist/bioinformatician (Latinne), and human epidemiologists (Dawson, Li, Martinez). Our human epidemiology team will work directly with country teams in Malaysia and Thailand to manage human surveillance, IRB applications and approvals, and ensure compliance with all human subjects work. EHA's senior veterinarian (Field) and wildlife field biologist (Phelps) have extensive experience working that bats, rodents, and primates in SE Asia and will coordinate all training and field research in Malaysia and Thailand and ensure compliance with IACUCs.

and full-time program assistant (Hamel) will provide administrative support. The EID-SEARCH data management, epidemiological analysis, and modeling activities will be led by co-Is Olival and Zambrana who have led all modeling and analytics on USAID USAID PREDICT for the last 10 years. They will oversee a programmer/data scientist (Mendelsohn), evolutionary biologist/bioinformatician (Latinne), and human epidemiologists (Dawson, Li, Martinez). Our human epidemiology team will work directly with country teams in Malaysia and Thailand to manage human surveillance, IRB applications and approvals, and ensure compliance with all human subjects work. EHA's senior veterinarian (Field) and wildlife field biologist (Phelps) have extensive experience working that bats, rodents, and primates in SE Asia and will coordinate all training and field research in Malaysia and Thailand and ensure compliance with IACUCs.

**Fig. 16: Administration and program management for the EID-SEARCH**

The EID-SEARCH core laboratory team includes global experts in virology, molecular pathogenesis, and the development of assays, reagents, and therapeutics for high consequence viral zoonoses (Co-Is Wang, Anderson at Duke-NUS; Baric, Sims at UNC; Broder, Laing at USU; Keusch, Corley at NEIDL). The core laboratory team will work with in-country diagnostic labs in Thailand (Wacharapluesedee, Hemachudha at the TRC-EID, Chulalongkorn University) and Malaysia (Hughes, Lee, CM Ltd.). Wacharapluesedee and Hughes will additionally serve as country coordinators for the EID-SEARCH, liaising directly with EHA on weekly conference calls, and working with in-country partners to ensure the smooth operation and coordination of clinical and community surveillance and wildlife research in Thailand and Malaysia, respectively. **A Core Executive Committee** comprising PI Daszak, Deputy Lead and Co-I Olival, and leads from each core partner and country: Co-Is Hughes, Wacharapluesedee, Baric, Wang, Broder, Keusch (or alternates), will conduct

regular conference calls and in-person meetings to facilitate rapid decision making within the EID-SEARCH. **This committee will also convene to manage EID-SEARCH response to outbreaks.**

**4.1.b Project Management in Thailand and Malaysia:** Wacharapluesedee and Hughes have collaborated directly with EHA for >15 years, including acting as country coordinators on the USAID PREDICT project for the last 10 years (project end date Sept. 2019). They maintain strong ties with Ministries of Health (MOH), Agriculture and Environment, multiple universities and research institutions, clinics, and hospitals, in their respective countries and across the region. The EID-SEARCH will use these connections to disseminate results, obtain permissions to conduct sampling, and also rapidly respond to and assist with outbreaks as they happen. Peninsular Malaysia, Sarawak, and Sabah are the three main Malaysian administrative regions, and effectively operate as three separate countries, with different regulations and government structures. We therefore provide specific details on the management of EID-SEARCH activities in each:

Coordination among Peninsular Malaysia, Sabah and Sarawak will be led by co-I Hughes (Conservation Medicine Ltd), and follow a successful model we implemented under USAID-PREDICT. **On Peninsular Malaysia** this project will be administered through the Zoonosis Technical Working Committee (ZTWC) established under the PREDICT project with a binding MOU among EHA, CM Ltd. and ZTWC, and including officers from MOH, Dept. of Veterinary Services, and PERHILITAN (the Govt. wildlife agency). EHA will communicate weekly with Co-I Hughes to coordinate and monitor implementation of research and reporting to ZTWC. Co-I Hughes will coordinate activities at all other Peninsular Malaysia institutions: NPHL, the National reference laboratory for diagnostic confirmation of pathogens, will manage molecular and serological screening (BioPlex) of Orang Asli samples, and serological screening of syndromic samples from Sabah and Sarawak; the PERHILITAN molecular zoonosis laboratory will store and conduct molecular and serological screening on wildlife samples; and Universiti Putra Malaysia (UPM) Faculty of Veterinary Medicine will conduct molecular and serological screening (BioPlex) of livestock samples, should these be required. **For Sabah & Sarawak**, work will be administered through the Sabah Zoonotic Diseases Committee (SZDC), a working technical committee comprising appointed and authorized officers from Sabah State Health Dept., Department of Veterinary Services, Sabah Wildlife Dept. (SWD), Universiti Malaysia Sabah (UMS) and EHA, all of which are also committed through a signed MOU. Co-I Hughes will oversee work at all other partners in Sabah, including: the Kota Kinabalu Public Health Lab (KKPHL) for molecular screening of syndromic samples from Sabah and Sarawak; the SWD Wildlife Health and Genetic and Forensics Lab for molecular screening of Sabah wildlife samples; The Borneo Medical Health Research Center (BMHRC) for screening some Sabah wildlife and livestock samples, if required, and human syndromic samples from Sabah and Sarawak. **In Thailand** all human community and wildlife research and testing will be coordinated by co-I Wacharapluesedee from the TRC-EID center. Clinical surveillance will be overseen by senior clinical physician and co-I T. Hemachudha.

**4.1.c. Approval and release of results:** In our experience, it is critical when working in resource-poor countries, on potentially important pathogens, to strictly adhere to protocols for release of results. EID-SEARCH will liaise with existing points of contact in the Ministries of Health, Environment, and Agriculture in each our administrative areas to approve and release project findings publicly. Results from human screening will be shared with participants when they become available, as per our IRB agreements ensuring no violations to anonymize data requirements (**see Protection of Human Subjects**).

**4.2. Flexibility to extend the EID-SEARCH to new sites as needed:** The EID-SEARCH consortium partners maintain extensive working relationships with leaders in EID outbreak control, clinical investigations and research at over 50 clinics, research institutes and public health laboratories across Southeast Asia. Due to space constraints, we haven't listed each of these, nor have we solicited >50 Letters of Support for this project. However, each core EID-SEARCH partner has contacted their networks and obtained permission for inclusion in the broader goals of the EIDRC. As examples of these contacts, our core partner, the Thai Red Cross Emerging Infectious Disease Health Science Centre (TRC-EID) at Chulalongkorn University, also serves as the WHO Collaborating Centre for Research and Training on Viral Zoonoses and has ongoing research collaborations across WHO SEARO countries including Bangladesh, Bhutan, Democratic People's Republic of Korea, India, Indonesia, Maldives, Myanmar, Nepal, Sri Lanka, (Thailand), Timor-Leste; and has recently served as a training hub for scientists from Malaysia, Myanmar, Laos, the Philippines, and China to learn methods of wildlife sampling and diagnostic screening. Our Thai clinicians (Co-I T. Hemachudha and KP P.

Hemachudha) provide regular case consultations and clinical trainings for doctors across SEARO countries, including with Yangon General Hospital and the National Health Lab in Myanmar, 2018. To maximize leverage of this broad network, EHA has budgeted for annual meetings in SE Asia, in addition to regular smaller network meetings, with our core team and key public health experts from network labs in each of the 10 SE Asian countries. Additionally, we will set up a listserv and an internal communication network to facilitate collaboration and information exchange, including on the first reports of new disease outbreaks. Our annual and smaller network meetings will critically allow face-to-face meetings of the EID-SEARCH that will foster greater sharing of information on novel research and diagnostic approaches, pathogens that are of key pandemic potential, regions or populations at high risk of spillover, and information from the greater network on likely outbreaks of novel disease. This platform will coordinate sample sharing and diagnostic platforms and help build a rapid response to outbreaks in the region, guided by the PI, Deputy and the Executive Committee.

**4.3. Outbreak response:** EHA collaboration with expert networks around the world allows us to mobilize and enhance effective One Health response to disease emergencies (191), ranging from real-time situation updates and risk analyses to on-the-ground investigations (192-194). We will adopt management tools from Emergency Operating Center (EOCs) (195) and Incident Management Systems (IMS) (196), to shift resources where necessary to help respond to novel zoonotic outbreak events and other public health emergencies. EHA has extensive experience working with governments in low and middle income countries (LMIC) applying these principles of epidemic preparedness during outbreak responses we've been involved with under the USAID-PREDICT project. For example, at the request of the government of Bangladesh, we provided technical field and laboratory support for Nipah virus and avian influenza outbreak investigations, assisting with wildlife sampling as part of the outbreak response alongside human and domestic animal sampling. In India, we provided technical assistance in response to the Nipah virus outbreak in Kerala in 2018. Last month in Indonesia we assisted the Ministry of Health's Center for Health Laboratory in Makassar to provide technical assistance in a mysterious outbreak in a small village in South Sulawesi that killed 4 villagers and infected 72. Our network partners include the key government and govt. approved laboratories that would be directly involved in public health emergency response in their respective countries. The serological and PCR platforms that EID-SEARCH develops will be made available to the main government outbreak investigation teams for clinical work and research during the outbreak. EID-SEARCH will also offer assistance training and conducting animal sampling during an outbreak, epidemiological analysis and modeling to help identify likely reservoirs or likely pathways to spread. Technical and material support for lab, field and analytical activities during an outbreak will be provided by EHA, UNC, USU, Duke-NUS, and NEIDL, as well as in-country partners. Any clinical samples, viral isolates and sequence data will be shared among partners to promote the rapid development of new diagnostic assays, reagents, and therapeutics that can be deployed to the region or other regions as part of the larger NIH EIDRC network.

Finally, while the initial pathogen focus of our group is on CoVs, PMVs and FVs, our broad collaborative group has multidisciplinary expertise on a number of virus-host systems. For example: PI Daszak was PI on a subaward from PI Laura Kramer's U01 on Poxviruses and Flaviviruses, managing a multidisciplinary research project on West Nile virus ecology. He was also co-I on a 5-year NSF-funded project to understand West Nile virus dynamics and risk in the USA (197-201); Co-I Baric is a global leader in Norovirus research leading to the development of vaccines and therapeutics (202-205); Co-I Wang has conducted significant work on bat immunology, therapeutic, and reagent development, as well as being involved in a range of outbreak investigations, viral discovery programs and other research on a wide diversity of viral groups (206-215). Additionally, the serological and PCR-based diagnostic platforms being developed by Co-Is Wang and Broder are adaptable to other viral targets. The modeling tools developed by Co-Is Olival and Zambrana-Torrel can be used to predict the emergence and spread of diverse viral targets, including influenza, antimicrobial resistance, and vector-borne diseases (216-221). Our clinicians working in Thailand and Malaysia have a wide range of infectious disease investigations to adapt to any outbreak situation.

**4.4. Communications:** EHA will coordinate communication among all co-Is and key personnel, including:

- Multiple meetings per week with PI, Deputy Lead, Senior Program Manager (on project and task status)
- Weekly web/phone meetings between Program Manager and subawardee admin. staff
- Monthly web/phone conferences between EHA PIs and all subawardee PIs.

- Monthly web conferences between key personnel (research presentations/coordination)
- In-person Annual meetings with partner leads, key personnel at EHA and two in-person partner meetings annually between subawardees.
- Annual in-person meeting among all key personnel

**4.5. Problem identification and resolution:** Regular planning, monitoring, and evaluation meetings will be the primary mechanisms for problem identification. Minor problems (e.g. delays in sample availability or test results) will be dealt with internally through appropriate action and resolution monitored by PI Daszak and co-PI Olival, and our Senior Program Manager. In the event of significant problems, such as prolonged poor productivity, inadequate scientific collaboration, or major disputes regarding research direction or resource allocation, EHA will assist with resolving the problem through negotiation with relevant co-PIs and consultation with the Executive Committee. Should a resolution not be forthcoming, consultation with the EIDRC-CC, additional external technical advisors, and NIH staff may be warranted.

**4.6. Adaptive management and risk mitigation:** Maintaining a timeline and meeting milestones will require strict and continuous oversight of all project phases, frequent and regularly scheduled communication, and the ability to make decisions and implement strategies. To maintain our timeline on all projects, including the EID-SEARCH, we use an adaptive management approach to continually evaluate these trade-offs, to make decisions about when iteration is appropriate and when it is necessary to move forward with current information. Our ethos is that regular, scheduled communication among all staff, partners and collaborators will go a long way towards mitigating risks, especially if the process is collaborative and transparent.

## 5. Data Management Plan

EHA will house the Data Management and Analysis (DMA) team for EID-SEARCH, led by Co-PIs Olival and Zambrana-Torreilo and include Key Personnel Latinne and Mendelsohn. EHA has served as the data and analysis hub for numerous multi-institutional, multi-sectoral, international disease research groups, including acting as Modeling and Analytics lead for the PREDICT project (122), the Western Asia Bat Research Network (222) and EHA's Rift Valley Fever Consortium. We will leverage our experience and infrastructure from those projects to benefit the EID-SEARCH. **5.1. Project Database:** We will create a dedicated, centralized EID-SEARCH database to ingest, store, link, and provide for analysis all data associated with the proposed study and other expanded projects associated with the research network. The database will be SQL-based and use encrypted, secure cloud hosting services and enable export to archival and platform-independent formats. It will ensure data and metadata compatibility between project components, track data versioning and annotations. The system will be designed to work with both with both paper- and tablet-based field data entry and with the Lockbox laboratory information management systems (**Section 5.2**) in place in individual partner labs. The database will use existing metadata standards, including NCBI standards for genetic and molecular data and Ecological Metadata Language (EML) for field and wildlife data, as well as other standards and formats designated by the EIDRC CC. This will enable rapid publication and deposition of data. Granular security and privacy controls will be applied so that specific expansion projects undertaken in the network may be managed while maintaining data confidentiality as needed.

**5.2. Biological Specimen Management:** Project laboratories will use the Lockbox Laboratory Information Management System (LIMS), to manage the security, traceability, and quality of biological specimens. The LIMS will support sample barcoding at creation, tracking through transport, storage/inventory, and use via portable scanners. Lockbox supports CLIA and ISO 17025 as well as direct export to NCBI formats such as Sequence Read Archive. We will use the Lockbox LIMS application programming interface (API) to link to the central project database and associated samples with field and ecological data. We note that the project focuses on highly pathogenic viruses, including select agents; Lockbox LIMS supports sample tracking and movement compliant with US Select Agent Regulations and US Department of Commerce Pathogen Import and Export Control Regulations, and includes all necessary encryption, security, and backup protocols.

**5.3. Training:** Members of the DMA team will team will develop documentation and provide training for field and laboratory teams at all partner institutions in data management, metadata standards and data hygiene best practices. The DMA team will act as trainers and consultants for partner institutions in experimental

design, power analysis, data analysis, and computational and reproducibility issues, and visit each partner institution and/or field team base for training workshops and analysis consultations.

**5.4. Data Identification and Privacy:** For human clinical data and questionnaires, data will be identified by a unique identification code assigned to each individual and only this, de-identified code will be accessible in the project database, and destroyed at the end of the project - as per details provided in the Clinical Management Plan and Protection of Human Subjects forms.

**5.5. Computing Resources:** EHA operates a cluster of high-performance servers for data analysis activities, as well as infrastructure to launch cloud-based computing environments (**see EHA Facilities**). Our servers host all necessary software for statistical and bioinformatics work that is available to the DMA and partners anywhere in the world. We use a mixture of cloud services (AWS, Azure, Backblaze, GitHub) to provide redundancy, backup, version control, and rapid post-disaster recovery, and will be available to all project partners for analysis and training.

**5.6. Data and Code Sharing:** See details provided in the **Resource Sharing Plan**.

## **6. Clinical Management Plan**

**6.1. Clinical site selection:** Our consortium partners have been conducting lab and human surveillance research, including during outbreaks, for >20 years and have developed strong relationships with local clinical facilities and processes in SE Asia and in LMIC globally. The plan for selection of clinical sites will begin in the same geographic regions as those identified in Aim 1 with high zoonotic viral diversity. Clinical sites will additionally serve as the catchment healthcare facilities for people in our community-based surveillance of Aim 2. We have already developed successful working relationships with the major healthcare facilities in Thailand and Malaysia and will use these established partners to rapidly gain appropriate permits and begin data collection quickly. Focusing on these EID hotspots in select biogeographic areas (see **Fig 13**) also reduces the number of additional sites needed to meet our goals within our geographic range. The capacity and capability requirements for clinical sites are fairly minimal, and include ability to enroll patients that meet the clinical case definitions of interest, collect and temporarily store biological samples, and follow standards for data management and subject protection with locked filing cabinets to store all paper records and an encrypted computer. We will be enrolling inpatient and outpatient participants within 10 days of the presentation of symptoms to increase the chance of PCR detection of viruses so we will not wait for advanced normative diagnostic tests, that are likely unavailable in the more remote sites, to be completed. We will work with clinical sites to determine the best process for project staff, in most cases supporting the time of currently hired staff at each site. We will recruit and train hospital staff in project-specific procedures including enrollment of patients, sample types to be collected, storage of samples, administration of the questionnaire, and data management plans. During the development and onboarding of new clinical sites we will assess the physical needs of the site and what supplies will be required for collection of data.

**6.2. Standardized approach, oversight, and implementation:** Management and oversight for all study sites will be undertaken by the local country coordinator with support from our Core Administrative team at EHA. Our research team has over 10 years of experience building capacity on human subjects' research and has developed training resources and materials for standardized implementation of community and clinical research and SOPs for screening, enrollment, and retention of participants. The country coordinator will conduct regular site visits to the clinical sites and annual visits to observe, monitor and evaluate the research process, and conduct follow-up training if required. Through our work with clinical sites under the USAID-PREDICT project we have developed culturally appropriate screening measures for clinical sites that do not disrupt the flow or quality of medical treatment received by the patient. This was done by working collectively with clinical staff to evaluate current procedures and patient flow at the site to determine the most efficient while minimal invasive inclusion of our study into the daily working of the clinical site. Most efficiently this was done by adding minimal basic screening questions to the current clinical intake forms, which allows the clinical research officer to quickly scan charts or logs for potential patients to enroll avoiding potential enrollees from being overlooked if staff are too busy or not on duty. Patients will be enrolled following established clinical criteria (**see Section 6.3**), samples collected and brief surveys conducted to assess the participants contact with wildlife through: 1) occupational exposures; 2) animal contact; and 3) the environment. With permission

from each clinic, and consent from participants, we will review clinical records to collect data on medical history, clinical syndromes, and patient etiology. Additionally, we will be following up with clinical participants to determine how clinical presentation differs between CoV, henipavirus, or FV in exposed and unexposed participants, as well as in the time course of illness, severity of symptoms, and type of symptoms. The country coordinator will be continually monitoring the project database to ensure we hit target sample sizes. While patient's enrollment is limited by the number of individuals presenting at hospitals, in previous research we enrolled an average of 105 patients per year, ranging from 77-244.

**6.3. Clinical cohort setup, recruitment, enrollment:** We will recruit inpatients and outpatients from clinical sites to participate in the study after initial screening to determine if they meet the clinical case definitions for 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; 5) hemorrhagic fever, of unknown etiology or severe diarrhea with unusual presentation for symptoms to increase the chance of PCR detection of viruses. Once enrolled, biological samples will be collected by trained hospital staff. When possible, samples will be taken concurrently with samples being collected for normative diagnostics. We will collect 5mL of blood for whole blood and serum collection, samples will be aliquoted, at least one max. 500  $\mu$ L whole blood; two 500  $\mu$ L serum samples and two nasal or oropharyngeal swabs will be collected. Controls who test positive for CoVs, FVs, or Henipaviruses will be selected from the pool of participants admitted to the studies and whose samples tested negative for coronaviruses, henipavirus, or filoviruses. We will follow up 35 days after enrollment to collect an additional 5mL blood draw for collection of two 500  $\mu$ L serum samples and a standardized questionnaire supplement to collect additional data on the course of symptoms in the interim period. Following up 35 days post initial collection gives adequate time for 1) development of IgG and IgM, which occurs <28 days after onset of symptoms to evaluate the immunological progression of disease and 2) further the risk assessment of the participants to monitor contact with wildlife, people, and to assess the likely reservoir hosts to collect information to inform potential intervention programs.

**6.4. Utilization of collected data:** Sampling of wildlife and the enrollment of community surveillance participants and a clinical cohort of participants give us the ability to assess the viruses that are circulating in each of the three populations in a similar geographic region. We will use phylogenetic analysis to compare the relationship between wildlife viruses found and viruses found in human participants. Additionally, the questionnaire data will allow us to assess relative measures of human-wildlife contact that we will analyze the intensity of contact with species known to be at a higher risk for spillover against other risk to provide useful proxy information for spillover risk. The clinical cohort will be split into cases and controls. "Cases" are defined as participants whose samples tested positive for either CoV, henipavirus, or FV via PCR tests. "Controls" will be selected from the pool of participants admitted to the studies and whose samples tested negative. We will use nearest neighbor matching to pair cases demographically (e.g. age, sex, location) with controls at a 1-to-3 ratio or greater. In clinical study, we will use this procedure to determine how clinical presentation differs between virus-exposed and -unexposed participants, as well as in the time course of illness, severity of symptoms, and type of symptoms. We will model the outcomes to analyze correlation between biological results and risk factors related to high risk wildlife exposure. With this collective data set we aim to quantify and detect novel viruses likely to spillover regularly to people, are often unreported or misdiagnosed as their clinical manifestations, and are unknown to detect cryptic outbreaks causing previously 'hidden' clinical syndromes in people. Our strategy for targeted surveillance and detection of spillover and illness in at-risk human populations can be used as an 'early warning system' to conduct public health interventions and disrupt disease emergence.

**6.5. Development of reagents of value to the community.** Members of the EID-SEARCH consortium have substantial experience producing reagents, assays, and other products that are used widely by the clinical and research community, and some of which are on a pathway to commercialization. These include: PIs Daszak and Co-I Olival have produced software for analyzing the spread of novel viral agents through air travel networks; Co-I Baric has collaborated with a Norovirus surveillance collaboration with surveillance cohort at CDC and has developed therapeutics that have reached phase 2 and 3 clinical trials, He is currently working with Takeda Sanofi Pasteur on a Dengue therapeutic and with NIH on a tetravalent vaccine; Co-I Broder

developed a Hendra virus subunit vaccine that was commercially produced by Zoetis for horses and is labeled for human use under compassionate circumstances during outbreak situations.

**6.6. Potential expansion:** Expansion of the research project to other clinical sites or research areas could happen as new information is gathered, either through our research, the EID-SEARCH information network, or an outbreak being identified in the region by other organizations. If expansion is required we would rapidly shift research activities towards the clinical or community sites where the outbreak is active, using the same process we used to set up initial research locations. First, by working with local stakeholders to create a working relationship and on-boarding new clinical research staff through advanced trainings of project aims, SOPs on data collection and storage, and ethical guidelines. The network of infectious disease researchers in the community and hospital settings would allow for an accelerated response to any potential infectious disease outbreaks as staff are well trained on ethical guidelines for working with human subjects, data and specimen collection, storage, and transpiration, project staff would be on the front lines ready for the call to action. Ideally, our testing for viruses in priority viral families may lead to the discovery cryptic outbreaks before it spreads in the general public. Biological results coupled with survey data on key risk factors will provide necessary information for granular understanding of disease spread.

## **7. Statistical Analysis Plan:**

**7.1. Framework:** Statistical analyses across the project will be conducted under a common Bayesian framework. These models provide a unified, probabilistic approach best-suited for estimating effect sizes in heterogeneous populations of human clinical and wildlife subjects in observational studies. Within this Bayesian framework, we will use generalized linear mixed models to estimate population prevalences and seroprevalences, and estimate the effects of demographic, occupational and environmental factors affecting these. We will use occupancy models (223) to estimate total viral species and strain diversity and completeness of sampling within the human and wildlife sub-populations, and discrete phylogeographic models to identify taxonomic and geographic centers of viral diversification. All statistical analyses will be performed reproducibly using scripted, programmatic workflows (e.g., the R and Stan languages) and maintained under source code version control (git). As with data management, the DMA team will act as trainers and consultants for exploratory data analysis, power analysis, and study design with project partners, and the EHA computing cluster will be available for partners undertaking additional or expansion studies. Power analyses, current and expansion, are performed via simulation approaches allowing planning for complex, hierarchical variation in study populations. Power analyses and specific analytical components of this study are detailed under each Specific Aim.

**7.2. Data Quality Control and Data Harmonization:** All data will be examined at entry by field and lab teams upon data entry, followed by examination by DMA team members at upload and integration, for complete de-identification, completeness, accuracy, and logical consistency. The DMA will provide field and lab teams with reports, produced automatically, of data summaries, including aggregates, distribution, detected outliers and possible mis-entries. On a regular basis (quarterly or as-needed during data collection), DMA team members will review reports with field and lab teams to identify errors and update collection and entry procedures as necessary.

**7.3. Statistical Considerations for Behavioral Questionnaires and Clinical Metadata:** The data collected from the questionnaire will be analyzed to assess the reported measures of contact for each risk group under study, related to 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, rodents, and primates in/around house and other livestock animals (e.g. farming, butchering, slaughtering); 3) proximity of residence or workplace to environments of increased risks (e.g. nearby bat roosts); 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms in the past 12 months and lifetime. Specific measures we are interested in are the proportion of respondents indicating they consume wildlife, where wildlife is obtained for consumption, have hunted wildlife, butchered or slaughtered live animals, seen wildlife in their homes, been bitten or scratched by animals, etc. Comparisons of measures of exposure contacts and types between men and women, children and adults, different study regions will be conducted in order to explore the occupational, environmental, and demographic factors (gender, age, socioeconomic status (SES)) that influence contact with animals and to determine who is

most at-risk. Statistical analysis will be employed to identify differences between groups with a 95% probability of detecting a difference. Measures of contact related to different activities within specific groups will be compared to determine the activities that put groups at most risk. As appropriate multivariate analysis (e.g. ordinary linear regression, logistic regression, non-normal distributions of outcome, least absolute shrinkage and selection operator (LASSO) regression, etc.) will be utilized to evaluate the relationship between the outcome variables, positive biological results (PCR or serology) key measures of contact and the factors that influence frequency and types of human-animal contact.

## 8. Project Milestones and Timelines

**8.1 Milestones: End of Year 1: Aim 1:** Sample targeting locations, species (for wildlife), sample size justifications completed for whole project and reported to in-country teams; Sample testing, viral isolation, NGS, glycoprotein sequencing begun for all archival and some newly-collected samples; *in vitro* work begun; host-pathogen dynamic analyses; animal model work begun. **Aim 2:** Target human community populations identified and sample sizes calculated for some sites in each country; Community data collection, serological testing and RT-PCR testing begun; first epidemiological analyses of data begin in last quarter. **Aim 3:** Clinical cohort selection underway; clinical enrollment, data collection and sample analysis begun. First Annual meeting in last quarter. First publications submitted by end of year, summary overview papers or reviews.

**End of Year 2: Aim 1:** No sample targeting or sample size justification analyses needed. All other aspects underway **Aim 2:** All aspects underway **Aim 3:** All sub-aims underway. Second Annual meeting in last quarter. Further 2 publications submitted by end of year, including first data papers.

**End of Year 3: Aim 1:** No sample targeting or sample size justification analyses needed. All other aspects underway **Aim 2:** All aspects underway **Aim 3:** All sub-aims underway. Third Annual meeting in last quarter. Further 3 publications submitted by end of year, largely data papers.

**End of Year 4: Aim 1:** No sample targeting or sample size justification analyses needed. All other aspects underway **Aim 2:** All aspects underway. Receptor binding work completed. **Aim 3:** No further cohort selection required; all other sub-aims underway. Fourth Annual meeting in last quarter. 3 further publications submitted, including first papers analyzing risk factors, pathogenic potential of novel viruses submitted.

**End of Year 5: Aim 1:** No sample targeting or sample size justification analyses needed. No receptor binding assays continuing. Serological and PCR testing completed end of 2<sup>nd</sup> quarter. Glycoprotein, *in vitro* and *in vivo* analyses, analysis of viral risk continue to end of project. **Aim 2:** No further community targeting or sample size work. Community data collection completed at end of 2<sup>nd</sup> quarter. All other aspects continue to end of project **Aim 3:** All sub-aims underway. Final Annual meeting in last quarter. Further 3 publications submitted.

### 8.2. Timeline:

ACTIVITIES	YEAR 1				YEAR 2				YEAR 3				YEAR 4				YEAR 5			
	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4
AIM 1	1.4.a. sampling targets	■	■	■	■

**Subject:** EIDRC impact scores from NIH  
**Date:** Monday, November 18, 2019 9:26:16 PM  
**Attachments:** [Study section roster 1573258030732.pdf](#)  
[EIDRC Southeast Asia v7 FINAL FINAL.pdf](#)  
**Importance:** High

---

Dear All,

Just to let you know that we've got the results back from NIH. EHA submitted two EIDRC proposals, and we were linked to a third one as a subcontract. Out of these, the only one to get a score was the Southeast Asia EIDRC (EID-SEARCH) which you are all collaborators on. I also know of another good group that wasn't scored, so just to get a score is actually a good result...

**Our 'impact score' was 32**, which normally would put us right on the edge of being funded. I've already contacted the NIAID program officer (Jean Patterson) to ask about the likelihood of being funded. She told me that NIH staff are currently working out the structure of the network and a funding plan. She felt our proposal was well-received and scored well enough to be considered, and she asked me to hold off for a week or two and then they'd know more.

My take on this is that they're now deciding what the geography and scope of the network should be, how many EIDRC centers they can afford to fund, and then they'll decide priorities for funding. With this being strongly driven by NIAID's internal concerns about their reach into different geographies, it's really going to be a decision driven by their own considerations of who else is in the mix and what strengths/weaknesses different proposals have. That means we're in with a chance, but we don't really know the factors driving a decision.

I'll contact NIAID again in a few days, but in the meantime, please do the following: 1) try not to share this information with colleagues because we don't want to have a situation where they scored better than us and we got funded, leading to a bad feeling (or worse, the other way round!); 2) if you meet people from NIAID, tell them how keen and enthusiastic you are about the proposal and the work we're conducting (I've attached the final text again as a reminder) – you never know how this might help. Key people at NIAID who will be making this decision are: Tony Fauci (head of NIAID), Cristina Casseti (Deputy Head, and in charge of this line of work), Jean Patterson (Program Officer directly in charge of the EIDRCs), Eun-Chung Park (also directly in charge of this work), Pat Repik (I think she's involved).

Finally – I've attached the Review Committee Roster for you to look at who the people are who either liked or disliked our proposal! I know a few of them, and I'm sure you know the others...

Will be in touch as soon as I hear more.

Cheers,

Peter

**Subject:** EIDRC grant submitted

**Importance:** High

Dear All,

Just to let you all know that the grant was successfully submitted today with time to spare, and no errors. It's in the system, and it's all down to the reviewers now! Thanks to all of you for your help and support in getting this finalized and completed. Please pass on my personal thanks to the Co-Investigators, Key Personnel and Consultants who you also brought into the team.

I've attached a pdf of the final proposal text and will send the Word version in a few minutes. It's actually a good read, and I'm especially grateful to Hongying who generated all the cool graphics, based largely on Ralph's previous NIH grant proposals.

As you read the text, please remember that the wording is very carefully targeted to a typical US-based NIH reviewer, and to the Program Officers, with the sole purpose of trying to win the grant. If I've exaggerated or made mistakes, or used language that isn't quite right, I apologize, but I did it for the key goal of getting funded.

In the meantime, please don't share this proposal beyond our group on this email chain, so we don't give our competitors an edge!

Good luck, and I'll be keeping my fingers crossed all summer in the hope that we win this...

Cheers,

Peter

**Subject:** EID-SEARCH Comments

Thanks everyone for sending the comments back. Working on v5 now, while others in the office are cranking out sample size calculations, new figures, human and vert. subjects and all the additional information needed after the research plan.

As I go through all your comments, I'll send the occasional email with questions to clarify specific points, so please be on standby for a quick turnaround.

Cheers,

Peter

Dear All,

Here's version 4. Apologies for the delay. It's in better shape now, but there are still lots of areas that need your attention. Please put in time today, and tomorrow to edit and firm up the text.

I've put your names in some of the comment boxes where I need specific help but I also need you to read this critically now and edit and tighten it up. We have 30 pages of space, and our research plan is now 21 pages, so we need to lose maybe 3 or 4 pages. There are also some weak points, specifically on Filoviruses, on the details of where we'll do our clinical work, and on what we'll do with the animal models for henipias and filoviruses.

Please get comments back with me before Wednesday 26<sup>th</sup> 4pm New York time, so that I have Wednesday evening and all day Thursday to incorporate them. In the meantime, I'll be working with folks here on better figures, and all the extra sections that come after the research plan. I'll need you all to help with those on Thursday while I'm finishing off the draft.

Thanks to all of you in advance and look forward to the next round.

Cheers,

Peter

**Subject:** EIDRC-SEA v.3

**Importance:** High

Dear all,

Thanks to everyone for comments and text for the earlier draft at the beginning of the week. Kevin's spent the last couple of days pulling all the comments together into one draft and inserting his changes, and I've now attached a v3 of the draft. It's still rough, and now too long, but it's getting there. I wanted you to look at this rough version because I'm stuck in Liberia in meetings Friday, then flying back home Saturday. I'll continue editing this draft on the plane and will be working solely on this grant from home on Sunday, Monday, Tues, Wed, Thurs.

Please work on this rapidly if possible. If you can all push your comments through, using track changes, and get them back to me **by Sunday evening New York Time**, I will turn round a polished draft by Tuesday, giving us time for significant last go-over on Wed, Thurs. It's tight, but unfortunately, it is what it is, so please commit the time if you can!! As well as general edits (using track changes, with references in comment boxes), please do the following...

Linfa/Danielle – We especially need your input in section 1.1, 1.3, 1.4 and 2.5

Ralph/Amy - Please work your magic on this draft, inserting text, editing and reducing text, and making sure the technical details of the characterization are correct and fit the proposed work on CoVs, PMVs and Henipaviruses

Chris/Eric – Eric – congratulations on your (b) (6) and thanks for working on it at this time!  
Chris – please help and edit/finesse the language in the relevant sections for you

Tom – Your edits crossed over with Kevin's changes, so please insert all the bits that were new in the last version you sent to me, into this version. I think these are mainly the sections and comments from the other Malaysian colleagues, but please check and re-insert all key text. We especially need to be specific about which partner in Malaysia is doing what cohorts, and where, and about who's doing the testing

Thanks again all, and I'm looking forward to non-stop work on this as soon as I get on my flight in 24 hours...

Cheers,

Peter

EARLY STAGE INVESTIGATOR  
NEW INVESTIGATOR

## **1R01AI143978-01A1 EPSTEIN, JONATHAN**

### **INCLUSION OF CHILDREN PLAN UNACCEPTABLE EARLY STAGE INVESTIGATOR NEW INVESTIGATOR**

**RESUME AND SUMMARY OF DISCUSSION:** This application focuses on Nipah virus outbreaks in Bangladesh and seeks to understand why outbreaks appear to only occur in the western part of Bangladesh despite the virus, host (*Pteropus medius* fruit bats), and the primary route of transmission (date palm sap consumption) being present throughout the country. Given the virulence, the increase in outbreaks and the limited knowledge of the driving factors of this virus transmission, the significance is very high. The revised application is responsive to prior critiques and is more focused. Strengths are the significance, the expertise of the impressive investigative team, the field site, the multidisciplinary approach of integrating field studies, animal models and modeling, and the feasibility of the approach. Notwithstanding these strengths, the following weaknesses in the approach slightly detract from the impact of this application. Some weaknesses are the consideration of sap consumption as a proxy for exposure, the use of increase in seroprevalence as a proxy for the prevalence of viral carriage, the insufficient number of subjects for risk factor analysis, and the small number of hamsters for transmissibility studies. Other weaknesses are the exclusion of children and the lack of consideration of the confounding effect of recency of Nipah introduction in the East.

**DESCRIPTION (provided by applicant):** Nipah virus is a zoonotic paramyxovirus, carried by old world fruit bats across Africa and Asia, which causes severe, fatal encephalitis in humans and can be transmitted from person to person. In Bangladesh, where outbreaks in people occur annually, the primary route of transmission is the consumption of raw date palm sap. Date palm sap is harvested and consumed most intensively in western Bangladesh, an area referred to as the "Nipah belt," however, date palm sap consumption, NiV, and its bat reservoir, *Pteropus medius*, are present throughout Bangladesh. It is unclear why outbreaks have not been detected in eastern Bangladesh. Cryptic spillover of NiV creates a significant risk that more pathogenic and transmissible strains will emerge and lead to large epidemics. This multidisciplinary project will determine whether NiV outbreaks have occurred in eastern Bangladesh and how differences human behavior, infection patterns in bats, and the circulation of potentially less pathogenic strains of NiV influence outbreaks outside of the Nipah belt. This project combines human exposure studies with multi-site longitudinal infection studies in bats and in vivo experimental infections comparing clinical outcomes among diverse strains to achieve the following specific aims: 1) To compare NiV exposure and its behavioral determinants among human populations inside and outside the Nipah belt in Bangladesh. We will test the hypothesis that NiV spillover has occurred in Bangladesh in communities outside the Nipah belt. We'll use behavioral questionnaires and a multiplex Luminex serological assay to screen high risk populations for IgG antibodies against NiV and determine if Nipah exposure has occurred and how behavioral risk varies by locality. 2) To compare Nipah virus temporal dynamics in *Pteropus* bat colonies inside and outside of the Nipah belt. We will conduct longitudinal bat NiV field studies in six locations (3 western, 3 eastern), characterize local bat demography, measure changes in seroprevalence over time; determine viral shedding patterns and genetic variation among strains. Through experimental bat infections in a BSL 4 lab, we will determine whether bats with antibodies against NiV (previous exposure) may be re-infected and shed virus. This will answer a critical question about transmission dynamics and allow us to test the hypothesis that viral shedding occurs with different frequency in eastern bats compared to western bats, which may influence zoonotic transmission. 3) To compare pathogenicity and transmissibility of diverse Nipah virus isolates from bats inside and outside the Nipah belt, using animal models. Malaysia type NiV and Bangladesh type have different clinical profiles in people. NiV genetic variation may account for lower human infection rates in eastern Bangladesh. To test this hypothesis, we will compare transmissibility and pathogenicity of diverse NiV strains isolated from *Pteropus medius* in a Syrian hamster model under BSL 4 conditions.

**PUBLIC HEALTH RELEVANCE:** Nipah virus is an emerging zoonotic virus carried by fruit bats and causes a severe encephalitis with greater than 70% mortality. In Bangladesh, small outbreaks occur annually but only in the western part of the country, however, repeated spillover events from bats provide an opportunity for a genetic strain to emerge that is both more pathogenic and more transmissible, which could cause a much larger epidemic. Through a combination of field studies, laboratory experiments, and mathematical modeling of Nipah virus in bat populations, this project aims to understand why Nipah virus outbreaks appear to only occur in the western part of Bangladesh despite the virus, host (*Pteropus medius* fruit bats), and the primary route of transmission (date palm sap consumption) being present throughout the country.

## CRITIQUE 1

Significance: 2

Investigator(s): 1

Innovation: 2

Approach: 5

Environment: 1

**Overall Impact:** This resubmission application from a New Investigator, proposes to address why outbreaks of Nipah virus occur in one region of Bangladesh and not in others. In doing so, the proposal will provide key information on the transmission dynamics and natural history of Nipah virus and provide insights on the reservoir, viral pathogen and exposure factors that may influence spillover infections. This application is bold and exciting and has many strengths which include the PI and study team who are leaders in the field of Nipah research, the field and laboratory capacity that has been established to implement the project and the highly innovative approach which integrates field investigations of humans and reservoirs, experimental animal models of infection and modeling. There are however major weaknesses with respect to the scientific rigor of Aim 1. Nevertheless, the application generated significant enthusiasm which was reflected by the overall impact score.

### 1. Significance:

#### Strengths

- The proposed studies will provide important descriptive information on the spatial and temporal distribution of seropositivity in bats, which may provide insights into the underlying transmission dynamics.
- Likewise, the experimental bat infection addresses key knowledge gaps in the natural history of Nipah in the primary reservoir.
- If successful, Aim 3 will set the stage to identify pathogen-specific factors that influence disease severity and transmissibility.
- Many parts of the proposed studies are supported by strong scientific premise.

#### Weaknesses

- The rigor of proposed Aim 1 studies is a concern since the factors that influence a spillover infection are complex (bat abundance, frequency and degree of source contamination, etc.) and extend beyond sap consumption.

### 2. Investigator(s):

#### Strengths

- The PI, although a new investigator, has an impressive track record of accomplishments in the field of emerging infectious disease.
- The study team are leaders in the field of Nipah virus research and one of the few groups who can implement this ambitious project

#### **Weaknesses**

- None noted

### **3. Innovation:**

#### **Strengths**

- The integration of multidisciplinary field, laboratory and modeling approaches to study the natural history and transmission of Nipah is an exciting and highly innovative feature of the application.
- The proposed experimental bat infection studies, as well as the hamster transmission model are novel.

#### **Weaknesses**

- None noted.

### **4. Approach:**

#### **Strengths**

- The field sites distributed in regions of differing outbreak risk is a strength.
- The serial trapping surveys of bats are well designed and should yield sufficient numbers to delineate the dynamics of seropositivity.
- The proposed experimental bat and hamster infection models and bank of well-characterized viral isolates is another strength of the proposal.

#### **Weaknesses**

- Sap consumption in Aim 1 may not be a robust proxy for exposure and details are not provided on how this exposure will be measured and evaluated in the models. Alternative hypotheses for sporadic spillover infection (in contrast to disease during outbreaks) are not considered.
- Although 3,000 participants will be recruited, seroprevalence may be low and even if it does reach 2%, there may not be sufficient numbers to perform robust risk factor analyses.
- The use of increase in seroprevalence as a proxy for the prevalence of viral carriage/shedding is a potential weakness. The proposal does not describe how criteria for seropositivity in bats was established.
- The description of the SIRS model is sparse and how uncertainty will be addressed
- Although the proposal states at power of 81%, the sample of three naïve hamsters per group seems small for the proposed transmissibility studies.

### **5. Environment:**

#### **Strengths**

- Outstanding field and laboratory capacity which include BSL4 facilities.

#### **Weaknesses**

- None noted.

**Study Timeline:**

**Strengths**

- NA

**Weaknesses**

- NA

**Protections for Human Subjects:**

Acceptable Risks and/or Adequate Protections

**Inclusion of Women, Minorities and Children:**

- Sex/Gender: Distribution justified scientifically
- Race/Ethnicity: Distribution justified scientifically
- For NIH-Defined Phase III trials, Plans for valid design and analysis: Not applicable
- Inclusion/Exclusion of Children under 18: Excluding ages <18; not justified scientifically
- Children are at risk for Nipah as evidenced by prior outbreaks

**Vertebrate Animals:**

YES, all criteria addressed

**Biohazards:**

Acceptable

**Resubmission:**

- The resubmission has responded to many of the critiques, particularly those raised about the ambitious nature and the lack of scientific rigor.

**Applications from Foreign Organizations:**

Justified

**Select Agents:**

Acceptable

**Resource Sharing Plans:**

Acceptable

**Authentication of Key Biological and/or Chemical Resources:**

Acceptable

**Budget and Period of Support:**

Recommend as Requested

**CRITIQUE 2**

Significance: 1  
Investigator(s): 1  
Innovation: 2  
Approach: 4  
Environment: 1

**Overall Impact:** This ambitious proposal by Dr. Epstein and colleagues proposes to use multidisciplinary approach to examine drivers of Nipah virus spillovers and outbreaks. The team has the necessary expertise and a suitable environment for doing the proposed research. The topic is important especially given the fatality rate of Nipah virus infections and the potential to cause larger outbreaks or epidemics. Overall there is enthusiasm, however there are some significant concerns around the design of the human serosurvey. In particular, the investigators propose to match on date palm sap consumption a cross east-west sites which is inappropriate given that is a main exposure they would like to examine. Some concern also exists around the exclusion of children from the study population and the possibility of confounding by recentness of Nipah introduction given the study design.

**1. Significance:**

**Strengths**

- Nipah virus is a high priority pathogen with a high case fatality rate and no effective interventions
- Repeated spillover events and the potential for human-to-human transmission highlight the need to fill critical gaps in knowledge about factors contributing to outbreaks

**Weaknesses**

- None noted.

**2. Investigator(s):**

**Strengths**

- The PI, Dr. Jonathan Epstein, is well-qualified to lead this study based on his history of conducting similar studies on emerging pathogens and on his expertise in Nipah virus
- Investigators have a history of working together productively

**Weaknesses**

- None noted.

**3. Innovation:**

**Strengths**

- Multidisciplinary approach to understanding Nipah virus spillover and transmission.
- Use of bats as a lab animal model to inform parameters for mathematical models that are not possible/extremely difficult to measure in the wild.

#### **Weaknesses**

- Human study proposed is not particularly innovative.

#### **4. Approach:**

##### **Strengths**

- Proposed studies seem to be appropriately powered, assuming the 2% seroprevalence in the East in Aim 1 which is impossible to predict without a serosurvey.
- Bat studies will provide valuable information on viral dynamics and seasonality of Nipah.
- Modeling approaches are appropriately sophisticated.

##### **Weaknesses**

- Since the authors plan to look specifically at date palm consumption as one of their primary exposures of interest, it is highly inappropriate to match on date palm consumption. The matching proposed is at the village level and by household consumption categories (high, medium, low), however, matching even roughly on an exposure of interest will bias that point estimate.
- Study is limited to adults; however, children may consume date palm (and perhaps Tari?) or participate in production and there have been a number of documented cases of Nipah in children in Bangladesh including at least one documented outbreak where nearly all cases were boys <15 years of age. Additionally, seropositivity in children would be more likely to indicate recent infection which would likely better match with exposure data collected through the surveys.
- Given the focus of IgG antibodies and the limitation of the studies to adults who have had many years to become seropositive, it is possible that findings may be confounded by when the virus was first introduced into the area. For example, if Nipah circulation has begun more recently in bats in the East.

#### **5. Environment:**

##### **Strengths**

- Institutions in US, and particularly the institutions in Bangladesh provide a great environment for the proposed research.

##### **Weaknesses**

- None noted.

#### **Study Timeline:**

##### **Strengths**

- Not Applicable

##### **Weaknesses**

- Not Applicable

**Protections for Human Subjects:**

Acceptable Risks and/or Adequate Protections

Data and Safety Monitoring Plan (Applicable for Clinical Trials Only):

Not Applicable (No Clinical Trials)

**Inclusion of Women, Minorities and Children:**

- Sex/Gender: Distribution justified scientifically
- Race/Ethnicity: Distribution justified scientifically
- For NIH-Defined Phase III trials, Plans for valid design and analysis: Not applicable
- Inclusion/Exclusion of Children under 18: Excluding ages <18; not justified scientifically
- Study limited to adults and exclusion of children is not justified by stating that children are not disproportionately affected by Nipah. Human subjects' sections have not been fully updated to account for changes in the study design between the initial submission and the resubmission.

**Vertebrate Animals:**

YES, all criteria addressed

**Biohazards:**

Acceptable

**Applications from Foreign Organizations:**

Justified

- Nipah virus doesn't circulate in the US

**Select Agents:**

Acceptable

**Resource Sharing Plans:**

Unacceptable

- Viral sequences should be made available on GenBank or another appropriate site rather than github.

**Authentication of Key Biological and/or Chemical Resources:**

Acceptable

**Budget and Period of Support:**

Recommend as Requested

### CRITIQUE 3

Significance: 3  
Investigator(s): 1  
Innovation: 2  
Approach: 3  
Environment: 1

**Overall Impact:** The previous criticisms were acknowledged, and the PI has presented a more focused and less extensive proposal that is judged to have many strengths. Accordingly, the problem being investigated has high relevance, the investigative team is strong, and they have a compelling approach to understanding the relative importance of infection derived from spillover from bats compared to direct human to human transmission. Their idea that viruses cause outbreaks in bats more frequently in the Nipah belt because the strains are more virulent than in the east. This sets the stage for more likely spillover in the west than in the East. It will not explain, however, how the differences arose in the first place or if the pattern will be retained and will not be recapitulated in the East. Their plans to compare strain pathogenicity differences by animal studies in BL4 facilities with bats (Australia) and hamsters (Montana) with strains collected from the different regions of Bangladesh are logical and should evaluate their ideas. However, such studies may not reveal how to limit the problem in the Nipah belt. Overall, this improved proposal has excellent potential to better understand the epidemiology of a most relevant zoonotic disease.

**THE FOLLOWING SECTIONS WERE PREPARED BY THE SCIENTIFIC REVIEW OFFICER TO SUMMARIZE THE OUTCOME OF DISCUSSIONS OF THE REVIEW COMMITTEE, OR REVIEWERS' WRITTEN CRITIQUES, ON THE FOLLOWING ISSUES:**

**PROTECTION OF HUMAN SUBJECTS: ACCEPTABLE**

**INCLUSION OF WOMEN PLAN: ACCEPTABLE**

**INCLUSION OF MINORITIES PLAN: ACCEPTABLE**

**INCLUSION OF CHILDREN PLAN: UNACCEPTABLE**

Justification for excluding children under 18 is unacceptable.

**VERTEBRATE ANIMALS: ACCEPTABLE**

**COMMITTEE BUDGET RECOMMENDATIONS: The budget was recommended as requested.**

Footnotes for 1 R01 AI143978-01A1; PI Name: EPSTEIN, JONATHAN H

NIH has modified its policy regarding the receipt of resubmissions (amended applications). See Guide Notice NOT-OD-14-074 at <http://grants.nih.gov/grants/guide/notice-files/NOT-OD-14-074.html>. The impact/priority score is calculated after discussion of an application by averaging the overall scores (1-9) given by all voting reviewers on the committee and multiplying by 10. The criterion scores are submitted prior to the meeting by the individual reviewers assigned to an application, and are not discussed specifically at the review meeting or calculated into the overall impact score. Some applications also receive a percentile ranking. For details on the review process, see [http://grants.nih.gov/grants/peer\\_review\\_process.htm#scoring](http://grants.nih.gov/grants/peer_review_process.htm#scoring).

## MEETING ROSTER

### Clinical Research and Field Studies of Infectious Diseases Study Section Infectious Diseases and Microbiology Integrated Review Group CENTER FOR SCIENTIFIC REVIEW CRFS

02/14/2019 - 02/15/2019

**Notice of NIH Policy to All Applicants:** Meeting rosters are provided for information purposes only. Applicant investigators and institutional officials must not communicate directly with study section members about an application before or after the review. Failure to observe this policy will create a serious breach of integrity in the peer review process, and may lead to actions outlined in NOT-OD-14-073 at <https://grants.nih.gov/grants/guide/notice-files/NOT-OD-14-073.html> and NOT-OD-15-106 at <https://grants.nih.gov/grants/guide/notice-files/NOT-OD-15-106.html>, including removal of the application from immediate review.

Consultants are required to absent themselves from the room during the review of any application if their presence would constitute or appear to constitute a conflict of interest.

**Introduction to Resubmission:** We thank the reviewers for their helpful comments and note their enthusiasm for the overall project, its significance, innovation, impact on health and our multidisciplinary team, including: "...the PI has a very impressive track record in this area that give confidence the scientific aspects of the project can be successfully undertaken. The premise is supported by strong preliminary data"; "the science of the application is well-structured to investigate the hypothesis and is highly likely to generate important data on Nipah virus;" the "combination of epidemiological and basic research approaches is a strength;" and that "bat infection experiments to understand viral infection and potential for re-infection of seropositive bats from the region is highly innovative." We have significantly changed our resubmitted research plan in response to their criticisms, as follows:

**1) *The proposal is overly ambitious.*** We have significantly reduced the scope and complexity of the project by: (1) removing the targeting of hunters from Aim 1. This simplifies the protocol, reduces the need to find this rarer population, and improves the analytical power of the core aim of understanding palm sap consumption effects; (2) removing the generation of bat cell lines from Aim 2. We considered reducing intensity of bat sampling but find that our design is necessary for adequate power. We are confident we can implement this study, having a field team in Bangladesh that is experienced in frequent sampling at multiple sites.

**2) *The project team is large and activities complex, making management difficult / confusion about who is PI and project workflow.*** The PI (Epstein) has 10 years of experience managing projects of similar scope and complexity in Bangladesh (and four other countries) under USAID PREDICT, which includes repeated wildlife (bat, rodent, primate) and human sampling at multiple study sites in Bangladesh working with the co-investigators and field team listed in the current proposal. We have added a new figure detailing management structure and workflow by aim. In addition, we increased Dr. Flora's time from 2 to 3 months per year to give her more time to coordinate human surveillance activities.

**3) *Concern about not obtaining bat viruses.*** We have already successfully obtained 11 bat Nipah virus isolates from *P. medius* from two locations in Bangladesh, now published [1], which were from roost urine collection and bat swabs. Also, while our data suggests extended inter-epidemic periods, they are shorter than our than our sampling period. We expect all six bat study populations to be shedding at different points during the study period. Our sampling strategy also includes intensive bat urine collection at these sites and during human outbreaks which predictably happen each winter and which have yielded most of our isolates, to date.

**4) *The power calculations are not well described.*** We have detailed the analytical approach and power calculations for each aim.

**5) *Clarify human clinical expertise / bat experiment experience:*** Co-Is Mahmud Rahman and Merjady Flora have extensive human clinical/epi expertise. As former and current director of IEDCR they have overseen human surveillance and multiple Nipah outbreaks. Experienced medical officers from IEDCR will perform all blood draws on human subjects. Vincent Munster at NIH RML has previously designed and performed bat and hamster BSL-4 infections (see [2-5].)

**6) *Confounding effects of human-to-human transmission:*** **Aim 1** now more clearly tests the hypothesis that spillover has occurred in the East. Reviewer 1 raises a valid point about serology being unable to differentiate between an exposure from bats (spillover) and from other Nipah cases (human transmission). However, 1) our goal is to determine whether people have been exposed to Nipah virus outside the Nipah Belt, so in either case, a seropositive individual signifies local exposure that was previously undetected; and 2) we will incorporate village and household-level clustering into our models, to control for human transmission effects and measure the effect of zoonotic exposure via palm sap. Distant cases = separate exposure events likely linked to a local spillover event.

**7) *The bat experiments do not test the stated hypothesis / don't address sex-based differences.*** The bat experiment, which the other reviewers found "highly innovative" and had enthusiasm for answers a critical question about susceptibility after prior exposure and directly informs the dynamic models that will test our hypothesis under **Aim 2.** We have kept this in the resubmission because it is vital to our main goals and a novel approach. It is not feasible to house multiple male hamsters or bats together without risk of injury or death from fighting. Therefore, we have predominantly female cohorts and will not assess sex-based effects.

## RESEARCH STRATEGY

### A. SIGNIFICANCE

Nipah virus (NiV) is an emerging zoonotic paramyxovirus (genus *Henipavirus*) that has caused repeated outbreaks in Bangladesh and India with mean case fatality rates greater than 70% [6-8]. *The World Health Organization has recently prioritized NiV and related henipaviruses among the ten most critical pathogens that threaten global health and for which countermeasures must be urgently developed* [9]. Old world frugivorous bats (*Pteropus* spp.) are natural reservoirs of henipaviruses in Asia and Australia [10, 11]. Nipah virus has several characteristics that make it a global health priority. 1) Its bat reservoir occurs throughout Asia, overlapping human and livestock populations, giving it geographically broad opportunity to cause outbreaks [10]; 2) henipaviruses can be transmitted directly from bats to people or via domestic animals [10]; 3) NiV can be transmitted from person to person [12]; 4) spillover has repeatedly occurred in highly populous and internationally connected regions; 5) repeated spillovers of strains with varying person-to-person transmission rates indicate the ability to evolve **pandemic potential** [13]; and 5) it is associated with a high mortality rate in people and currently has no vaccine or treatment [10, 13]. In 2018, NiV outbreaks occurred in Bangladesh and southern India, approximately 1100 miles apart. While NiV outbreaks in Bangladesh occur seasonally, there are regions in Africa and Asia where bats and henipaviruses occur but where no human cases have been identified, leaving open the possibility that cryptic spillover is occurring. A major gap in assessing NiV risk is a lack of understanding of why outbreaks happen in some locations where there are bats and virus, and not others. Outbreaks in Bangladesh have primarily been associated with date palm sap consumption, followed by human-to-human transmission [14]. However, outbreaks in Malaysia and the Philippines have demonstrated alternate routes of infection: aerosolization of virus by infected pigs with respiratory disease and exposure to bodily fluids or infected tissue from infected horses via butchering or meat consumption, respectively [15] Unrecognized human or animal case clusters increase opportunity for the emergence of more virulent and transmissible strains [16].

Within Bangladesh, there is a strong spatial clustering of observed NiV cases in the western part of the country, termed the *Nipah belt* [8]. While sap consumption is most intensive in the Nipah belt, the bat reservoir, NiV, and sap consumption occur throughout Bangladesh [16]. No human clusters of NiV encephalitis have been detected in Bangladesh outside of the Nipah belt. **The major goal of this proposal is to determine whether sap-consuming populations in eastern Bangladesh have been exposed to NiV, and to determine how ecological dynamics and viral genetics each contribute to spatial differences in exposure and outbreak risk.**

This proposed project has broad significance. It will determine whether zoonotic transmission (“spillover”) of NiV has occurred in regions of Bangladesh beyond where outbreaks have been observed (**Aim 1**). It will broaden our understanding of what factors may influence human outbreaks by 1) measuring differences in viral dynamics within bat reservoir populations in locations where NiV outbreaks have and have not occurred (**Aim 2**) and 2) by comparing genotypic and phenotypic characteristics of bat viral isolates from different areas under controlled experimental conditions (**Aim 3**). These studies will also improve our understanding of transmission patterns in other geographies where henipaviruses occur. This broader understanding of NiV risk aligns with WHO’s prioritization strategy [9], and may be used to better target interventions such as vaccine deployment. (The Coalition for Epidemic Preparedness and Innovations (cepi.net) has very recently funded the development of a NiV vaccine) and educational outreach campaigns in resource limited settings.

### B. INNOVATION.

This project is innovative in its **multidisciplinary approach** to understanding NiV spillover. **We will test complementary hypotheses** on the drivers of NiV spillover, using a combination of human surveillance and behavioral studies, ecological field studies and mathematical models, and viral phylogenetics and infection studies using **novel bat lab animal models**. Combining field and laboratory methods with mathematical modeling will allow us to gain a far deeper system-wide understanding of what drives NiV spillover. For the first time, we will apply a state-of-the art, viral genus-wide serological multiplexed assay to wildlife and human sera to screen for IgG antibodies specific to each known henipavirus. Our study will conduct, for the first time, experimental infections using multiple, diverse, wild-type bat viral isolates in the natural NiV host *Pteropus medius*. This will allow us to determine how these bats respond immunologically when infected or re-infected with NiV, and better explain henipavirus dynamics in wild bats to predict seasonal and interannual risk of NiV spillover. This will help advance the science of comparative immunology and viral tolerance in bat hosts by establishing a new host-virus model, while answering specific and fundamental questions about henipaviruses

in their natural reservoir.

## C. APPROACH

The question of why outbreaks of Nipah virus occur in certain locations and not others has broad implications for zoonotic viral epidemics: henipaviruses exist in bat reservoirs across Africa and Asia, where bats, people and livestock interact in different ways and the pathogenicity of these viruses in humans is unknown. The recent outbreak in Kerala, India is a reminder that spillover is possible wherever Nipah virus, its bat reservoir, and people interact [17]. A better understanding of why Nipah might emerge in one location versus another could allow deployment of effective interventions where they're most needed. **Our overall hypothesis is that spillover occurs across Bangladesh, and is driven by differences in human behavior and dynamics of viral circulation in local bat populations, and likelihood of a subsequent outbreak is influenced by viral strain.** We test this hypothesis by 1) using serology to compare NiV exposure in people inside and outside the Nipah belt and across different sap consumption profiles (**Aim 1**); conducting longitudinal studies of multiple pteropid bat populations inside and outside the Nipah belt and using dynamic models to analyze timing, intensity, and drivers of viral shedding (**Aim 2**); and conducting BSL-4 experimental animal infections to compare genotype and phenotype of diverse NiV isolates from bats. By understanding behavioral, ecological, and virological drivers of Nipah virus spillover, public health authorities can more accurately target surveillance and intervention strategies (e.g. vaccination) to control outbreaks and prevent a pandemic.

### C1. INTRODUCTION

Nipah virus epidemiology and ecology. In Bangladesh, there have been more than 15 NiV outbreaks, occurring nearly every year since 2001 [18]. Human cases have exclusively occurred November to April, within the western part of the country, referred to as the “Nipah belt” [13]. Date palm sap has been the predominant route of transmission between bats and people [8]. We recently showed that the bat reservoir of NiV in Bangladesh, *P. medius*, is infected throughout the country [19] and that people outside the Nipah belt also drink date palm sap [16]. Surveillance has been concentrated within the Nipah belt [20], and proximity to hospitals is a strong predictor of case reports [21], but broad awareness of NiV among clinics across the country and nationwide surveillance through media reports suggests that a cluster of cases would likely be reported [21, 22].

Differences in human behavior are known to drive exposure to wildlife reservoirs of emerging viruses (e.g. Ebola, SARS CoV, MERS CoV) and risk of spillover [23-25]. Sap consumption occurs across Bangladesh, but is more intensive in the western region [16]. In May 2018, a NiV outbreak was reported in Kerala, southern India – a completely new location more than 1100 mi from previous outbreaks in West Bengal and Bangladesh. The outbreak in Kerala, India, occurred in an area where date palm sap is not cultivated and spillover may have occurred through another route [17]. A case control study of risk factors other than sap found 40% of exposure risk of Nipah cases was associated with observing bats feeding in trees around houses at night [26].

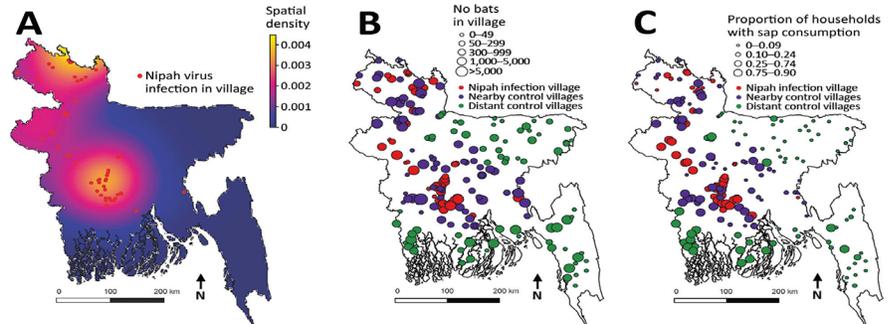

Little is known about Nipah virus dynamics in *P. medius* in Bangladesh. While human date palm sap consumption explains a significant portion of NiV spillover risk, and consumption is generally higher in the western part of the country, there is sap consumption across Bangladesh and some cases would be expected in eastern Bangladesh [16]. Viral dynamics within bats may also influence the number and location of spillover events in a given year [21]. Zoonotic bat-borne viruses such as Ebola, Marburg, Nipah, Hendra and coronaviruses are thought to have seasonal spikes in infection that coincide with annual or semi-annual synchronous birth pulses [27-32]. Seasonal NiV shedding patterns have been observed in *P. lylei* in Thailand, but studies are limited to viral detection in pooled urine samples from underneath roosts, so there is no information about which individual bats are shedding. In Malaysia, we found serological evidence of Nipah virus infection in both *P. vampyrus* and *P. hypomelanus* throughout the country, with mean seroprevalence of 32.8% and 11.1%, respectively however, viral infection rates were estimated to be low and no clear seasonal infection pattern was observed [33]. *Pteropus* species are highly mobile and colonies are interconnected through bat immigration, forming a metapopulation structure [33-36]. Human NiV outbreaks occur almost annually and have all occurred in winter months (Nov-Apr), which is when sap is harvested. However, there is variability in the number, location and size of outbreaks that occur year-to-year, and some years have had none [18]. This may be due to variability in the timing of viral shedding within local bat populations.

Comparing the periodicity and intensity of Nipah virus infection among different bat populations across Bangladesh is important for understanding drivers of spillover and the observed spatial and temporal patterns of human outbreaks.

Viral genetics may also influence observed outbreak patterns, particularly when it is only severe cases are detected through existing surveillance mechanisms [26]. Certain strains of Nipah virus may be more transmissible among people, and superspreaders have been identified in several outbreaks [14, 17]. Two distinct clades of NiV have been described using partial gene sequences from humans and animals: a Bangladesh clade, which includes sequences identified in India and Bangladesh; and a Malaysian clade, which comprises sequences from Malaysia, Cambodia, and Thailand [37]. Strains of NiV from these two clades are associated with differences in pathogenesis, epidemiological and clinical profiles in humans and animal models [38-42]. Primate models and human clinical data indicate that the Malaysia genotype is less pathogenic than the Bangladesh genotype, having less upper respiratory tract involvement, which may influence transmission [42]. Ferret models also showed less oral secretion when infected with a Malaysia strain than a Bangladesh strain [43]. Nipah virus cases in Bangladesh have shown more strain diversity than in the Malaysia outbreak [14], and local human infections likely reflect the strain circulating in local bat populations at the time of spillover. Comparing pathogenicity among viral strains from different regions has been challenging because there have been few NiV isolates obtained from bats or people [11, 44]. Recently, whole genomes from 10 isolates from *Pteropus medius* in Bangladesh were characterized by our group [1]. **The objective of this proposal is to identify how human behavior, viral ecology and viral genetics in bats drive Nipah virus spillover across Bangladesh.**

**C2. AIM 1: Compare NiV exposure and its behavioral determinants among human populations inside and outside the Nipah belt in Bangladesh.** C2.1 *Rationale and preliminary data.* Our group has studied Nipah virus epidemiology in humans, bats and livestock in Bangladesh since 2006, including leading an R01 (TW05689 Daszak, PI), a K08 (AI067549, Epstein, PI) and under USAID PREDICT in collaboration with icddr, b and the Institute for Epidemiology, Disease Control & Research (IEDCR). **PI, Epstein has managed wildlife and human zoonotic virus surveillance (including Nipah virus), behavioral studies, and laboratory work with the coinvestigators named in this current proposal under USAID's PREDICT project since 2009.**

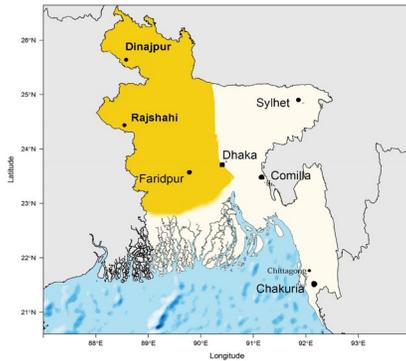

We examined how date palm sap consumption influences NiV exposure by conducting a country-wide case-control study, surveying villages inside the Nipah Belt that either had (case) NiV cases or did not, and villages outside the Nipah Belt [16]. Data related to number of date palm trees present, household consumption, *Pteropus* bat abundance, and hunting was collected from 207 villages (**Figure 1A-C**). Our finding that date palm cultivation and consumption was

**Figure 1.** A) Locations of identified bat-to-human transmission of NiV and spatial intensity of transmission events, Bangladesh, 2001–2012. B) Relative sizes of the *Pteropus medius* bat populations in case and control villages (including within 5 km of each village). C) Proportion of households in case and control villages with persons who regularly consume fresh date palm sap.

more intensive in the Nipah belt (Figure 1A), but that bats and sap consumption occur throughout the country (Figure 1C), led to our hypothesis that undetected NiV spillover occurs beyond the Nipah belt.

Viral surveillance of people exposed to wildlife. Our team is experienced with human surveillance and includes medical officers from IEDCR, the national public health agency responsible for Nipah virus outbreak investigations. Our group is currently conducting human surveillance for known and novel zoonotic viruses in three of our proposed study locations: Faridpur, Dinajpur, and Rajshahi, where there have been prior NiV outbreaks. Under our current USAID-funded PREDICT project, **we have already collected biological samples (blood, oropharyngeal and urine samples) and detailed behavioral questionnaires from 500 people**, including people in rural villages. The work proposed here will allow us to determine whether eastern populations with known date palm sap consumption rates have been exposed to Nipah virus, how exposure

**Fig 2.** Map of Bangladesh study sites

rates compare to western populations, and whether different risky behaviors occur in eastern and western Bangladesh.

**C2.2. Research design.** We propose to conduct a **serological and behavioral survey of individuals in six locations across Bangladesh to determine whether people in rural populations outside the Nipah belt have been exposed to Nipah virus and how palm sap consumption, geography, and other behaviors influence exposure.** This work will be done with our partners at the Institute for Epidemiology, Disease Control & Research (IEDCR) within the Ministry of Health, and icddr,b (see letters of support). We will identify six study locations: three within the Nipah belt (in Faridpur, Rajshahi, and Dinajpur districts) and three outside the Nipah belt (in Sylhet, Comilla, and Chittagong districts) that represent a range of household sap consumption rates based on our previous findings (**Figure 1C and 2**) that 50% to 90% of households

had someone who drinks 1 or more glasses of date palm sap per day [16]. We will use demographic data from our previous case control study to select sites in each district, capturing the range of intensity of sap consumption from low to high [16]. Villages will be paired west-east by high, medium, and low household consumption. We will randomly select households within 50km radius of a central point at each site and enroll each adult member within the household until we reach a sample size of 500 individuals per site. This gives a study cohort that includes both genders and a range of ages. Fifty km is estimated to be the distance people may reasonably travel within a day, as well as bat foraging range.

Trained medical officers from IEDCR will collect up to 10mL blood from each enrolled subject for serological testing. Serum will be separated on ice overnight, transferred to cryovials and transported to IEDCR in liquid nitrogen dry shippers. We will screen serum from all subjects for IgG antibodies against Nipah and all other known henipaviruses (Hendra, Cedar, & Mojiang) using a Luminex multiplex assay developed by the Broder lab and the CSIRO Australian Animal Health Laboratory in Geelong [45]. The assay will be performed at icddr,b, which has a Luminex machine. This assay has previously been used to screen human, livestock, and bat sera in Africa [46-48], Australia [44, 49], and Bangladesh, including our 6-year longitudinal study of bats and a livestock survey (**C2, Fig 3 and [50]**). Positive controls for the Luminex-based and confirmatory screening assays will be monoclonal antibodies (mAbs) and polyclonal antisera generated using the recombinant viral protein antigens as well as known positive bat and human serum samples. Confirmatory assays. The first line confirmatory tests for our Luminex-based assay will be a Nipah virus IgG ELISA [51]. IgG-negative serum samples will also be screened by an IgM Nipah ELISA at IEDCR, which is already standard practice during Nipah outbreak investigations [52]. This activity will build technical capacity for NiV detection within partner labs that are part of the national One Health Lab network and that routinely perform NiV diagnostic testing for the Government of Bangladesh (see icddr,b and IEDCR letters of support).

Our social scientists will administer a questionnaire to enrolled subjects to capture history of encephalitis, confirmed NiV diagnosis or contact with a suspected NiV case, contact with bats, hunting and eating bats, household proximity to a bat roost, frequency and volume of drinking date palm sap, collecting or eating bitten fruit from the ground, and exposure to pigs, cattle and goats [53-56]. These behavioral data will be analyzed with serological data to determine behavioral risk for NiV exposure.

**Data Analysis.** We will use generalized linear mixed models (GLMMs) to estimate effects of region, sap consumption, and other potential risk factors, clustering observations at site and household level to control for local effects of person-to-person transmission. Assuming a conservative background seroprevalence of 2%, a sample size of 3000 individuals (500/site), allows us to a) detect the presence of any NiV IgG antibodies in the population at each site with >95% confidence; b) identify differences in seroprevalence based on region with 78% power and 95% confidence; and determine effects of sap consumption (80% power, 95% confidence) on seroprevalence. (Power calculated via 1000 simulations [57] from a GLMM with effect sizes (odds ratios) of 2 and 10% standard deviation of variance among sites).

**C2.3) Expected outcomes.** Luminex provides a continuous quantitative output (mean fluorescence index, MFI) which can be used to detect reactive antibodies in a samples and compare strength of reactivity against multiple antigens using a single sample [45]. We will compare the MFI across all specific henipavirus antigens to assess which samples are NiV positive and which may be reacting to an antigenically-related henipaviruses [46, 50, 58]. In the absence of a definitive “positive” specific reaction from Nipah soluble glycoprotein, we would

interpret reactivity from the N protein and other henipavirus glycoproteins as an indication of antibodies against an unknown henipavirus.

**C2.4) Potential problems and solutions.** There is a possibility that we will not find anyone with IgG antibodies in some of the locations of our study, particularly in the eastern region. We used a very conservative assumption of low baseline seroprevalence (2%) and high variance to calculate a sample size that gives us confidence that we will identify seropositive individuals. While there is no published data describing baseline henipavirus exposure rates in areas not associated with outbreaks, we have based our estimates on Ebola virus (also bat-borne Ebola seroprevalence in populations not associated with EVD outbreaks have been reported between 0% and 24% [59], and our own work has found seroprevalence of 1-5.5% of antibodies against SARS-like coronaviruses in populations without SARS cases. Ultimately, our sample size would allow us to be confident that a negative finding was real, and so we could look comparatively at-risk factors in western and eastern locations and identify behavioral, bat, or virus-related differences (**from aims 2 and 3**).

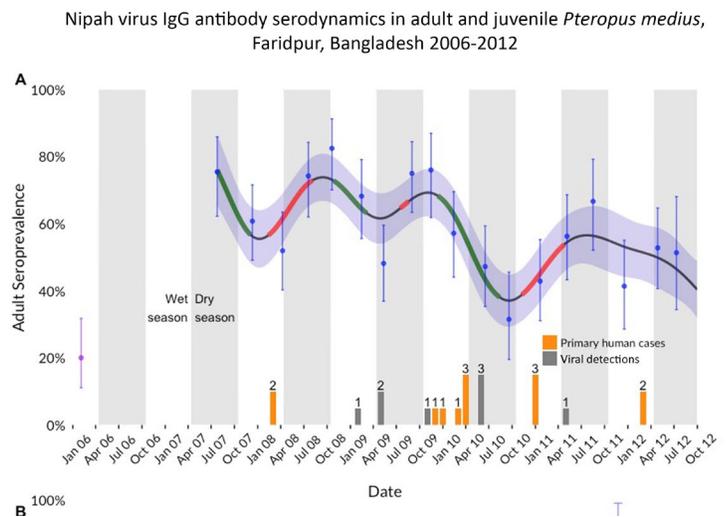

**C3. AIM 2: Compare Nipah virus temporal dynamics in *Pteropus* bat colonies inside and outside the Nipah belt, Bangladesh.**

**C3.1. Rationale and preliminary data.** NiV and Hendra virus infections are relatively rare in pteropid bats [19, 33, 60]. In Australia, Hendra virus has been detected in 1%-3% of bats sampled and 2.5% of pooled urine samples sampled [44]. In Malaysia, we detected NiV in less than 1% of bats [61].

However, serology data indicates that NiV circulates broadly within and among bat colonies. In Bangladesh, we screened more than 3,000 *P. medius* for NiV over 6 years and found 20-80% seroprevalence across different sites and periods, including a 6-year longitudinal study of a single population in Faridpur (**Figs 3&4**); Our work on spatial and temporal patterns of bat henipavirus infections has generated hypotheses on drivers of spillover risk [33, 36, 44, 62], and preliminary data for this proposal, including: **Location-based differences in Nipah virus seroprevalence in bats.** We detected anti-Nipah IgG antibodies in each of eight bat colonies sampled across Bangladesh between January 2006 and November 2012 ranging from 20% (95% CI: 10%-30%; n=99) in Rajbari to 56% (95% CI: 49%-63%; n=100) in Tangail.

Seroprevalence varied significantly among locations ( $\chi^2 = 55.61$ ,  $p < .001$ ), but we did not detect differences between sites within and outside the Nipah belt. Timing of sampling could explain some of the differences, but we also found that the population structure, which can influence viral dynamics, varied across space [63, 64]. We previously used satellite telemetry to show that *P. medius* exists as a metapopulation, and that connectivity among susceptible bats across multiple roost sites may allow henipavirus persistence even at low incidence [19, 36]. However, the more sedentary nature of *P. medius* in Bangladesh compared to *P. vampyrus* in Malaysia, and the short infectious period for NiV may create a patchy landscape of viral dynamics and diversity across bat populations in Bangladesh. This may explain the high viral diversity in disparate bat populations in Bangladesh (e.g. Faridpur vs. Comilla) and, by proxy, in human cases at different sites [36]. We also found that *P. medius* prefers to roost close to human settlements, rather than in intact forest [64]. Availability of roosting habitat and landscape types, including urban centers, as well as individual variation in viral shedding (e.g. bat superspreaders) can influence henipavirus dynamics [35, 65].

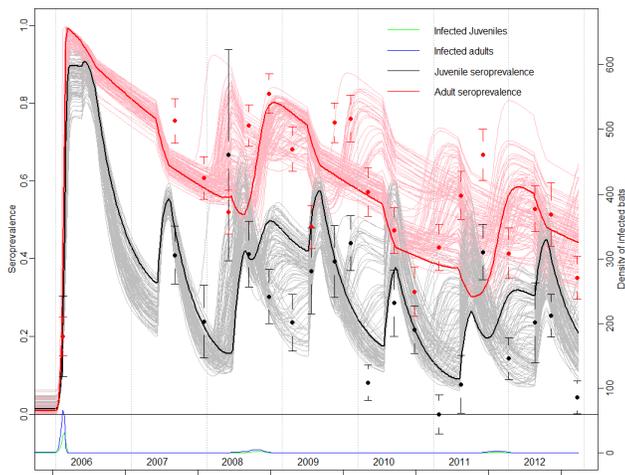

**Evidence for NiV in bats outside the Nipah belt.** Between 2006 and 2014, we detected NiV RNA in individual bats and pooled roost urine both inside (Rajbari, Thakurgaon, and Faridpur) and outside (Comilla and Sylhet) the Nipah Belt. **Of the pooled urine samples, three positive samples from Bhanga (n=19) and 16 from Joypurhat (n=19) were collected during active human outbreaks.** The estimated viral prevalence in individual bats from Rajbari in January 2006 was 3.8% (95% CI: 0% -11%; n=78). Viral prevalence estimates (18 sample points, 100 bats each) during the longitudinal study in Faridpur ranged from 0% to 3% (95% CI: 0%-10%; n=100) (see C3.1c). **The estimated detection rate from pooled urine samples across the entire**

**Fig 3. Seroprevalence fluctuations in the Faridpur bat population.** Observed data (blue points  $\pm 1$  SE) and GAM time-series fit, with periods of significant increase (red), and decrease (green). Bars indicate viral detections and local human cases.

study was 2.7% (+/- 1.6%; n=829).

**Temporal fluctuations in bat NiV seroprevalence are equal to or larger than location-based differences.** We found significant fluctuations in adult and juvenile seroprevalence in a single bat population sampled repeatedly over a six-year period (**Figs 3 & 4**). Juvenile seroprevalence ranged from 0% to 44% (95%CI 37%-51%), and decreased over the first year of life, with significant lower prevalence from mid-October to mid-December. Adult seroprevalence ranged from 31% (95% CI: 20%-46%) to 82% (95% CI: 77%-87%) and went through three periods of significant increase during the study, approximately two years apart (**Figure 3**). These periods did not occur in the same season each year. Each period was preceded by significantly decreasing seroprevalence [19]. **Sporadic human outbreaks may be explained by fluctuations within an approximate two-year NiV inter-epidemic period in bats.** We developed a parameterized mechanistic model of NiV transmission using demographic, serological, immunological, and virological data from our longitudinal study in Faridpur and published data (**Figure 4**). Model simulations suggest henipaviruses require periodic re-introduction via recrudescence or immigration to persist. Persistent henipavirus infection was observed in an isolated island population of *E. helvum* [58, 66], and NiV recrudescence has been observed in *P. vampyrus* [67] and in humans [68], indicating that **recrudescence leading to outbreaks within colonies is a likely mechanism of viral persistence.** However, re-introduction or recrudescence of NiV may not

**Figure 4. Mechanistic model simulations of NiV serological dynamics in adult and juvenile bats in Faridpur.** The observed data (red and black points  $\pm 1$  SE) and model fit (solid lines) for the fraction of adults and juveniles seropositive for NiV (left axis), and the model estimated density of infected adult and juvenile bats (bottom panel and right axis).

guarantee viral circulation in bats and depends on the proportion of susceptible adult bats at the time. Further, our longitudinal data was collected from a single bat population within the Nipah belt, it is unknown whether this is representative of bat viral dynamics across Bangladesh. **The high spatial variation in seroprevalence we found across sites may be due to either differing timing of viral circulation or differences in overall circulation rates.** Bat populations in other parts of Bangladesh may have different viral dynamics due to their size, connectivity, environment, or the genotypes of henipaviruses circulating locally. **We propose to conduct six parallel longitudinal studies of additional bat populations and model the viral dynamics, and experimental tests of reinfection as a driver of circulation, to test the hypothesis that transmission dynamics are heterogeneous across space, which may influence the frequency of spillover into human populations.**

*C3.1b Research Design: field sampling and modeling bat viral dynamics:* We will conduct six parallel 36-month longitudinal studies of NiV infection in *P. medius* at three

locations within the Nipah belt, including the Faridpur population previously studied, Rajshahi, and Dinajpur, in western Bangladesh; and three locations in eastern Bangladesh: Sylhet, Comilla, and Chakuria (**Figure 2**). We will select bat roosts that are comparable in size and structure to the Faridpur colony (e.g. number of bats, area of trees containing the roost, proximity to village center and closest urban center), which had ~1,000 bats at its maximum size. We will capture and sample 60 bats at each site every two months for 36 months. We will perform roost counts at flyout (dusk) on the first night of each sampling trip. We will capture adult and juvenile bats, but sample no more than 10 juveniles per period. Given the range of seroprevalence we observed previously (20% - 56%), 50 adult bats will allow us to determine seroprevalence differences of at least 20% with >95% confidence. Bats will be captured using mist nets, and anesthetized using isoflurane gas and a portable vaporizer as previously described [69]. Field personnel will wear appropriate personal protective equipment, including dedicated long clothing, an N95 or P100 respirator, nitrile gloves and safety glasses [69]. We will record each bat's age class (juvenile or adult), sex, mass, and body condition, and collect up to 3.0ml blood, and either urine or urogenital swabs. All bats will be released at the site of capture following sampling. One set of urine samples will be placed in Trisol and the other in viral transport medium and immediately stored at -80C in a liquid nitrogen vapor cooler (dry shipper). Blood will be collected in 3.0ml vacutainer tubes with clotting factor (red top) and allowed to stand vertically on ice overnight so that serum separates. The following morning, serum will be aliquoted into two cryovials and frozen neat at -80C.

To maximize detection of viral RNA and virus isolation when bats are shedding, a locally resident team of

field technicians will collect pooled urine samples twice per week from underneath the study colony at each site using 2x3m plastic sheets while bats return from foraging at approximately 0600h as conducted previously [70-72] and (**section C4.1**). Technicians will wear full PPE as described above but with hooded Tyvek suits and face shields. Pooled samples from each sheet will be split and aliquoted into lysis buffer and VTM, placed into a liquid nitrogen dry shipper and sent to icddr,b every 15 days. Urine samples will be tested by experienced technicians, trained in biosafety, at icddr,b using a real-time PCR assay that targets the N gene region of NiV [73]. When a positive PCR reaction is discovered, urine samples will rapidly be collected from individual bats in the colony to maximize opportunity for isolating multiple viral strains. We will also test urine samples using a consensus RT-PCR paramyxovirus assay that targets the nucleocapsid gene region, and has previously detected novel Nipah-related viruses in *P. medius* under our USAID-EPT PREDICT funding [74, 75]. Samples will be stored in a -80C freezer at icddr,b or IEDCR until tested.

*Data Analysis:* We will characterize and compare bat-viral dynamics using two modeling approaches: a nonparametric model to measure the periodicity and seasonality of NiV circulation events in the bat populations; and a mechanistic, stochastic, model to derive epidemiological parameters to compare across populations. For the nonparametric approach, we will use Generalized Additive Mixed Models (GAMs) [76], to fit curves estimating the time-varying seroprevalence at all sites. Seasonal and inter-annual effects will be estimated separately. This model will allow us to determine (a) periods with significantly increasing seroprevalence from which we can infer active viral circulation in the bat population, (b) the degree to which seasonality and periodicity of viral circulation are consistent and predictable within sites, (c) the degree to which seasonality and periodicity are common among sites in the region, and (d) across all sites. We estimate that we will be able to detect differences between eastern and western sites in overall seroprevalence of 20% with >95% power, and differences in timing of one quarter with 75% power. (Estimated via 1000 GAMM simulations with site-to-site standard deviation of seroprevalence 20% and timing of 1 month, 95% confidence).

To estimate epidemiological parameters we will fit a stochastic, age-structured, Susceptible-Infected-Recovered-Susceptible (SIRS) model which includes bat demographic processes. We will use partially observed Markov Process framework (POMP) [77] to fit this model. This will allow us to estimate the number of infected individuals based on the recovered (seropositive) dynamics, as well as a time-varying  $R_0$  value in the bat population, transmission rates among different age classes, infectious periods, and re-infection rates. As with GAMs, parameters from captive bat experiments will be incorporated resolve key ambiguities that cannot be resolved from the time-series data, primarily bounding recrudescence and antibody waning parameters.

C3.1d *Expected outcomes.* We expect that there will be differences in the temporal dynamics of each bat population. We do not expect significant differences in roost demography based on location (adults vs. juveniles, male vs. female). **Our preliminary data suggests that we will see at least one episode of viral circulation within a three-year period at each field site.** We are confident that we will be able to capture differences in infection dynamics among our study sites. Our previous experience is that viral isolations were infrequent but high during high circulation events in bats, including around human outbreaks. **We estimate we will generate 15 new isolates if each site has only a single high-circulation event over the course of the study,** in addition to those collected at outbreak events. (Assuming 50% positive during such events, which were 84% in our previous work).

C3.1e *Potential Pitfalls and Solutions.* It is possible that our selected bat roost will be disturbed or destroyed during the study. Bats utilize multiple roost sites within at least a 10km radius and regularly shift among these sites [19]. Therefore, we would be able to identify nearby roosts that represent the same local bat population. We will microchip bats at each site to determine whether the new site includes bats from the initial site.

### C3.2 **Experimental wild-type NiV infection of *P. medius* with and without anti-NiV IgG antibodies.**

C3.2a. *Rationale and preliminary data.* Studies of NiV transmission in free-ranging bats are limited by low infection rates. Serology data, while more readily obtained, is an indirect measure of infection. For example, IgG antibodies indicate past infection, but it is difficult to know exactly when, or to which virus a bat was exposed, **and it is unknown whether IgG positive bats can recrudescence, be re-infected by, or shed virus.** Experimental infections will provide fundamental information about henipavirus pathogenicity and transmission that is impossible to obtain from sampling wild bats. Previous studies of NiV infection provided data about viral replication, shedding and host immunological response in pteropid bats, but relied on a human NiV isolate for inoculation [11], which limited the interpretability of results [11]. Recently, our group has obtained 11 viral isolates from *P. medius* (Section C4), allowing us to study wild-type NiV in its appropriate host under

controlled experimental conditions. Very few laboratories have experience conducting experimental bat infections using zoonotic viruses – especially viral select agents. Among them are AAHL in Geelong, with whom we've conducted Nipah and Hendra infections in *Pteropus* species [11] and Rocky Mountain Laboratories in Montana [4], with whom we are currently collaborating under this proposal and who now have facilities designed to house pteropid bats and will receive our Nipah isolates (see **letter of support & MTA**). **Our aim is to conduct an experimental infection at NIH RML to determine whether seropositive *Pteropus* bats can be infected by NiV and sustain a productive viral infection.** This will allow comparison of the duration and intensity of viral shedding in bats with no detectable antibodies to Nipah, representing susceptible members of a colony, and those with MFI readings equal to a positive IgG titer that represent “recovered” or resistant individuals. These empirical data cannot be obtained through studies of free-ranging bats and is critical for parameterizing our models so as to be able to compare viral dynamics across sites.

PI Epstein and Co-I Daszak are among the few **that have experience internationally transporting *Pteropus* bats.** We organized successful capture, quarantine, and export of *Pteropus vampyrus* from Malaysia to CSIRO AAHL, Australia for experimental infection studies [11]. We will catch and quarantine 60 adult female *Pteropus medius*. Bats will be sourced from Raipur District, where we have previously isolated NiV [1](**section C4.1: Aim 3**). We will house them humanely in a closed facility that has double fencing and prevents exposure to wild bats as we have done previously [11, 67], and test all 60 bats for NiV IgG antibodies using a Luminex assay and IgG ELISA and for viral RNA in urine and saliva using a real-time NiV PCR weekly for three consecutive weeks. We will select 34 individuals for shipment: 16 without detectable IgG antibodies; and 16 with IgG antibodies of a similar MFI level (within 10% of mean MFI) using the Luminex assay described above (**section C2.2**), plus two additional controls for histopathology. Our experienced team will handle bats while sampling, and animal care staff will also be trained in biosafety and use of PPE when feeding/cleaning quarantine cages (dedicated clothing, nitrile gloves, eye protection and N95 respirators. The remaining bats will be released by our team at the original roost site. The seropositive and seronegative groups will be separated after the initial test and held in quarantine until all individuals have three successive negative PCR tests. Bats will then be exported from Bangladesh, with all appropriate CITES and export permits from the Bangladesh Forest Department, and US import permits from US Fish and Wildlife and US CDC, and sent to NIH RML where they will be housed as two separate groups under BSL 2 conditions until the start of the experiment.

#### C3.2b. *Research design: experimental infection of wild caught *Pteropus medius* with wild-type NiV.*

Bats will be moved into the BSL 4 lab 1 week prior to NiV inoculation so that they become acclimatized. We will then inoculate 32 bats (16 seropositive and 16 seronegative) with  $10^5$  TCID<sub>50</sub> NiV<sub>Ray</sub> which is currently in process of being transferred from AAHL to RML (**see MTA**). Bats will be inoculated with a combination of intranasal (25ul each nostril) and intraperitoneal (100ul) routes. Two mock inoculated bats will be included as controls and used for histopathology and DNA genomic sequencing. Mock inoculated bats will be inoculated with standard tissue culture media via the same routes and volumes described above. Animals will be monitored daily for signs of disease, including change in temperature and weight. Blood, oropharyngeal and urine samples or urogenital swabs and rectal swabs will be collected on days 1-15 PI. The experiment will run for 56 days. On days 4, 8, 16, 20, and 32, 48, and 56, 2 bats will be euthanized and we will collect trachea, heart, lung, liver, spleen, kidney, duodenum, coon, bladder, nasal turbinates, and brain for virological, clinical chemistry, gene expression, histopathological analysis. Throughout the experiment shedding from the respiratory and urogenital tract will be analyzed by qRT-PCR and virus titration. Pre-inoculation and end-date blood draws will be used to isolate PBMCs. An Elispot assay will be used to determine the level of pre-exposure to Nipah and the development of interferon- $\gamma$  secreting CD4 and CD8 T-cells after infection.

*Data Analysis:* We will use GLMs to compare outcomes between groups and GAMs to conduct area-under the curve analysis to measure viral shedding. We will have at least 89% power to detect infection rates as low as 10% in the seropositive bats as late as the last day of the experiment when the fewest of each group (9) will be available for testing (95% power, Wald exact binomial test).

C3.2c *Expected outcomes.* **This experiment will provide critically important information missing from mechanistic models of Nipah transmission within bat populations,** and would allow us to more accurately understand viral outbreaks in bats and spillover to humans. We expect to see the seropositive group have limited or no viral replication post inoculation. We may see viral replication in endothelial cells and in certain organ tissue, but without viral excretion. If the seronegative bats are truly naïve, we would expect to see a

productive infection over a 10-18 day period that includes shedding of virus in urine and saliva [78]. The duration and intensity of viral infection in the seropositive individuals will be an important outcome and will be highly informative.

**C3.2d Potential problems and solutions.** One limitation of this experiment is that we may not be able to differentiate between seronegative bats that have never been exposed to NiV (naïve) and those with prior exposure but with titers below the Luminex detection threshold. We have observed high (>70%) seroprevalence and individual seroreversion (change from seropositive to negative) in individual recaptured bats, and in experimental studies, so we know that individual titers wane over time [19, 79]. This suggests that most bats are exposed to NiV at some point. To assess the historic exposure status of the animals we will develop a bat interferon- $\gamma$  Elispot assay to detect IFN- $\gamma$  secreting CD4 and CD8 T-cells. **This experiment reflects a natural state where most adult bats in a colony are either seropositive or have been previously exposed and are susceptible.**

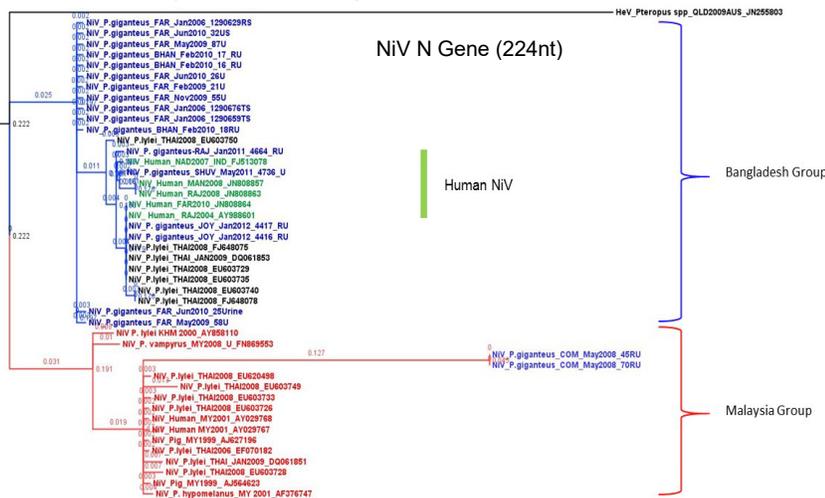

**C4. AIM 3: Compare pathogenicity and transmissibility of diverse Nipah virus isolates from bats inside and outside the Nipah belt, using animal models. C4.1 Rationale and preliminary data. Nipah virus genetics appears to influence its pathogenicity and transmissibility, but the relationship between genotype and phenotype has not been adequately studied.**

In the first recognized NiV outbreak in Malaysia 1998-99, person-to-person transmission was observed rarely [80-82], but in Bangladesh person-to-person transmission has accounted for over one-third of recognized cases [53]. Only 14% of patients infected during the Malaysian outbreak presented with cough, and only 6% had abnormal chest radiographs [83]. By contrast, 62% of confirmed Nipah patients in Bangladesh had cough, 69% developed difficulty breathing with chest radiographs often showing substantial pulmonary involvement [84]. Differences in human-to-human patterns of spread and mortality rates have been observed in different outbreaks in Bangladesh, and superspreaders identified in some [8, 85]. Further, we detected non-neutralizing antibodies against NiV in 44% of 138 pigs in Bangladesh with no history of severe respiratory or neurologic disease, suggesting that they may have been exposed to a less pathogenic strain of NiV [50, 54, 86].

Animal models have shown differences in pathogenicity, disease progression, and transmissibility among NiV strains. In nonhuman primate models, the Bangladesh (NiV-B) strain was more pathogenic than the Malaysia strain, NiV-M [42]; in Syrian hamsters, NiV-M caused more rapid onset of disease [40] and ferrets had significantly higher viral load in oral secretions when infected with NiV-B suggesting a greater likelihood of NiV-B being transmitted through close contact [38]. Syrian hamsters are a lab animal model that replicate human respiratory and neurological disease when infected with NiV [2, 87, 88]. Our group has extensive

experience performing transmission and pathogenicity experiments with NiV using a hamster model, under BSL 4 conditions [2, 3, 5, 40]. **Our aim is to test the hypothesis that diverse bat Nipah virus strains from different locations in Bangladesh have differences in pathogenicity and transmissibility in the hamster model (at NIH RML).** If full genome human NiV sequences are obtained by IEDCR concurrently with bat NiV sequences during an outbreak, we will also compare them to assess genetic differences between local bats and humans and the clinical outcomes observed in the outbreak.

*Evidence for NiV diversity in bats in different parts of Bangladesh. We have strong evidence for naturally-occurring NiV strain variation and have detected*

**Fig 5. Nipah Virus phylogenetic tree:** Clustal W alignments on N (224nt), G (1826 nt) and P (2174 nt) gene sequences. *P. medius* NiV sequences shown in blue and human sequences from Bangladesh shown in green. Other sequences from bats, pigs and humans in Malaysia, Thailand, and Cambodia are in black or red. Sequences from Comilla cluster within the Malaysia NiV group.

more than 15 different NiV variants, including a **highly differentiated strain from eastern bat populations in Comilla (Figure 5)**. The N gene sequences from bat colonies in Faridpur collected between 2006 and 2011

were identical in the N gene region, showing stability over time. Human NiV N gene sequences collected from various locations within the Nipah Belt over the same time period show more nucleotide diversity than those from a single *P. medius* population over multiple years (Faridpur), but across the Nipah belt, human NiV sequences were nested within the larger diversity found in *P. medius*. By contrast, **the viral N-gene sequence detected from bats in Comilla, 150km east of Faridpur, was significantly (~20%) divergent from those in bats and humans in the western part of Bangladesh, and more closely related to Malaysia than Bangladesh NiV strains.** These findings suggest that geographic, not temporal, variation is the primary determinant of NiV natural sequence variation.

Genetic differences in NiV strains found in the East may, in part, explain why human clusters have not been observed. NiV Malaysia and NiV Bangladesh are about 91-94% similar. If a difference of 6% nucleotide diversity can affect the clinical phenotype (i.e. Malaysia vs. Bangladesh strains), then it is plausible that there would be phenotypic differences in a NiV strain that was 20% divergent from known strains.

**Bat viral isolates obtained during outbreak investigations.** We currently have a partnership with IEDCR, via an MOU, through which we participate in outbreak investigations where we can locate and intensively collect roost urine from bats at the site and time of human cases, as close in time as possible to the initial spillover event. **This approach has resulted in us obtaining 12 viral isolates from bats in a 2013 outbreak**, which we can use in animal model experiments at RML. In April 2013, we collected urine samples under *P. medius* roosts during an outbreak investigation in Raipur, Pabna. Full-length genome sequences were characterized from 10 of the bat NiV isolates [1]. All bat isolates had an almost identical genome sequence with 99.9% conservation among all ten genomes characterized in this study. The complete sequence identity match among the isolates obtained during the outbreak investigation in Raipur suggests there were not multiple strains co-circulating in the Raipur bat population at the time of sampling, supporting our previous study in Faridpur where prevalent strains may persist over time in a population. In addition to the outbreak-associated isolates, we isolated virus from an individual bat in Sylhet (eastern Bangladesh) during normal sampling activities[1]. There has not yet been any experimental study using outbreak-associated bat viral strains *in vivo* that links viral genetic characteristics with clinical and epidemiologic outcomes. Previous experiments with NiV have relied on using highly passaged viral cultures from Malaysia, which were derived from pigs and passaged through many cell lines; or Bangladesh strains from humans which were also passaged through cell lines [11, 43]. **Our group has the only set of viral isolates from *Pteropus medius*, the actual natural reservoir and source of human infection in Bangladesh. We also now have a proven methodology for sampling bats that has significantly increased our NiV detection and isolation rate.** Our isolates from Raipur and Sylhet are currently being transferred from AAHL (Geelong) to NIH RML (see MTA) which will allow us to use them in the proposed animal model experiments. **RML will conduct these experiments as a collaborative endeavor, (charging only for supplies) which makes them achievable under this proposal timeline and budget.**

#### C4.2. Research Design

##### C4.2.a Experimental infection of hamsters with bat NiV strains to assess pathogenicity and transmissibility.

We will select six of the most genetically diverse bat NiV isolates obtained from *P. medius* and use them in Syrian hamster experimental infections to compare transmissibility and pathogenicity. **This will be conducted in two separate experiments – one to compare pathogenesis among viral strains, and a second to compare transmissibility.** The experimental design for the analyses of differences in pathogenicity and transmissibility between different isolates of Nipah virus has previously been used by our group to determine difference between Nipah virus Malaysia and Nipah virus Bangladesh [2, 5, 40, 89, 90]. We will use six different isolates, including two already obtained (**see section C4.1**) to infect Syrian hamsters. All experimental animal studies will be conducted by Co-I Munster under BSL 4 conditions at NIH NIAID Rocky Mountain Lab (see RML letter of support). We will use animal models to compare the transmissibility and pathogenicity of diverse NiV **wild-type** strains obtained from bats. We will select candidate strains for use in the experiment by conducting a whole genome phylogenetic analysis for each isolate and look at % similarity of each gene region to a base genome, which will be the genome from our isolate in Raipur. We will examine nucleotide-level nonsynonymous mutations across genomes for evidence of positive selective pressure, and identify the % nucleotide and amino acid differences between each isolate and the Raipur genome. We will select 2 additional isolates from within the Nipah belt and 2 from outside the Nipah belt that have the greatest phylogenetic distance from the basal (Raipur) genome. Since it is currently unknown exactly how genetic differences correspond to phenotypic differences, this approach maximizes our opportunity to look at diversity and disease outcome and whether location influences genetic diversity (e.g. the 20% partial N-gene divergent

NiV we found in Comilla). We will use an adaptive selection strategy should new information arise during the project period that would allow us to more effectively choose isolates for the experiments.

**Bat Nipah virus isolation.** As soon as a suspected Nipah virus cluster is identified by IEDCR, and an investigation initiated, we will travel to the outbreak site and identify 3 bat roosts located within 5km of the index case's village. We will collect urine under each roost daily for 10 consecutive days by laying down 4 2mx3m plastic sheets under each roost daily, and pooling all urine droplets on each tarp to make one sample. Each sample will be divided evenly and placed in a cryotube with Trisol for testing by real-time PCR at icddr, b [73] and another tube with VTM for viral culture which will be stored at -80C until testing. PCR-positive bat samples and their paired VTM sample will be sent to NIH RML for whole genome sequencing and viral culture under BSL 4 conditions [37]. Briefly, vero cells in 96-well plates will be prepared in EMEM containing 10% fetal bovine serum and 1x Antibiotic-Antimycotic. 50 µl of each individual sample will be added to two wells and incubated for 90 min. Inoculum will be removed and 200 µl EMEM was added to each well. At 7 days post infection (dpi) at 37°C the plates were checked for cytopathic effect (CPE) and subsequently frozen at -80°C. Putative virus culture from wells showing CPE will be passaged a second time by inoculation of a 24-well plate containing 80% confluent Vero cells in EMEM with 80 µl culture supernatant from each of the positive wells. Plates will be incubated at 37°C for 90 min, inoculum removed and 1 ml EMEM added. Plates will then be incubated at 37°C for 5 days. For a third passage, 300 µl of culture supernatant will be transferred to a 25 cm<sup>2</sup> flask containing 80% confluent Vero cells. The flasks will be incubated for 90 min at 37°C then the inoculum will be removed and 5 ml EMEM added. The flasks will be incubated at 37°C and viral supernatants harvested at 2-3 dpi. Supernatants will be clarified by centrifugation at 10,000 RCF for 5 min and frozen at -80°C.

**Whole genome sequencing for phylogenetic comparisons.** A virus enrichment strategy [91] will be used at RML for bat NiV samples to obtain the full genome sequence for the NiV isolates. All reads will be mapped to NiV sequence JN808863 using the Map to Reference function in Geneious (Geneious version 7.1.6). The consensus nucleotide sequence will be selected by majority rules at each site. To ascertain the 5' and 3' ends due to low coverage and PCR errors and chimeras, full genome Nipah virus sequences from GenBank will be aligned using MAFFT in Geneious. A 90% similarity threshold will be used to generate consensus 5' and 3' sequences of 120 nucleotides. Full genome henipaviruses will be downloaded from GenBank and an alignment generated with the MAFFT plugin in Geneious. Node robustness will be tested using 1,000 bootstrap replicates under the GTR+  $\Gamma$  model in PHYML [92].

### **Experiment 1: Comparing pathogenicity of NiV strains from inside and outside the Nipah belt.**

In this study, we will analyze the differences in NiV phenotypes in the Syrian hamster model. We will use six experimental groups of 10 animals – one for each selected bat viral isolate, and a control group with 5 animals. Animals will be challenged intranasally with  $10^{3-5}$  TCID<sub>50</sub> of NiV. Control group will be inoculated with uninfected cell supernatant. A single intranasal inoculation will be delivered in a 60 µL dose (30 µl/nare). Oral and nasal swabs will be taken daily following infection. On day 5 after challenge, four animals from each group will be euthanized to monitor virus replication. The remaining six animals will then be monitored for survival for up to 28 days. All manipulations will be conducted on animals anesthetized with inhalational isoflurane. Blood samples will be collected from the hamsters before inoculation and at the endpoint. No more than 10% of the blood volume in a two-week period will be collected. A single, terminal blood sample will be collected at the end of the experiment. Animals will be anesthetized and bled via cardiac puncture. Virus titers and viral RNA load will be measured from swabs obtained from the nose and throat. Virus titers and viral RNA load will be measured in target organs, such as the lung, brain and spleen. Survival rates will be analyzed for all groups.

### **Experiment 2: Comparing transmissibility of NiV strains from inside and outside the Nipah belt.**

In this experiment, we will analyze the contribution of shedding and contact transmission using the same viral isolates as in experiment 1. We will use 6 groups of 12 hamsters (70 total). Each group will have two sets of 6 hamsters. For each group of six, three will be inoculated with NiV, then on day 1 after inoculation, an additional set of 3 naïve hamsters will be put together with the inoculated animals. All naïve animals will be monitored for clinical signs and survival for up to 28 days. In order to obtain consistent results we will do 2 sets of six animals per NiV strain. Video of each experimental group will be collected for 3 hours on day 1-4 post inoculation and contact behaviors characterized. As in Experiment 1, nasal and oral swabs will be collected daily and a pre-inoculation and terminal blood sample will be collected to screen for antibodies. Several different parameters will be investigated in the experiment outlined above. Virus titers and viral RNA load will be measured in target organs, such as the lung, brain and spleen from animals reaching end-point criteria. Survival rates will be analyzed for all groups. Seroconversion will be analyzed using a NiV G specific ELISA assays.

**Data Analysis:** We will analyze outcomes of hamster model infections using GLMs, with strain being the main effect and survival rate, viral titer, and presence of clinical signs as the outcome. To avoid multiple comparison issues, we will model viral titer across tissue types and clinical signs as a single, multivariate outcomes rather than a series of individual measures. We expect to capture large, qualitative phenotypic differences between strains similar to those between Bangladesh and Malaysia strains measured in experiments with comparable sample sizes [39, 93], where differences in viral titer in organs between strains were an order of magnitude - essentially binary responses. For such binary responses, assuming 3X difference in probability of outcomes (0.75/0.25), we will detect differences in symptoms measured in euthanized animals (4) with 68% power, differences in remaining animals (6) with 81% power, and differences measured in all animals (10) with 94% power. We will detect differences in transmission (also a binary outcome) with 81% power. (Exact binomial Wald statistics used in all cases). To determine whether there will be significant differences in the time to death between viruses, a log-rank test will be performed. In addition, area under curve analyses will be performed to determine difference in magnitude of shedding.

**C4.2.b Comparing human and bat NiV sequences obtained during human NiV outbreaks.** IEDCR has agreed to send PCR-positive human samples to RML for whole genome sequencing. If we are able to sequence full Nipah virus genomes from humans and bats within the same outbreak, we will conduct comparative phylogenetic and functional genomic analyses to look at mutations that have occurred after spillover and also to test the hypothesis that human viral genomes are most similar to the virus circulating in local bats compared to virus in bats from other locations.

**C4.2c Expected outcomes. We have been successful in isolating NiV from bats.** The hamster experiments will provide key information about differences in tissue tropism, clinical signs, and how strain genetics may influence transmission and epidemic profiles. Our whole genome phylogenetic analysis will provide new insight into which gene regions show greatest positive selective pressure, and how genetics correlates with epidemiologic and clinical profiles.

**C4.2d Potential problems and solutions.** Challenges in isolating virus from bats: **First, we already have 12 bat NiV isolates in hand from 1 location within and 1 outside the Nipah belt [1] demonstrating that both collection methods (outbreak urine collection and individual bat sampling) have been successful.** We are confident that we will obtain at least four additional isolates necessary to fulfill the requirements for this aim. Human Nipah outbreaks occur annually. There were an estimated 57 NiV spillovers (bat-to-human transmission) detected in Bangladesh between 2007 and 2013 [21], an average of more than 9 spillovers per Nipah season. We conservatively estimate that IEDCR will detect and investigate three outbreaks per year, from which we may obtain viral isolates from associated bats. We expect to have at least 15 opportunities to isolate virus (3 from outside the Nipah belt, 3 from within, plus at least 9 outbreaks).

**Project management and timeline.**

**Project Management: Overall project:** J. Epstein (PI, EHA)  
**Study design:** J. Epstein, P. Daszak (EHA), M. Rahman (icddr); **Field coordination:** M. Flora (IEDCR) A. Islam (EHA); **Lab testing & analysis:** Z. Rahman (icddr), C. Broder (USUHS); **Viral isolation & animal experiments:** V. Munster (RML), **Data management, statistical analysis & modeling** (N. Ross)

---

Chris,

I'm going to resubmit our Nipah R01 on Oct 7th. I've had extensive discussions with EunChung about it - it got really close to being funded, but now it's got to go back in as a new submission.

Given your stellar track record with NIH, would you be willing to go through it and the reviewer comments with me and let me know what you think we could change to get it funded?

-Jon

## **1I80VP000180-01 Olival, Kevin**

**RESUME AND SUMMARY OF DISCUSSION:** This proposal plans to improve the diagnostic capability for detection of coronaviruses (CoV). Coronaviruses are responsible for Severe Acute Respiratory Syndrome, Middle East Respiratory Syndrome, and perhaps other severe and acute infections. The intent in this proposal is to leverage existing relationships in Jordan and the Republic of Georgia to develop a new assay system for coronavirus surveillance based on microsphere luminescent multiplex technology in animals and humans and to detect disease.

The discussion raised several questions with regard to the stage of development of the assay, the strength of the preliminary data to date, the selection of geographic areas for field testing, and additional issues. Specific points included:

- The assay system is at a preliminary stage of development and still requires validation.
- The preliminary data are not sufficiently robust to proceed with field testing and the time required to have sufficient confidence in the multiplex read out may be more than currently estimated
- A performance comparison of the candidate assay with other existing methods is not described
- Other parts of the world with a U.S. military presence have higher endemic rates of coronavirus infections and may harbor larger reservoirs. The selected areas may have limitations to fully test the system and assess its utility and potential impact.
- A method to distinguish samples from people that were exposed from samples from infected individuals is missing.
- The human subject protection excludes children, who well may be a significant at risk population and additional reservoir for infection. An approach to include children would form a more complete description of the ecology and risk factors for infection.
- The disposition of people that have a positive signal with regard to treatment and follow up is not described.

**DESCRIPTION (provided by applicant):** Emerging coronaviruses (CoVs), e.g. Severe Acute Respiratory Syndrome coronavirus (SARS-CoV) and Middle East Respiratory Syndrome coronavirus (MERS-CoV), represent a significant threat to global health and security. EcoHealth Alliance, together with partners from Uniformed Services University, propose to increase trans-regional medical readiness for emerging CoVs by strengthening early detection and biosurveillance capabilities where they are needed most – in partner nation laboratories in the Middle East (Jordan) and Europe (Georgia) at the front line of disease emergence. Our multi-disciplinary project integrates novel diagnostic assay development, field surveillance at the human-animal interface, training and laboratory capacity strengthening, and data analytics to identify risk factors for CoV emergence and inform strategies for better force health protection. We propose five specific aims: Aim 1) Develop recombinant MERS-CoV and SARS-CoV protein antigens for a multiplex microsphere-based serological assay. Aim 2) Determine the seroprevalence of MERS-coronavirus across the human-camel value chain in Jordan to inform locations, seasons, and epidemiological interfaces of greatest risk. Aim 3) Transfer cost-effective Luminex-technology and multiplex serological assays to partner nation laboratories to accelerate early detection capabilities for emerging zoonotic diseases. Aim 4) Leverage an ongoing DoD-funded bat-borne disease surveillance project in CENTCOM and EUCOM countries to screen specimens for coronaviruses using multiplex serological assays. Aim 5) Develop and validate coronavirus ‘hotspot’ risk maps to improve situational awareness and force health protection. Modeling outputs and timely project results will be synthesized for policy makers in short reports throughout the project. Our proposed activities meet the outlined Global Health Engagement objectives and CENTCOM Demand Signal as follows: Novel research that leverages ongoing efforts focused on MERS-CoV; Develop, optimize, and transfer low-cost, multiplex technologies to strengthen partner nations’ lab capabilities and early detection for emerging pathogens; and combine human and

animal surveillance data with advanced disease risk mapping analytics to prioritize warfighter and force health protection. Together, our proposed research program will integrate the development, optimization, installation and application of a robust and cost-effective platform for CoV biosurveillance covering a large trans-regional footprint within CENTCOM and EUCOM. 1

**PUBLIC HEALTH RELEVANCE:** Emerging viruses represent a significant threat to global health and security in the US and globally. One group of viruses of particular concern are Coronaviruses – which include SARS coronavirus that caused a pandemic in 2002-03 killing 10% of people infected, and MERS coronavirus continuing to infect people in the Middle East with a mortality rate of 35%. This project will develop new, cost-effective tools for the early detection of coronaviruses, and transfer those diagnostic platforms where they are needed most – in partner nation laboratories at the front line of disease emergence. We will screen human, camel, and bat samples and use this information to better understand and protect against the risk of coronavirus emergence. ! 1!

## CRITIQUE 1

Significance: 3

Investigator(s): 3

Innovation: 4

Approach: 4

Environment: 3

**Overall Impact:** The investigators propose to develop a Luminex multiplex microsphere serologic assay that will test for 4 MERS-CoV antibodies as well as SARS-CoV antibodies. Using multiple antigens, having the antigens in their native folded shape and using the Luminex platform are expected to increase sensitivity to be able to detect mild or asymptomatic infections. For preliminary, data they describe a 16-glycoprotein antigen that they have developed to detect multiple henipaviruses and filoviruses that are currently being validated and a Western blot showing that they have a stably expressed one SARS antigen and one MERS antigen that will be used in the proposed assay. They state that they will also validate their assay using samples from experimentally infected animals. The assay is expected to be completed by the end of year one. The multiplex assay and equipment and training for the assay will be disseminated in year 1 and 2.

They will then use the serologic assay to evaluate camels and camel workers in Jordan and will also screen archived samples from 1,000 people in Northern and Middle Jordan who have varying degrees of camel contact as well as an additional 1,000 bats from Jordan, Georgia and Turkey. Based on this data they will develop a “hotspot” risk map.

This proposal aligns with the scientific priority to “leverage ongoing efforts focused on MERS CoV.” MERS and SARS are important emerging pathogens that have high mortality and the capacity to cause serious outbreaks. Accomplishing these aims would impact on detection of emerging pathogens in a region where active military personnel are present.

The investigators are experienced in the Luminex multiplex assay development and the epidemiology of emerging viruses. However, the preliminary does not indicate that the multiplex assay will be fully validated by the end of the first year and the approach does not include a comparison to current methods. It will likely take more effort for validation if this is going to be a reliable tool for determining seroprevalence. This is very concerning because all of the other aims of the grant rely on the assay being better than current assays to be successful.

A weakness in the approach is that all of the human samples being tested are samples that have potentially been exposed to MERS, which makes it very difficult to determination of specificity.

The investigators do not plan to use the current serologies as a comparison in samples that they collect from camels and camel workers.

The investigators do not have alternative approaches to the assay not performing well.

There is no plan to refine the assay if individual components are unnecessary or are redundant.

The expression of one of four of the assay antigens is encouraging but leaves some concern about the proposed timeline.

Also of concern, is that the investigators cite a reference that they misinterpret as evidence that current serology is insensitive. In fact, this reference demonstrated that ELISA and plaque neutralization/reduction assays were sensitive in asymptomatic camel workers. The investigators stated that the T-cell assay in the reference were more sensitive than standard serology, which was not the case.

Also of concern is the fact that the incidence of MERS is much lower in Jordan with 28 cases being reported since 2012 compared to 1,854 cases in Saudi Arabia and there is no reason given for why these studies are not being done in Saudi Arabia where 83% of all cases have been reported. This decreases the likelihood that an adequate number of seropositive samples will be found and that it may not reflect the epidemiology of the significant hotspots of transmission. If there are logistical issues that prohibit the study of the disease in the area of greatest risk, then those issues should be stated in the grant.

## **1. Significance:**

### **Strengths**

- MERS CoV and SARS CoV are important emerging pathogens and better methods of surveillance would improve epidemiologic investigations.
- Identifying points with greater levels of infection risk would allow for interventions to decrease transmission to humans.
- Strengthening partner labs in Jordan and Georgia will be beneficial in detection and surveillance.

### **Weaknesses**

- Little evidence is presented that current immunoassays are insufficient.

## **2. Investigator(s):**

### **Strengths**

- The investigators are highly accomplished in all of the areas of research that are outlined and establish collaboration with investigators from Jordan and Georgia.

### **Weaknesses**

- None

## **3. Innovation:**

### **Strengths**

- Development of a novel multiplex assay and potential discovery of MERS-CoV transmission risk.

### **Weaknesses**

- None noted.

#### **4. Approach:**

##### **Strengths**

- The multiplex immunoassay with antigens in their native conformation may provide a more sensitive and specific test for MERS-CoV.
- The hypothesis that camel crowding in wholesale markets increases transmission is well founded and would be amenable to public health interventions.

##### **Weaknesses**

- This proposal is based on the premise that the current serologic assays are not sensitive. The evidence provided does not fully support this and the primary study referenced is misinterpreted. Aims 2-5 are dependent on aim 1. This is concerning because the preliminary data presented for the previous 16 antigen multiplex assay does not demonstrate a field validated assay or preliminary data regarding MERS-CoV validation. And, of the proposed MERS-CoV proteins, only the S2 has been expressed.
- Given that the seroprevalence of MERS-CoV is unknown in the population being tested determining specificity will be difficult to assess without testing in a non-exposed population.

#### **5. Environment:**

##### **Strengths**

- Substantial resources and collaborations.

##### **Weaknesses**

- Jordan's lower incidence of disease may not model risk in areas of higher transmission.

#### **Protections for Human Subjects:**

Acceptable Risks and/or Adequate Protections

Data and Safety Monitoring Plan (Applicable for Clinical Trials Only):

Acceptable

#### **Inclusion of Women, Minorities and Children:**

- Sex/Gender: Distribution justified scientifically
- Race/Ethnicity: Distribution justified scientifically
- For NIH-Defined Phase III trials, Plans for valid design and analysis:
- Inclusion/Exclusion of Children under 18:

#### **Vertebrate Animals:**

YES, all criteria addressed

#### **Biohazards:**

Acceptable

**Applications from Foreign Organizations:**

Justified

**Resource Sharing Plans:**

Acceptable

**Authentication of Key Biological and/or Chemical Resources:**

Acceptable

**Budget and Period of Support:**

Recommend as Requested

**CRITIQUE 2**

Significance: 2

Investigator(s): 1

Innovation: 1

Approach: 3

Environment: 2

**Overall Impact:** This project is truly a complete research project; assay development, through to application of this assay to assess epidemiological assessment of risk areas and mapping. This will increase our understanding of the epidemiology of CoVs and inform the risk of future transmission to humans. The team is strong and includes investigators in the study areas and includes investigators from the study country locations and has full support of public health bodies in these places.

**1. Significance:**

**Strengths**

- Addresses a pathogen which have /are currently causing large issues
- Understanding more about the possible spillover events is of vital importance
- This clearly addresses a priority area under this grant call.

**Weaknesses**

- Does not address what could be done with the greater understanding of where spillover could occur- could anything be included that would suggest ways to mitigate transmission?

**2. Investigator(s):**

**Strengths**

- Team with experience of successfully implementing this type of project
- Experience of such modelling and mapping work
- Experience with the serological platform
- Local partners in the Middle East

**Weaknesses**

- None noted.

### **3. Innovation:**

#### **Strengths**

- Testing of new multiplex assays
- Application of fairly newly developed modelling techniques
- Combination of all these disciplines is innovative

#### **Weaknesses**

- None noted.

### **4. Approach:**

#### **Strengths**

- Transfer of technology to partner institutions in Jordan and Georgia
- Development of serological testing
- Testing relevant possible animal reservoirs with this assay
- Application of modelling techniques to determine spillover events- however how these will be validated is not made clear in the application

#### **Weaknesses**

- Risk not addressed for what happens if serological test is not sufficiently good for this work
- Does not add to the evidence body about some of the other epidemiological factors that will impact the probability of spillover or the factors that lead to a spillover event that then causes severe disease in humans

### **5. Environment:**

#### **Strengths**

- Across multiple excellent diverse institutions
- Leveraged previously collected large banks of serum samples, collected by the PI's organization and other organizations that have provided their support
- All lab resources appear to be available in all locations
- Appear to have full support of ministry of health in Jordan

#### **Weaknesses**

- Bat samples are collected by a study with PI not included in this study, however letters of support are included.

### **Protections for Human Subjects:**

Acceptable Risks and/or Adequate Protections

### **Inclusion of Women, Minorities and Children:**

- Sex/Gender: Distribution justified scientifically

- Race/Ethnicity: Distribution justified scientifically
- For NIH-Defined Phase III trials, Plans for valid design and analysis:
- Inclusion/Exclusion of Children under 18: Excluding ages <18; justified scientifically

**Vertebrate Animals:**

YES, all criteria addressed

**Biohazards:**

Not Applicable (No Biohazards)

**Applications from Foreign Organizations:**

Justified

**Resource Sharing Plans:**

Acceptable

**Authentication of Key Biological and/or Chemical Resources:**

Acceptable

**Budget and Period of Support:**

Recommend as Requested

**CRITIQUE 3**

Significance: 2  
Investigator(s): 1  
Innovation: 2  
Approach: 5  
Environment: 1

**Overall Impact:**

**1. Significance:**

**Strengths**

- Little well defined understanding of serology of CoV in camels and spread to humans though they are thought to be primary hosts for these viruses.

**Weaknesses**

- None noted.

**2. Investigator(s)**

### **Strengths**

- Well qualified

### **Weaknesses**

- Less medical, may benefit from a clinical medical personnel to add to the extensive lab and veterinary medicine personnel

## **3. Innovation**

### **Strengths**

- Applying new technology to facilitate surveillance and improve laboratory detection facilities in Jordan and Georgia

### **Weaknesses**

- None noted.

## **4. Approach:**

### **Strengths**

- Well spelled out approach to the study and components of the study

### **Weaknesses**

- Protection of people that are deemed + for virus and implications are not delineated.

## **5. Environment**

### **Strengths**

- Partner locations and organizations with the appropriate technology and capacity to conduct study

### **Weaknesses**

- None noted.

### **Protections for Human Subjects:**

#### Unacceptable Risks and/or Inadequate Protections

- What will happen to participants who have virus detected, especially for pregnant women. What arrangements have been made for care.

#### Data and Safety Monitoring Plan (Applicable for Clinical Trials Only):

- Not provided. Need to provide

### **Inclusion of Women, Minorities and Children:**

- Sex/Gender: Distribution justified scientifically
- Race/Ethnicity: Distribution justified scientifically
- For NIH-Defined Phase III trials, Plans for valid design and analysis:
- Inclusion/Exclusion of Children under 18: Excluding ages <18; not justified scientifically
- No mention of why not children

**Vertebrate Animals:**

YES, all criteria addressed

**Biohazards:**

**Applications from Foreign Organizations:**

Justified

**Budget and Period of Support:**

Recommend as Requested

**THE FOLLOWING SECTIONS WERE PREPARED BY THE SCIENTIFIC REVIEW OFFICER TO SUMMARIZE THE OUTCOME OF DISCUSSIONS OF THE REVIEW COMMITTEE, OR REVIEWERS' WRITTEN CRITIQUES, ON THE FOLLOWING ISSUES:**

**PROTECTION OF HUMAN SUBJECTS: ACCEPTABLE FOR ENROLLMENT BUT QUESTIONS WITH RESPECT TO FOLLOW UP CARE**

**INCLUSION OF WOMEN PLAN: ACCEPTABLE**

**INCLUSION OF MINORITIES PLAN: ACCEPTABLE**

**INCLUSION OF CHILDREN PLAN: OPERATIONALLY ACCEPTABLE TO EXCLUDE CHILDREN LESS THAN 18 YEARS BUT NOT SCIENTIFICALLY JUSTIFIED**

**VERTEBRATE ANIMALS: ACCEPTABLE**

**COMMITTEE BUDGET RECOMMENDATIONS: The budget was recommended as requested.**

**Subject:** Panel Review of our GHERI FY18 submission  
**Date:** Tuesday, July 16, 2019 1:17:22 PM  
**Attachments:** [GHERI\\_Olival2018\\_summarystatement.pdf](#)  
[ATT00002.bin](#)

---

Eric and Chris,

Attached is the panel summary statement from our GHERI proposal we submitted on CoV assay development, and MERS and bat borne CoV surveillance.

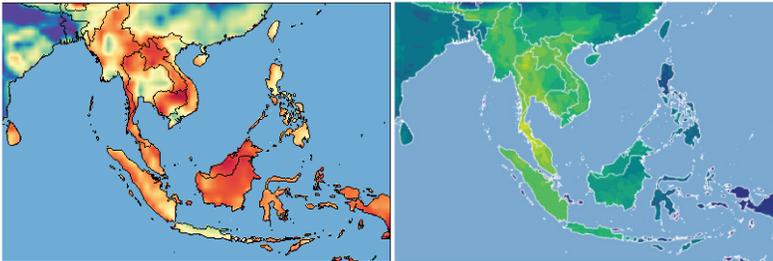

Disappointing we didn't get this, and unfortunately MERS isn't listed as a priority for FY19, so not sure this will be worth putting back in. Let me know your thoughts after reviewing the FY19 priorities.

In any case, Reviewer 1 was most critical, Reviewers 2 and 3 ranked it quite high overall. The main criticism were related to the assay development, validation, justifying the need for additional MERS/CoV serological assays, and our study design (i.e. not doing it in Saudi Arabia, and sampling unexposed people with an additional assay for validation).

Cheers,  
Kevin

## II. Research Strategy:

**1. Significance:** Southeast Asia is a critical hotspot for emerging diseases due to its high biodiversity of wildlife and their viruses, and the presence of key ecological and socioeconomic drivers of emergence (**Fig. 1**) (1). These include dense human populations living in networks of rural and urban communities, with strong cultural and occupational connection to wildlife and livestock farming and trading, and intimate connection to global travel networks (2). The region is undergoing rapid environmental and demographic change, both of which increase the risk of disease emergence and spread. Pathogens that emerge in this region often spread and sometimes enter the USA (e.g. prior influenza pandemics, SARS) and threaten global health security.

**Fig. 1:** Southeast Asia, and in particular, parts of Thailand and Malaysia are hotspots of risk for disease emergence (**left**), and predicted high diversity of 'missing' or as-yet undiscovered viruses, yellow = highest diversity (**left**). From (1-3).

Not surprisingly novel viruses, including near-neighbors of known agents, have emerged in the region leading to often unusual clinical

presentations (**Table 1**). This adds to a significant background burden of repeated Dengue virus outbreaks in the region (20), and over 30 known *Flavivirus* species circulating throughout S. and SE Asia (21). The events in Table 1 are dominated by three viral families: coronaviruses (CoVs), paramyxoviruses (PMVs - particularly henipaviruses) and filoviruses (FVs), which are initial examples of our team's research focus and capabilities. These viral groups have led to globally important emerging zoonoses (4, 5, 22-31), causing tens of thousands of deaths, and costing billions of dollars (32-34). Furthermore, near-neighbors of known pathogens in these families have been reported throughout the region, including by members of our consortium: henipaviruses in bats in Thailand, Cambodia, Philippines, Laos, Indonesia, China, Malaysia, Bangladesh and India (35-41); a novel henipavirus, Mòjiāng virus, in wild rats in Yunnan (14); serological evidence of FVs in bats in Bangladesh (42) and Singapore (43); Nipah- and Ebola-like viruses in *Hipposideros*, *Cynopterus* and *Rhinolophus* species in Malaysia (Hughes *et al.*, in prep.); evidence of novel FVs in bats in China (44-46), including Měnglà virus

Viral agent	Site, date	Impact	Novelty of event	Ref.
Nipah virus	Malaysia, Singapore 1998-9	~246 human cases, ~40% fatal	2 <sup>nd</sup> emergence of a zoonotic henipavirus, 1 <sup>st</sup> large outbreak	(4-6)
Melaka & Kampar virus	Malaysia 2006	SARI in family group, individual	1 <sup>st</sup> disease due to bat-origin reoviruses, also Singapore, Vietnam etc.	(7-10)
Reston filovirus	Philippines 2008	Seropositive people killed pigs,	No prior FVs in pigs	(11)
Thrombocytopenia Syndrome virus	E. Asia 2009	100s of deaths in people	Novel tick-borne zoonosis with large caseload	(12)
Reston filovirus	Shanghai 2011	PCR positive pigs	Further evidence of pig RESTV infection	(13)
Mòjiāng virus	Yunnan 2012	Death of 3 mineworkers	1 <sup>st</sup> evidence of rodent origin henipavirus in people	(14)
Nipah-like virus	Philippines 2015	Killed horses	No prior horse infection for NiV, known for HeV	(15)
SARSr-CoV & HKU10-CoV	S. China 2015	Seropositive people	1 <sup>st</sup> evidence human infection HKU10 & SARSr-CoV	(16)
SADS-CoV	China 2017	>25,000 pig deaths seronegative people	Novel emergence of bat-origin CoV	(17)
Nipah virus	Kerala 2018, 2019	Killed 17/19 people 2018, 1 infected 2019	1 <sup>st</sup> outbreak of NiV outside Bangladesh, W. Bengal focus	(18, 19)

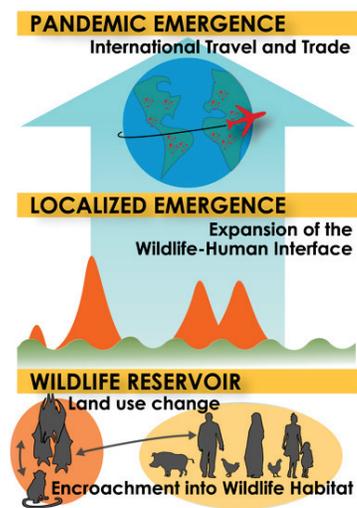

that appears capable of infecting human cells (47); novel PMVs in bats and rodents consumed as bushmeat in Vietnam (48); a lineage C  $\beta$ -CoV in bats in China using the same cell receptor as MERS-CoV to infect human cells *in vitro* (49); MERSr-CoVs in bat guano harvested as fertilizer in Thailand (50), and directly in bats (Wacharapluesadee *et al.*, in prep.); 172

**Table 1:** Recent emergence events in SE Asia indicating potential for novel pathways of emergence, or unusual presentations for known or

related viruses.

novel  $\beta$ -CoVs (52 novel SARSr-CoVs) and a new  $\beta$ -CoV clade (“lineage E”) in bats in S. China that occur throughout the region (24, 49, 51, 52); 9 novel wildlife-origin CoVs and 27 PMVs in Thailand, and 9 novel CoVs in Malaysia reported by us from USAID-PREDICT funding (51, 53). These discoveries underscore the clear and present danger of zoonotic events in the region. The wide diversity of potentially pathogenic viral strains also has significant potential use in broadly active vaccine, immunotherapeutic and drug development (49).

Most high-impact zoonotic viruses originate in wildlife reservoirs, sometimes spilling over first into livestock ‘amplifier’ hosts, or directly into localized human populations with high levels of animal contact (**Fig. 2**). Efforts to prevent emerging zoonoses have targeted these high-risk populations in regions prone to disease emergence (31, 54). However, these regions tend to be in the developing world, where nations often lack the resources to investigate novel zoonotic events, or wildlife reservoirs of zoonoses, and prioritize more immediate public health concerns such as Dengue virus or NTDs (20). Zoonotic disease surveillance and control is also hampered by inadequate information on basic disease ecology (e.g. range of wildlife reservoirs, risk factors for spillover) and pathogen biology (viral diversity, pathogenesis), and by logistical challenges sharing novel diagnostics, animal models, samples and reagents at sites where outbreaks begin (55). Countermeasure and vaccine development is challenged by the small number of isolates available, and the presence of closely-related strains, some with evidence of transmission to people but with unknown pathogenicity. For example, using NIH and other funding, we found serological evidence of exposure to African henipaviruses in 3-4% of a sample of people in Cameroon, with a significant risk factor being butchering of bats; and serological responses to bat SARSr-CoVs in 6/209 (2.87%) and bat HKU10-CoV in 2/412 (0.5%) people living close to a bat cave in Yunnan, all novel viruses with unknown clinical impact (16, 56). We discovered two novel bat-borne reoviruses, Melaka and Pulau viruses, and showed that 14/109 (13%) of people living in close proximity to bat roosts on Tioman Island, Malaysia were exposed to these viruses (7) as well as 12/856 (1.4%) of a random sample screened in Singapore (8). Previous studies in the Philippines found farmers and butchers who had contact with sick pigs tested positive for Reston ebolavirus antibodies but had not experienced illness (11), and it was our team that discovered Philippine bats as natural reservoir hosts for Reston virus (57). In preliminary screening in Malaysia with funding from DTRA we found serological evidence of exposure to henipaviruses (Hendra, Nipah and Cedar) in 14 bats and 6 human samples, and Ebola (Zaire and Sudan)-related viruses in 11 bats, 2 non-human primates (NHP) and 3 human samples (Hughes, in prep.).

Even when spillover leads to outbreaks of illness and mortality, they are often unreported, undiagnosed or misdiagnosed. We initiated targeted syndromic surveillance of encephalitis patients in Bangladesh clinics and showed that Nipah virus (NiV) causes repeated annual outbreaks with an overall mortality rate of ~70% (58). NiV has been reported in people in West Bengal, India, which borders Bangladesh (28), in bats in Central North India (59), and now in people in Kerala, South India in 2018 and 2019, raising the specter of future spillover at other sites in the region (18, 60).

**Fig. 2: Our Early Warning Approach:** Most zoonotic viruses emerge from wildlife hosts, sometimes via livestock (**lower panel**), to cause small scale outbreaks (green) or larger chains (red) of human-to-human transmission (**middle**). In some cases, these spread more widely via air travel (**upper**). Our EIDRC proposal targets each stage: SA1 examines the diversity and spillover potential of viral threats in targeted SE Asian wildlife; **SA2** seeks evidence of their spillover into focused high-risk human populations; **SA3** identifies their capacity to cause illness and to spread more widely. Figure from (54).

Under a current NIAID R01, we have shown that we can use analytical approaches to target surveillance of wildlife and people and identify likely sites of spillover. We used phylogenetic analysis of bat hosts and their CoVs to identify a key cave complex in SW Yunnan Province that harbors all the genetic elements of SARS-CoV (61), as well as a series of SARSr-CoVs that can infect human cells *in vitro*, cause SARS-like clinical signs in humanized mice, and evade vaccine treatment and therapeutics (24, 49, 51, 52, 62-64). We conducted risk factor surveys and biological sampling of human populations living close to this cave and found serological evidence of spillover in people highly exposed to wildlife (16). **This work provides proof-of-**

**concept for an early warning approach that we will expand in this EIDRC to target other viral groups in one of the world's most high-risk EID hotspots.**

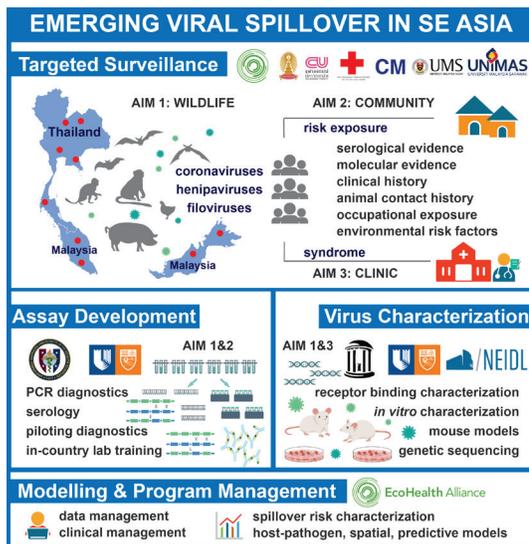

The overall premise of this EIDRC proposal is that there is substantial evidence that: 1) diverse CoVs, henipaviruses and FVs related to known human pathogens are circulating in wildlife reservoirs in Southeast Asia; 2) these viruses likely spillover regularly to people, are often unreported or misdiagnosed, and their clinical manifestations and potential to cause pandemics are unknown and underestimated; and 3) our strategy for targeted surveillance and detection of spillover and illness in at-risk human populations can be used as an 'early warning system' to conduct public health interventions and disrupt disease emergence. To scale-up this approach, we propose to launch EID-SEARCH (the **E**merging **I**nfectious **D**iseases - **S**outh **E**ast **A**sia **R**esearch **C**ollaboration **H**ub), to better understand, and respond to, the risk of zoonotic viral emergence in Southeast Asia. We will initially focus on the diversity of known and novel CoVs, henipaviruses, and FVs in wildlife reservoirs. We will use this work to build our center's interactive network throughout the region, bridge barriers, provide early focal point for basic and translational studies, develop sample handling and storage routines, communication networks, cohort management, infrastructure development, and cross-training in surveillance and novel diagnostic platforms. We will develop and transfer technology to test these viruses' capacity to infect human cells and mouse models, develop new specific and sensitive serological and molecular diagnostic tools, conduct surveillance of human communities with high risk of exposure to wildlife, and clinical cohorts to identify evidence of spillover of viruses causing previously 'cryptic' clinical syndromes in people. We will test the capacity of novel viruses to infect human cells and/or mouse models, and thus assess potential for spillover and spread which will feed into our risk models. Our group also has extensive experience in other viruses, including vector-borne flaviviruses, and alphaviruses, and will use this experience to provide robust long-term surveillance, diagnostics, and basic science opportunities. While the current proposal focuses its basic and applied research agendas on this group of viral EID, we note that the EID-SEARCH is poised to rapidly respond to any outbreak. **Thus, FVs, henipaviruses and CoVs are examples of sentinel surveillance systems in place that illustrate EID-SEARCH's capacity to identify and initiate a rapid response targeting any novel microbial pathogen that emerges in this region.**

**2. Innovation:** Previous work by our consortium has developed strategies to target surveillance in wildlife and people to better anticipate and identify early spillover events and pre-empt outbreaks of emerging viruses. In the EID-SEARCH we scale up this approach in a central research "hub" made up of leading laboratories, clinics and surveillance sites in three critically high-risk EID hotspot countries in SE Asia. EID-SEARCH's reach is expanded through its regional network of collaborators that covers nearly all of the greater SE Asia region. The innovation of the EID-SEARCH is in: 1) Its multidisciplinary approach that combines modeling to target geographic and taxonomic sampling targets with on-the-ground zoonotic disease surveillance in human and wildlife populations; 2) the biological characterization approach that identifies how likely viruses are to be able to infect people, and enables evaluation of existing countermeasure technologies; an approach that is grounded in our successful work on SARSr-CoVs; and 3) the strategic sampling of both high-risk communities with extensive animal contact at the front-lines of viral spillover and syndromic clinical cohorts that present with signs of novel viral emergence, to identify risk of viral spillover in an early warning system approach (**Fig. 2**). **In Aim 1, we will target viruses in archived and newly collected wildlife samples, and characterize their risk of spillover to people.** We will use spatial and phylogeographic analyses to identify the geography and species of wildlife to test samples from, and to further characterize viruses we have recently discovered. We will use *in silico* methods (novel ecological-phylogenetic risk ranking and mapping of receptor binding domains), cell culture, and animal models to assess their potential for spillover into high-risk human populations. **In Aim 2, we will conduct targeted cross-sectional serological surveys of human communities with high levels of animal contact to find evidence of viral spillover, and identify occupational and other risk factors for zoonotic virus transmission.** We will use serological tests targeting viruses identified in Aim 1 to identify the baseline spillover of known or novel CoVs, henipaviruses and FVs in these populations. Serological findings will be analyzed together with subject metadata (including a simple animal-contact survey, location data, viral sequence/isolates etc.) to identify zoonotic risk factors and routes of exposure from specific wildlife or vector species. **In Aim 3, we will use syndromic surveillance of clinical human cohorts to identify evidence of viral etiology for otherwise 'cryptic' outbreaks.** We will enroll and

collect biological samples from patients in local clinics and hospitals who present with syndromes previously linked to known viral agents and live within communities at high risk for disease emergence. We will conduct molecular and follow-up serological diagnostic assays to identify likely viral etiology of syndromes that may represent otherwise cryptic events. Where viruses are identified, we will attempt to isolate or molecularly re-derive them, and use survey data, ecological and phylogenetic analysis to identify likely reservoir hosts and inform intervention programs. Our US partner BSL-4 laboratory, NEIDL, will attempt isolation and characterization of viruses requiring BSL-4 of containment (e.g. novel filoviruses, close relatives of Hev/NiV).

**3. Approach: 3.1. Research team:** The EID-SEARCH builds on long-term collaboration among world leaders in emerging virus research with proven experience collaborating internationally on field, lab and human surveillance research (**Fig. 3**). Over the past two decades, our consortium partners have conducted high profile research on EIDs within the region and globally, including identifying the wildlife reservoirs for NiV and Hendra virus (HeV), MERS- and SARS-CoVs (24, 27, 59, 61, 65-67), discovering SADS-CoV (17), and developing an array of serological, molecular, *in vitro* and *in vivo* approaches to characterizing high-risk CoVs, henipaviruses, and FVs (62-64, 68-81). Our team has substantial experience conducting human surveillance in the community and during outbreaks (Sections 2.2.a., 2.2.b., 2.2.c, 3.2.a, 3.2.b), including: USAID-PREDICT, and DTRA-funded viral surveillance of indigenous communities in Peninsular Malaysia and syndromic surveillance of hospital patients in Sabah (Co-I Hughes); collection of >2,000 serum samples from healthy blood donors and sanitation workers, febrile and influenza like illness (ILI), and diarrheal stool samples from children under 5 years of age across Borneo Malaysia (Co-I Kamruddin); collaboration on the MONKEYBAR project with the

London School of Hygiene and Tropical Medicine to analyze risk and prevalence of the zoonotic malaria *Plasmodium knowlesi* through case control and cross-sectional studies in Sabah villagers (n=~800, 10,000 resp.) and clinical observational studies to determine the etiology of central nervous system infections and acute undifferentiated febrile illness in Sabah. (Co-Is William, Rajahram, Yeo); and community-based surveillance of hundreds of bat-exposed villagers in Thailand (Co-Is Wacharapluesedee, Hemachudha). As a proof-of-concept of how our team can rapidly scale up resources for diagnostics and surveillance in the face of a new EID, in 2016, we discovered a novel bat-origin HKU-2 CoV (82, 83) killing >20,000 pigs in S. China, designed PCR and serological assays, surveyed pig farmers for evidence of exposure, and conducted experimental infections, pathogenesis and molecular studies, **all in the span of 3 months** (17, 84).

**Fig. 3:** EID-SEARCH scope, core institutions, and roles.

The administration of this center (**Section 4.1.**) will be centralized at EcoHealth Alliance (EHA) led by PI Daszak, who has >20 years' experience managing international research collaborations on emerging zoonoses, and has collaborated with all partners in the EIDRC consortium for 5-20 yrs on NIAID- and USAID-funded research. He will oversee all activities in this EIDRC, supported by Deputy lead, Dr. Olival – who has managed human and wildlife disease surveillance projects in SE Asia for >10 years, and a **Core Executive Committee (Section 4.1.a)**. Co-Is Olival and Zambrana are leaders infectious disease analytics, and head the modeling and analytics work for USAID-PREDICT. Co-Is Wang, Baric, Broder, Anderson, and Laing have developed a unique array of *in vitro* cell culture, serological and molecular reagents to identify and characterize emerging viruses in people and animals (henipaviruses and other PMVs, CoVs, FVs and many others). Co-Is Wacharapluesedee, Hemachudha, and Hughes and collaborators have coordinated clinical and community surveillance of people, and of wildlife and livestock within Thailand and Malaysia for the past 15 years, in collaboration with Ministries of Health, Agriculture and Environment. Finally, this consortium has extensive external funding from NIH, DoD, USAID, DHS and other USG agencies supporting laboratory, analytical and field studies directly related to the current proposal, and will bring substantial leverage to our EIDRC.

**3.2. Geographical focus:** The three core (hub) countries for this proposed EIDRC are Thailand, Malaysia and Singapore, three contiguous EID hotspot countries that stretch through one of the most significant foci of EID origins globally. Our proposed work includes sampling wildlife and people in Thailand, Peninsular Malaysia, Sarawak and Sabah, and thus contains overlapping wildlife biogeography with India, Bangladesh, Myanmar, SW China, Laos, Cambodia, Vietnam, Philippines, and Indonesia. It encompasses diverse cultural and socioeconomic backgrounds which have correspondingly diverse and intensive interactions with wildlife reservoirs and the global travel network. We have already begun sampling of wildlife hunters, livestock workers, wildlife farmers and market workers, rural villagers living close to high risk wildlife species, people otherwise highly exposed to animals in these countries, and clinical cohorts, as part of current/prior NIH, DTRA, and USAID funding. Our core member's extensive network of collaborators in clinics, research institutes and public health laboratories in almost every other Southeast Asian country positions the EID-SEARCH within a much larger catchment area for emerging zoonoses and will allow us to rapidly scale up to include additional sites in response to an outbreak or shift in research priorities. We will conduct regular meetings with key research, public health and community leaders, including >50 leading laboratories/institutions in 10 countries (Section 4.2) to maintain these collaborative relationships with the core members of our consortium (Fig. 4).

We will use these, and our annual meetings, to share information on novel research and diagnostic approaches, pathogens that are of key pandemic potential, regions or populations at high risk of spillover, and information from the greater network on likely outbreaks of novel disease. This platform will coordinate sample sharing and diagnostic platforms and help build a rapid response to outbreaks across the region.

**Fig.4 :** Map of Southeast Asia indicating three hub countries for this proposed EIDRC (**Red**: Thailand, Singapore, Malaysia) and countries in which Key Personnel have existing collaborating partners via other funded work (**Green**), indicating that EID-SEARCH provides access to key collaborators and sites throughout the region.

**3.3. Capacity for linkage with other NIAID studies, and scaling up to respond to outbreaks:** EID-SEARCH US-based partners include senior scientists with significant experience on NIAID-funded projects, extensive collaborations with other NIAID-funded scientists, and previous experience working with NIAID leadership through workshops, review of programs (e.g. PI Daszak's role in NIAID CEIRS external review), and work on study sections. These contacts ensure that the EID-SEARCH senior leadership will be ready and able to rapidly set up data, sample and reagent/assay sharing protocols with NIAID researchers, the other EIDRCs, the EIDRC CC and other NIAID research centers. EID-SEARCH in-country partners include senior medical doctors and infectious disease specialists at national and regional hospitals in each country and administrative state in this proposal. On news of potential outbreaks, **EID-SEARCH will rapidly mobilize its core staff and their extensive collaborative network across almost all SE Asian countries (Fig. 4) (Sections 4.1.a, 4.2. 4.3)**. The core analytical approach can be used to rapidly identify sampling sites and targets to harvest vectors, vector borne arboviruses, birds and mammalian species that harbor most other viral threats. Through existing projects such as the USAID PREDICT Project and DTRA-funded biosurveillance projects, EHA is currently partnered with hospitals and researchers across South and Western Asia, West and Central Africa, and Latin America. Our partners already have capacity to conduct human and wildlife sampling and testing for novel viral agents, so expanding in geography or scale is readily achievable given sufficient resources.

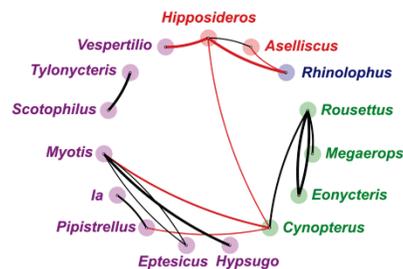

**Aim 1: Identify, characterize and rank spillover risk of high zoonotic potential viruses from wildlife.**

**1.1 Rationale/Innovation:** The vast majority of emerging zoonotic pathogens are linked directly or indirectly to wildlife host, particularly from important mammalian groups like bats, rodents and NHPs (3). Our previous work on wildlife origin viruses demonstrates that zoonotic viral emergence tends to occur in specific regions with high diversity of wildlife that harbor viruses of zoonotic potential, and human populations that have close contact to these wildlife (Fig. 1) (2, 3). In Aim 1 (see Fig. 9 for overview), we will strategically conduct EID surveillance by applying risk analytics to prioritize the regions, wildlife species, and human populations that

have a particularly high risk of viral spillover. We will target high-risk zoonotic host reservoirs (bats, rodents and NHPs) in these regions and apply novel predictive models to estimate viral diversity and host range to identify wildlife species that have been ignored or under-sampled by previous zoonotic disease surveillance efforts. We will strategically collect specimens from these species and screen them, together with some of the tens of thousands of recently collected samples we have archived, for known and novel agents. We will begin screening using conserved PCR assays to identify known and novel viruses in high risk RNA viral families, *Coronaviridae*, *Paramyxoviridae*, and *Filoviridae*. We will expand to other groups of pathogens, including arboviruses, pending available resources and priorities established with the EIDRC coordinating center (EIDRC-CC) and other regional EIDRCs. Using risk ranking algorithms and a series of ecological and virological risk factors, we will triage the wildlife viruses we discover for further genomic characterization and viral isolation. On this subset of viruses, we will then use *in vitro* and *in vivo* approaches (viral rescue, cell lines, gene edited humanized transgenic mice and the collaborative cross genetic reference mouse population) previously developed and widely used by our team to predict capacity of novel viruses to infect people and spillover (63, 85-88). These high-risk viruses and their close relatives will be targets for human community serosurveys and clinical sampling in Aims 2 and 3, respectively.

**1.2 Preliminary data: 1.2.a. Geographic targeting:** EHA has led the field in analyzing where the highest risk of zoonotic spillover is across the globe, identifying SE Asia as a major EID hotspot (1, 2). These hotspots are sites where high wildlife biodiversity, human population density and rapid ecologic change collide (**Fig 1**). Using host and ICTV viral data for all known mammalian viruses, and generalized additive models to correct for sampling bias, we are able to predict the relative number of yet-to-be-described viruses that a species harbors (3). This demonstrates substantial undiscovered viral diversity in mammals across Southeast Asia, and particularly in regions of Thailand, Singapore and Malaysia (**Fig. 1**). Separately, we found that factors driving spillover (host diversity, climate) differ from those driving spread in human populations (population density, bushmeat hunting, livestock production) (89). We therefore analyze capacity for viral spread as a separate risk factor, using our unique demographic and air travel and flight data modeling software (90, 91). In the current proposed work, we will use all the above approaches to target wildlife sampling (archival and new field collections) in Aim 1, to inform sites for human sampling in Aim 2, and to assess risk of spread in Aim 3.

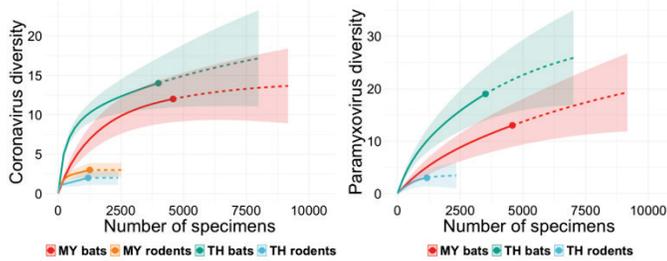

**1.2.b. Reservoir host species targeting:** Our analysis of all known mammalian host-viral associations demonstrates that bats, rodents and NHPs represent the three most important reservoirs for zoonoses, responsible for the highest proportion of known and predicted viral diversity of zoonotic potential (3). Thus, the bulk of our proposed wildlife sampling and testing will consist of these three taxa with a focus on bats, because this group is the known or hypothesized reservoir for the majority of high-impact zoonotic CoVs, PMVs and FVs (50, 92-94). Bats have the highest proportion of predicted zoonotic viruses in any mammalian group (2), and are exceedingly diverse in Southeast Asia (~500 species). To further prioritize taxonomic sampling targets within these diverse geographic hotspots, we used a novel Bayesian phylogeographic algorithm to identify host genera and species that are the most important centers of evolutionary diversity for a given viral group, e.g. bat genera for  $\beta$ -CoVs (**Fig. 5**) (51). This approach will be extended to other mammal taxa and viral families of interest, allowing us to identify the reservoir hosts of specific zoonotic viral groups, where viral diversity is likely highest.

**Fig 5:** Preliminary analysis of sequence data collected under prior NIH funding, identifying SE Asian bat genera with the highest  $\beta$ -CoV evolutionary diversity. We will apply this Bayesian discrete phylogeographic model to identify taxonomic and geographic centers of viral diversification and sharing for relevant PMV, CoV, FV and other virus clades. Line thickness proportional to probability of virus sharing between two genera. Inter-family switches in red.

Finally, we have designed a strategy to estimate sampling gaps, using a viral 'mark-recapture' approach we previously published (95, 96) (**Fig. 6**). Using prior data for bat, rodent and NHP viral discovery vs. sampling rates, we can identify the likely total viral diversity for specific host groups in a region, and use this to estimate sample sizes to discovering the majority of unknown viruses within a specific family or genus. **In the current**

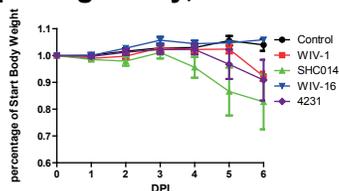

**proposal**, we will use these analyses to estimate geographic and species-specific sampling targets **to more effectively identify new strains to support experimental infection studies and risk assessment.**

**Fig. 6:** Estimated CoV (**left**) and PMV (**right**) diversity in bats and rodents from Thailand and Malaysia, using data from PCR screening and RdRp sequences from >10,000 specimens in bats and 4,500 in rodents. Bats have 4X more viral species than rodents, controlling for sampling effort. We estimate that additional collection of 5k-9k bat specimens and testing of our archived bat and rodent specimens alone will identify >80% of remaining CoV and PMV viral species in these key reservoirs, yielding >800 unique viral strains.

**1.2.c. Sample testing to identify known and novel viruses:** We have conducted extensive wildlife surveillance for novel viruses across Southeast Asia in prior NIAID funded work and as part of the USAID PREDICT project. Under the 10-year PREDICT program globally, we identified 912 novel and 210 known viruses, more than the total number of viruses previously recognized in mammals by the ICTV (97). This work included collecting nearly 300,000 individual mammal samples from 14 EHA-led PREDICT countries, and PCR-screening of more than 60,000 individual specimens (53). In southern China alone, we identified 178  $\beta$ -CoVs, of which 172 were novel, discovered a new  $\beta$ -CoV clade, “lineage E” (41), diverse HKU3r-CoVs (179 sequences) within a 'sister' clade to the SARS-CoV lineage, and a new bat-origin SADS-CoV, responsible for killing >25,000 pigs in Guangdong Province (17). We have collected 28,957 samples from bats, rodents and NHPs in Thailand and 47,178 in Malaysia, **but have only tested a minority of these using PCR.** We have identified 100 novel viruses in Thailand and 77 in Malaysia. **Furthermore, we have only sequenced a small segment of one gene for all novel viruses found. We have archived duplicate samples which are now available for use in this project**, including fecal, oral, urogenital, serum samples, and biopsies from bats, rodents, and NHPs. In the current proposed work, we will attempt to sequence, isolate and characterize those viruses that our analyses below suggest are most likely to be able to infect humans.

**1.2.d. In vitro & in vivo characterization of viral potential for human infection:** Using Coronaviridae as an example, we have conducted *in vitro* and *in vivo* experiments to characterize the pathogenic potential of novel SARSr-CoVs from bats. We isolated three SARSr-CoVs from bat feces: WIV1, WIV16 and Rs4874, with Spike (S) protein sequences that diverged from SARS-CoV by 3-7% (24, 61, 98). We conducted full-length genome sequencing of 12 other novel SARSr-CoVs, some highly similar to outbreak SARS-CoV in the most variable genes (61). Using our reverse genetics system we constructed chimeric viruses and rederived full length recombinant SARSr-CoV from in silico sequence. All 3 SARSr-CoV full length isolates and the two chimeric viruses replicated efficiently in Vero E6 cells and in HeLa cells expressing hACE2, civet and bat ACE2, but not in those without ACE2 (24, 61, 98). We used the SARS-CoV reverse genetics system (72) to generate a chimeric virus with a mouse-adapted SARS-CoV backbone expressing SHC014 S protein with 10% sequence divergence from SARS-CoV S. This and the other full length and chimera viruses replicated in primary human airway epithelium, using the human ACE2 receptor to enter into cells (62). Thus, **SARSr-CoVs with diverse variants of SL-CoV S protein without deletions in their RBD can use human ACE2 as receptor for cell entry.** The Baric lab has a well-established hACE2 and DPP4 transgenic mouse model that **we used to assess the capacity of novel SARSr-CoVs and MERS-CoV to infect humans and cause disease (85, 99).** Infection of bat SARSr-SHC014 or WIV1 caused SARS-like clinical signs in the transgenic hACE2 mouse model **that weren't reduced by immune-therapeutic monoclonals that attenuate SARS-CoV pathogenicity, nor after challenge following vaccination against SARS-CoV (62) (Fig. 7).** We repeated

this virus characterization approach with chimeras using HKU3r-CoV S proteins that are ~25% divergent from SARS-CoV S, **and found that they are unable to use the ACE2 receptor.** Additionally, we were unable to culture HKU3r-CoVs in Vero E6, or human cell lines.

**Fig. 7:** Body weight change in hACE2 transgenic mice after SARSr-CoV infection, demonstrating that bat-origin SARSr-CoVs cause similar clinical signs to outbreak SARS-CoV strain (4231) (62, 63).

A similar approach to the above pipeline for CoVs will be applied to novel henipaviruses we discover during our research. The broad mammalian tropism of HeV and NiV (68) is likely mediated by their usage of highly conserved ephrin ligands for cell entry (19, 100). A third isolated henipavirus, Cedar virus does not cause pathogenesis in animal models. **Co-Is Broder and Laing** have developed a reverse genetics system and rescued a recombinant CedV to test ephrin receptor usage/tropism and pathogenicity during henipavirus infections (77). CedV is unable to use the Ephrin-B3 receptor (77, 101) which is found in spinal cord and may underlie NiV encephalitis (102) and that pathogenesis also involves virulence factors V and W proteins. The putative henipaviruses, Ghana virus and Mòjiāng virus, predict V and W protein expression, with GhV able to bind to ephrin-B2, but not -B2 (103), and the receptor for MoJV remains unknown (104) but is likely ephrin-B2 (105). Our group has also used similar methods to test the hypothesis that novel Filoviruses discovered in wildlife are able to infect people. NiV, EBOV and MERS-CoV all infect primary microvascular endothelial cells, which are available at Co-I Baric's lab for EID-SEARCH collaborators (71, 106). Primary human lung endothelial cells are highly susceptible to Ebolavirus infection (107), and Huh7 cells can be used to isolate virus from clinical samples (108) offering advantages for reverse genetic recovery of novel FVs (109). The three filovirus genera, *Ebolavirus*, *Marburgvirus* and *Cuevavirus*, use Niemann–Pick type C1 (NPC1) protein as cell entry receptor (110). For novel filoviruses, cell culture would be carried out under BSL-4, however they can readily be characterized following identification of their encoded GP sequences which can be pseudotyped into recombinant GP-bearing vesicular stomatitis virus (VSV) pseudovirions (111). These pseudovirions can be safely used to characterize the tropism and entry filoviruses mediated by GP without a need for BSL4 containment. **Co-Is Wang and Anderson** used cells originating from various mammalian species to determine spillover and/or zoonotic potential of MLAV, a newly discovered Asian filovirus (47). Despite the low amino acid sequence identity (22–39%) of the glycoprotein with other filoviruses, MLAV is capable of using NPC1 as entry receptor. Cells from humans, monkeys, dogs, hamsters and bats were able to be infected with a MLAV pseudovirus, implying a broad species cell tropism with a high risk of interspecies spillover transmission.

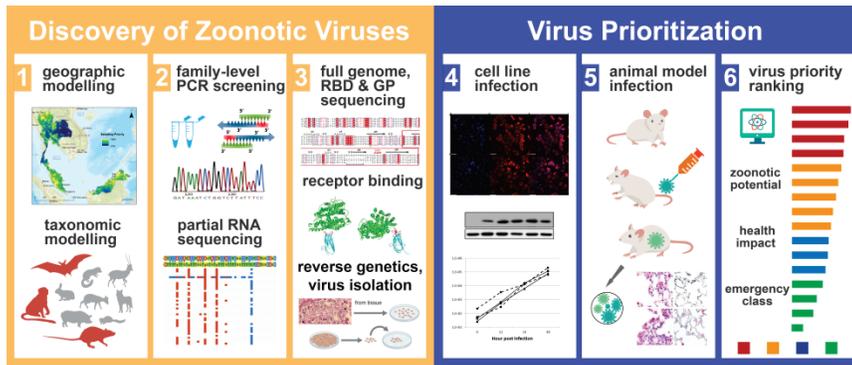

**Mouse models.** For novel viruses across all families, we will use the UNC collaborative cross mouse that captures 90% of the diversity within all mouse groups to assess the most suitable model for further experiments (112). We have used this model for CoV, FV (Ebola), Flaviviruses, and alphaviruses infections. Clinical signs such as weight loss, hemorrhage, encephalitis, and, acute or chronic arthritis were recapitulated in these mice following SARS, EBOV, West Nile virus and Chikungunya infections, respectively (86-88, 113-116). Note that CC OR3015 shows hemorrhagic disease phenotypes after EBOV infection (**Fig. 8**). **Bat Models.** Duke-NUS has developed two models for bat *in vivo* studies: a colony of *Eonycteris spelaea* (cave dwelling small fruit bat) and a bat mouse model, which contains the bat immune system in an immunodeficient mouse (117). In a proof of concept study, **Co-Is Wang and Anderson** infected *E. spelaea* bats with MERS-CoV to demonstrate their susceptibility and suitability for infection with a bat borne virus under BSL3 containment. These bats and the bat mouse model will serve to complement and expand studies from the UNC collaborative cross mouse, pending further funding from EIDRC CC.

Recombinant viruses, transgenic mouse models and experimental recombinant protein constructs described above will be made available to the EID-SEARCH consortium and other EIDRCs following standard procedures (**see Resource Sharing Plan**).

**Fig. 8:** EBOV Infection in Collaborative Cross Mouse. **Panel A/B:** Wt EBOV in two different CC lines demonstrate different disease patterns. **Panel C/D:** Hemorrhagic phenotypes on d. 6 (arrow) in spleen and liver, resp. From (86).

**1.3. General Approach:** We will conduct analyses to geographically- and taxonomically-target testing of samples from wild mammals that are most likely to harbor known high-profile zoonotic pathogens, or close relatives with potential to infect people. This includes selecting from tens of thousands of samples collected on recent projects and stored in freezers in our laboratories, and new sampling of wildlife in high risk locales. We will use viral family level PCR assays to identify and partially characterize viruses, then follow up sequencing of relevant receptor binding proteins to assess homology and predict binding affinity, then attempt to isolate and

biologically characterize viruses that phylogenetic and other data suggest have high spillover and pandemic potential. We will follow this with *in vitro* binding assays and cell culture experiments, and *in vivo* animal model infections to assess their potential to infect people and cause disease (**Fig. 9**). EHA will lead the study design, targeted sampling, and data analysis; Co-Is Hughes and Wacharapluesadee will lead field sampling and in-country testing; Duke-NUS, UNC, USUS will lead the serological and PCR diagnostic development and the *in vitro* and *in vivo* analyses, as well as cross-training and tech transfer to the hub labs in Thailand and Malaysia. This will include via support of one Malaysian Ph.D student, Mei-Ho Lee (CM Ltd.) who has worked with the EID-SEARCH collaborators for 9 years. The focus of her study will be infection potential of novel CoVs and PMVs already found in bats in Malaysia under preliminary data for this proposal.

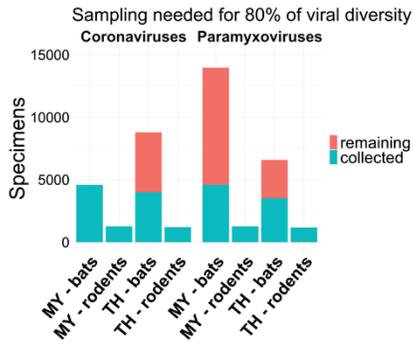

**Fig. 9:** Aim 1 will use analytical tools to target selection of archived and newly collected samples, conduct PCR and sequencing of novel viruses, recover by reverse genetics, and assess zoonotic potential using *in vitro* and *in vivo* models and analyses.

**1.4 Wildlife samples: 1.4.a. Geographic and taxonomic targeting for newly collected wildlife samples:** We will prioritize sites within each country that rank highest for both the risk of zoonotic

disease emergence (2) and the predicted number of 'missing' zoonotic viruses (3). Our preliminary analysis (**Fig. 1**) suggests priority areas include: the Kra Isthmus (S. Thailand) and adjacent forests in N. Peninsular Malaysia, NW Thailand (near the Myanmar-Laos border), and lowland rainforests of Sarawak and Sabah. In each of these 'hottest of the hotspots' regions, we will identify 2-4 distinct sampling sites based on the geographic distribution of key hosts we prioritize for additional wildlife sampling. We will priority rank bat, rodent, and NHP species using host trait-based models (3). We will also identify species predicted to be centers of evolutionary diversity for CoVs, PMVs, and FVs using ancestral host reconstruction of available sequence data and Bayesian discrete phylogeographic models (118-120). We will leverage our strong collaborations with wildlife experts in Malaysia and Thailand, including many of whom are based at our core partner institutions, to ground-truth geographic and taxonomic model outputs with local expert knowledge to ensure the sampling plan is realistic based on current species distributions, population size estimates, seasonality, and accessibility to sites. Most zoonotic viruses are naturally carried by multiple wildlife host species, and there are strong, predictable relations between host phylogeny and viral taxonomy (3). We will use a combined network analysis and phylogeographic model to rapidly predict and prioritize new (unsampled) hosts for important, novel viruses we discover during our research. We have shown this relatively simple model (using just wildlife species range overlap and phylogenetic similarity between host species) is both generalizable to estimate host range for all mammalian and avian viruses *and* robust – accurately predicting hosts 98% of the time when cross-validated using data from known viruses (121).

**1.4.b. Sample size justifications for testing new and archived wildlife specimens:** We calculate initial sample sizes targets using our preliminary data on average PCR prevalence from screening tens of thousands of bat, rodent and NHP specimens for CoV and PMVs based on previous studies in Malaysia and Thailand. We will refine these sample size targets, in real-time, over the course of our project using viral discovery curve analyses (**Fig. 6**) to either scale-up or scale-back new sampling and testing of archived specimens for each species depending on viral capture rates. We will only collect additional specimens projected from each prioritized taxa to achieve statistically robust sample sizes and to complement our archived specimens. For example, *Rousettus* spp. bats, known FV reservoirs, were not adequately sampled under PREDICT research in Thailand. Preliminary analysis indicates that, for all viral target families, we will require ~14,000 new samples to identify 80% of remaining viral species diversity in our study region, ~5,000 samples from Thailand and ~9,000 samples from Malaysia (**Fig. 10**). Viral strain diversity from a sampling effort this size is expected to number in the hundreds of strains. For example, given ~6% prevalence of CoVs in bat species previously sampled under the PREDICT project, a target of 14,000 individuals would yield ~800 PCR positive individuals,

representing, an estimated ~600 novel sequences/strains. Similarly, for PMVs, which have an average PCR detection prevalence of ~1.5%, sampling of 14,000 individuals would yield ~200 positives and an estimated 150 unique strains. Filovirus estimates are not feasible yet due to the small number of positive samples in prior

studies, but will be estimated as the project begins. From each mammal, we will collect serum, whole blood, throat swabs, urine and fecal samples or rectal swab using our previously-validated nondestructive methods. We will sample sites at different time-points throughout each year, and sample an equal number of males and females to account for seasonal or sex-specific differences viral shedding (**See Vertebrate Animals**) (122, 123). Dead or animals euthanized due to injury will be necropsied.

**Fig. 10:** Stacked bar plot showing number of currently-archived specimens (blue) and new specimens required (orange) to discover 80% of predicted number of CoVs and PMV species from high-risk bat and rodent taxa in Malaysia and Thailand.

**1.4.c. Sample collection, testing, viral isolation:** Wildlife will be captured and sampled using previously published techniques, by personnel wearing appropriate personal protective equipment (Tyvek suits or dedicated long external clothing, double nitrile gloves, leather gloves, an N95 or p100 respirator, and safety glasses) (53, 93, 95, 96, 122, 124). All samples will be placed in a vapor phase liquid nitrogen dry shipper immediately upon collection, and then transferred to a -80C freezer once back in the lab, until testing. Viral RNA will be extracted from bat fecal pellets/anal swabs. RNA will be aliquoted, and stored at -80C. PCR screening will be performed with pan-coronavirus (125, 126), filovirus (127) and paramyxovirus primers (128), in addition to virus specific primers where additional sensitivity is warranted in key viral reservoirs, i.e. Nipah virus or MERS virus specific primers (129, 130). PCR products will be gel purified and sequenced. We will attempt isolation on samples that contain viruses of interest (determined in **Aim 1.5 below**), using Vero cells and primary cell culture from the wildlife taxonomic order (bat, rodent and NHP cell lines). Over 70 bat cell lines are maintained at Duke-NUS from five different bat species. These include primary lung, brain, bone marrow, heart, kidney, intestine, liver, lymph node, muscle, spleen, PBMC and ovary/testes from *Eonycteris spelaea*, *Cynopterus bracyhotis*, *Rhinolophus Lepidus*, *Myotis muricola* and *Pteropus alecto* bats. In addition we have 8 immortalized cell lines, including those derived from lungs, therefore suitable for the isolation of respiratory viruses.

**1.4.d. Moving beyond RNA viruses:** To detect pathogens from other families, such as non-RNA viruses, we will combine conserved PCR assays with NGS. We will perform either unbiased NGS, or use a pan-viral enrichment library to sequence full-length genomes (131). We will conduct this work via EID-CC research projects or as part of outbreak detection/investigation in the region from DNA viruses or other agents.

**1.4.e. Sequencing Spike Glycoproteins:** Based on earlier studies, our working hypothesis is that zoonotic CoVs, FVs and henipaviruses encode receptor binding glycoproteins that elicit efficient infection of primary or continuous human cell lines (e.g., lung, liver, etc.) (16, 61, 62). Characterization these for SARSr-CoVs suggest that viruses up to 10%, but not 25%, different in the spike glycoprotein use human and bat ACE2 receptors for docking and entry. Uneven sampling gaps (e.g., no strains were found with 10-25% spike variation) prevent a thorough understanding of the transition point where the most divergent strains lose human ACE2 receptor usage. Our viral discovery curves (**Fig. 6**) suggest further sampling will reveal a rich diversity of as-yet-undiscovered SARSr-CoVs and strains of other viruses that fill in the phylogenetic tree between currently-described viruses. In this aim we will use phylogenetic and viral discovery analysis to specifically target bat species and regions that are under-sampled to allow sufficient power to identify and characterize missing strain diversity for potential zoonoses. We will sequence the S proteins of novel SARSr-CoVs to prioritize viruses for experimental work in Aim 3 to test this hypothesis. Likewise, we will test the hypothesis that phylogenetic related zoonotic receptor binding protein genes of MERS-related, Ebola-related and NiV/HeV-related viruses will also program efficient entry via human and ortholog receptors. For all novel virus strains, we will sequence the complete entry spike genes by amplifying overlapping fragments using degenerate primers as shown previously (24, 61). **Reverse Genetics:** Full-length genomes of selected CoVs, FVs or henipaviruses (representative across subclades) will be sequenced using NEBNext Ultra II DNA Library

Prep Kit for Illumina and sequenced on a MiSeq sequencer. PCR or Minlon sequencing will be performed to fill gaps in the genome. The full length spike gene sequences, including the amount of variation in the receptor binding residues that bind the appropriate human receptor will be used to select strains for Aim 3 experiments. We will sequence full length genomes of high risk strains that are antigenically distinct and escape SARS or MERS-CoV cross neutralization, synthetically reconstruct a small subset (1-2) and evaluate growth in Vero, BHK and Huh7 cells (63, 132). From full length sequences, synthetic clones will be ordered to recover recombinant viruses using reverse genetics as described by our groups (62, 63, 77, 109, 133, 134). Recombinant virus growth will be accessed in Vero, BHK, Huh7 and select bat cells and recovered viruses used for downstream studies. Virus strain prioritization is described below.

**1.5. Assessing risk for spillover. 1.5.a. Capacity to infect human cells:** We will use a series of cell cultures to assess the capacity of target viruses to enter human cells. For CoVs, FVs and henipaviruses, we will use primary human ciliated airway epithelial cells (HAE) and lung endothelial cell cultures derived from the lungs of de-identified transplant recipients. HAE are highly differentiated and grown on an air-liquid interface for several weeks prior to use (62, 63, 132). We will prepare HAE and lung endothelial cultures from three different patient codes in triplicate in collaboration with the tissue procurement facility at the Cystic Fibrosis Center at UNC. Cultures will be inoculated with chimeric bat SARSr-CoVs or novel FVs or henipaviruses to assess efficient replication. At 72 hpi, cultures will be fixed for immunofluorescent staining using antisera to the SARS-CoV conserved nucleocapsid protein (N) or to structural genes of the other viruses (64, 71). SARSr-CoVs that differ significantly in S protein sequence (11-24%) from epidemic SARS-CoV yet replicate *in vitro*, will also be evaluated for sensitivity to neutralization in Vero cells by PRNT50 assays using broadly SARS-CoV cross reactive human mAbs S227.14, S230.15, S215.17, and S109.8 (63, 135) or monoclonal antibodies targeting the Ebola or Marburg E glycoprotein (Available through BEI), or NiV/HeV glycoproteins (136). As controls or if antisera is not available, the S genes of novel SARSr-CoV or spike entry genes of other novel viruses under investigation will be inserted into VEE 3526 replicon vectors (VRP3526-S), packaged and used to vaccinate mice (137). Polyclonal sera against test bat-SARS virus or other spike genes will be harvested and tested for ability to cross neutralize SARS-CoV, GD03, WIV-1, SHC014, WIV-16, other novel SARSr-CoV and HKU3-SRBD by PRNT50 assay (63, 138, 139). Using PRNT50 titers with sera (n=4 each) among these viruses, antigenic cartography (140) will allow comparison of antigenic vs. phylogenetic distance, identifying the transition at which SARSr-CoV strains escape SARS-CoV based vaccines, informing immunotherapeutic and vaccine design strategies (141-143). Similar approaches will be applied to novel MERS-related viruses, other CoV, FVs or henipaviruses. While most wildlife-origin viruses with unknown transmission potential or pathogenicity in people uncategorized, we use BSL-3 for isolation as standard, and cell culture for potentially BSL-4 pathogens will be undertaken at collaborating institute NEIDL. To facilitate this, duplicate samples in culture medium from animals PCR +ve for FVs and very close relatives of NiV or HeV will be shipped to NEIDL (**See letter of support**) for culture, characterization and sharing with other approved agencies including NIH Rocky Mountain Laboratories where PI Daszak and Co-Is Baric have ongoing collaborations. Similarly, some duplicate samples of animals PCR +ve for CoVs will be shipped to UNC for further characterization by Co-I Baric. Where feasible and appropriate, training opportunities at NEIDL and UNC for in-country staff will be given, thereby enriching hands-on collaboration across sites.

**1.5.b. Host ACE2, DPPR, Niemann-Pick C1 (NPC1) and EphrinB2/EphrinB3 receptors:** We will sequence relevant host receptors for select mammalian wildlife species we find positive for strains of high-priority CoV clades, and all new henipaviruses and FVs. Of particular interest is homology across 18 bat and human orthologue ACE2 contact interface residues that engage the SARS RBD as a potential indicator of SARSr-CoV cross species transmission potential and growth in human cells (70). Likewise, variation in the NPC1 receptor has been shown to alter EBOV ability to infect in humans and bats, so this can be structurally mapped for prediction and downselection of strains (144). Signatures of positive selection in bat NPC1 were concentrated at the virus-receptor interface, with the strongest signal at the same residue that controls EBOV infection in *Eidolon helvum* cells. Thus NPC1 is a genetic determinant of FV susceptibility in bats, and some NPC1 variations likely reflect host adaptations to reduce FV replication and virulence (145). NiV and HeV use ephrin B2 or ephrin B3 as a receptor, and variation affects its ability to use human vs bat receptor molecules (103, 146).

**1.5.c. Host-virus evolution and predicting receptor binding:** We will use Bayesian and Maximum Likelihood phylogenetic analyses of RNA-dependent RNA polymerase (RdRp) sequences from PCR screening, receptor binding glycoproteins, and/or full genome sequence data (when available) to reconstruct the evolutionary history of the novel bat SARSr-CoVs, bat MERSr-CoV, FVs and henipaviruses that we identify. We will run co-phylogenetic analyses to map out instances of host-switching (147, 148) and ancestral state reconstruction analyses (Fig. 4) to identify the most important species for shaping evolutionary diversity for these viruses (51, 149), allowing for more targeted future surveillance and spillover mitigation interventions. For receptor binding glycoprotein sequence data from characterized viruses, we will apply codon usage analyses and codon adaptation indices, as used recently on henipaviruses (150), to assess the relative contributions of natural selection and mutation pressure in shaping host adaptation and host range.

**1.5.d. Viral strain prioritization:** Of the expected 100-200 novel SARSr-CoV strains, and approximately 600 total CoV strains, we will down-select to prioritize for further characterization based on S genes that are: i) different from SHC014, WIV1, SARS-CoV with diversity ranges of 10-25%; ii) have virus S RBD that could use human/bat receptors; iii) have recombinant chimeric spikes indicative of gene flow between clade I and II strains; iv) have bat ACE2 or DPP4 receptors that might select for spike RBDs that can use human receptors for entry (15/18 conserved residues in human/bat ACE2 molecules that bind SARSs-CoV S RBD domains are likely more efficient receptors than 3/18 conserved sites). Using structural models based on the SARS S glycoprotein, the extent and location of antigenic variation will be annotated onto the structure, further resolving the locations of highly evolving and conserved structural motifs/epitopes that function in protective immunity (135, 151-153). For novel henipaviruses, we will examine the receptor-binding proteins (e.g. envelope attachment (G) proteins) for sequence and structural homology with particular attention to conservation of amino acids that mediate ephrin receptor binding. We will prioritize strains that are predicted to interact with ephrin-B2 and expression V/W proteins to determine whether these viruses represent zoonotic threats. Using the recombinant Cedar virus (rCedV) platform, we will be able to rescue rCedV that express heterotypic G proteins to explore receptor utilization and tissue dissemination in animal models. We will assess ability to infect human cells using a continuous lung epithelial cell line, Calu3, which our group has previously used to generate data on NiV and HeV growth curves and a variety of host expression changes after infection (154). We will also use primary human airway cultures and microvascular endothelial cells to assess human infection for FVs, henipaviruses and MERSr- and SARSr-CoVs (155) (156). There is some evidence for NiV and HeV replication in mouse lung, low level titers in young animals, 10 fold higher titers in aged mice (157, 158). Thus it is likely these models could be improved in the collaborative cross mouse resource at UNC. We have identified CC lines that are highly vulnerable to wildtype SARS and others that develop hemorrhagic disease following mouse adapted Ebola infections (86-88).

**1.5.e. Animal models:** We will use transgenic mouse models and the UNC Collaborative Cross model to assess spillover potential of viruses. For work on CoVs, we will follow the protocols in the transgenic mouse model used by the Baric lab previously. Briefly, in the BSL3 lab, 10- to 20-week old hACE2 or hDPP4 transgenic mice will be intranasally inoculated with  $5 \times 10^4$  PFU of full length wildtype rbat CoV, or chimeric SARSr-CoV or MERSr-CoV encoding different bat CoV spike proteins respectively, then monitored daily for weight loss, morbidity, and clinical signs of disease. Mice will be euthanized at 2, 4, and 6 dpi (endpoint of 14 dpi), organs harvested and virus quantified by plaque assay or genome (mRNA1) RT-PCR. After 7 days in formalin, tissues for histopathology will be removed from the BSL3 and stained with H&E, and for immunohistochemistry using polyclonal antibodies against the N protein. We will conduct limited evaluation of existing countermeasures using therapeutic monoclonal antibodies *in vitro*. Existing SARSr-CoV or MERS-CoV mAbs (159, 160) will be diluted in DMEM starting at 1:20, and serial dilutions mixed with an equal volume of 50 PFU of chimeric bat SARSr-CoVs encoding different spike proteins and RFP indicator genes, then incubated on Vero E6 cells at 37°C for 1 h. Antibody neutralization titers will be evaluated by plaque quantification at 4-5dpi. In select instances, hACE2 transgenic mice will be injected with SARS-CoV mAbs, and infected with chimeric bat SARSr-CoVs. Clinical signs and morbidity will be assessed and tissue pathology examined and compared with mice without treatment of mAbs to determine the therapeutic effect on SARSr-CoV infection, and protection of SARSr-CoV by wildtype SARS-S based vaccines assessed as described (132, 161). We will sequence full length genomes of high risk strains that are antigenically distinct and escape SARS or MERS-

CoV cross neutralization, synthetically reconstruct a small subset (1-2), recover full length viruses and evaluate the ability of nucleoside analogues to inhibit growth in HAE cultures and/or *in vivo* (63, 132). For the Collaborative Cross model, we will infect six to eight mice from 6-8 Collaborative Cross mouse lines (10 weeks of age) with six test viruses/yr, intranasally or by subcutaneous infection with  $1 \times 10^4$  virus. Animals will be followed for weight loss, morbidity, mortality and other clinical disease symptoms (e.g., hunching, hindleg paralysis). One half the animals will be sacrificed at day 3 and day 7 pi. to evaluate virus growth in various organs, and organ pathology. In highly vulnerable lines, additional experiments will be performed using more animals, evaluating virus growth, clinical disease symptoms, respiratory pathology, tropism and organ pathology through day 28 pi. We anticipate that some CC lines will prove highly vulnerable to select wildtype viruses, because of host susceptibility combinations that promote severe disease outcomes.

**1.6. Potential problems/alternative approaches: Challenges with logistics or obtaining permission for wildlife sampling in sites we select.** We have a >20-year track record of successful field work in Malaysia, and >10 years in Thailand, and have strong established partnerships with local wildlife authorities and communities to ensure access. We have existing permissions in place which will be renewed at the start of this project. Due to the abundance of wildlife habitats in the region, if access to a site is withdrawn, we will rapidly identify a suitable, complementary site with similar bat species composition and abundance. Finally, we have already collected tens of thousands of wildlife samples from the region and will focus on these while waiting for permission. **We may not identify novel viruses in our sample wildlife species due to seasonality of viral shedding or other factors.** We have calculated sample sizes based on realistic detection rates from our extensive preliminary data, and are confident that we will detect and identify large numbers of potentially zoonotic pathogens, particularly for CoVs and PMVs. We acknowledge that FV strain diversity may be harder to capture, given relatively low seroprevalence in bat populations – suggesting lower levels of viral circulation (42, 43). However, our team was the first and only group to sequence FV RNA from Asian wildlife species (46, 47, 57), and we are confident that with our targeted sampling and testing strategy offers the best chance globally to identify additional strains of Ebola and related viruses. The sampling regions we have selected are subtropical, and our previous data, and even published studies in temperate regions (162), do not suggest a strong pattern of seasonality in CoV shedding, and where seasonal patterns do occur, i.e. for henipaviruses in Thailand (163), or can be predicted from wildlife serology data, we will be sure to conduct sampling at different timepoints throughout the year to account for this.

**Aim 2: Identify evidence and analyze risk factors for viral spillover in high-risk communities using novel serological assays.**

**2.1 Rationale/Innovation:** Rapid response requires early detection. Assessing the spillover of rare or novel zoonotic agents will require targeted surveillance of high-risk communities that interface frequently with wildlife that harbor high risk emerging viral strains. To enhance the low statistical probability of identifying these rare events, In Aim 2 we will target rural human communities inhabiting regions identified in Aim 1 as having high viral diversity in wildlife, that also engage in practices that increase the risk of spillover (e.g. hunting and butchering wildlife). We will initially identify 4 subsites in each of Thailand, Peninsular Malaysia, Sarawak, and Sabah for sampling. We will design and deploy human risk factor questionnaires, and specific and sensitive serological assays to identify the baseline frequency, and causes of, spillover of known and related novel viral pathogens in these populations. **We will use the results to test a key hypothesis: that hunting wildlife increases the risk of exposure to novel viruses, compared to the rest of the community.** The alternative hypothesis is that seroprevalence in the general community is not statistically different to those who hunt and butcher wildlife, because exposure to wildlife pathogens is largely through inhabiting a biodiverse landscape where wildlife make indirect contact with people (e.g. via fomites). For participants who report symptoms related to 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; 5) hemorrhagic fever; or 6) unusual presentation of high fever with severe diarrhea; all within the last 10 days, an additional sample type will be collected, two nasal or oropharyngeal swabs. Samples will be marked for additional PCR-based assays to identify presence of known and novel CoVs, henipaviruses and FVs, and for isolation and biological characterization of potential pathogens, using the approach laid out in Aim 1.

**2.2 Preliminary data on high-zoonotic risk human community surveillance: 2.2.a Biological sample collection in SE Asia:** Our long-term collaboration in the region has included qualitative and quantitative survey data, and collecting large archives of banked human sera and other biological samples from high zoonotic-risk populations. For example, under the USAID-PREDICT project, EHA has collected 1,400 and 678 specimens in Malaysia and Thailand respectively from people living in zoonotic disease interfaces, all of which will be available for retrospective serological testing by EID-SEARCH which we have ensured is compliant with our existing IRB. Our core group has collected and tested many thousand additional specimens from other important community cohorts (**Table 2**), and some of these will continue under EID-SEARCH (**Section 2.4**).

Country, site	Lead	# enrolled, focus	Findings
Peninsular Malaysia	Hughes	9,800+ samples, Orang Asli indigenous pop., for PCR/serol.	25+ novel CoVs, influenza, Nipah ab+ve, FV ab+ve
Malaysia Sabah	Kamruddin	1,283 for serology	40% JE, 5% ZIKV ab+ve
Malaysia Sabah	William	10,800 for zoonotic malaria study	High burden of macaque-origin malaria
Malaysia Sabah	Hughes	150 bat cave workers	Ongoing
Malaysia Sarawak	Siang	500 Bidayuh and Iban people	8% PCR prevalence HPV in women
Malaysia PREDICT	Hughes	1,400 high zoonotic-risk communities for viral PCR, serology	Ongoing. Multiple known and novel CoVs, PMVs, others.
Thailand	Wacharaplu-esadee	100s of bat guano harvesters/villagers	Novel HKU1-CoV assoc. clinical findings
Thailand PREDICT	Wacharaplu-esadee	678 high zoonotic-risk communities for viral PCR, serology	Ongoing. Multiple known and novel CoVs, PMVs, others.
Singapore	Wang	856, for Melaka virus	7-11% MELV ab+ve

**Table 2:** Biological sample collection from healthy populations conducted by members of **EID-SEARCH** in our hub countries.

Of particular interest is the access to indigenous communities in Peninsular Malaysia (Orang Asli) and Sarawak (Bidayuh, Iban people), and the bat guano harvesters in Thailand. These communities hunt, butcher and eat wildlife daily, and work in supremely high-risk zoonotic interfaces (e.g. bat caves). One of our indigenous community sites is experiencing an ongoing outbreak of unknown etiology that we are investigating currently (Section 3.2.a).

**2.2.b Human Contact Risk Factors:** EHA is the lead organization across all 27 USAID-PREDICT project countries for collecting data on, and analyzing the human aspects of, zoonotic spillover risk (164, 165). We conducted exploratory studies using standardized one-on-one semi-structured interviews and site observation data with people living in hotspot areas or engaged in high-zoonotic spillover risk activities, using these data to assess local social and cultural norms underlying wildlife contact (165). We then developed a risk factor survey to accompany human biological sampling to evaluate the type and frequency of animal contact, wildlife exposure in daily life, occupational risk in markets and long the wildlife value chain, and unusual illnesses reported over the past 12 months. We conducted cross-sectional studies in high risk populations in 27 countries, and study participants provided biological samples (oral/oropharyngeal swab, nasal/nasopharyngeal swab, urine sample/urogenital swab, fecal sample/rectal swab, whole blood, serum, plasma). For example, survey and biological samples were collected from: 1,585 participants from 7 sites in Yunnan, Guangxi, and Guangdong provinces, China; 1,400 participants from 4 sites in Malaysia; and 678 participants from 4 sites in Thailand. Samples were tested with novel serological assays and results analyzed against risk factors from survey data (16). In China, CoV-seropositive individuals were mostly farmers/peasants (8/9), living in Yunnan province (7/9), 41-60 yrs old (7/9), with domestic contact with rodents (6/9), that are male (6/9). Although these results are preliminary and don't provide detailed information on routes of exposure, they identify key subpopulations to target that would likely increase the opportunity for identifying evidence of spillover for other CoVs, PMVs and FVs. Data from PREDICT surveys have been used to help identify target populations in Aim 2, identify strategies to better target at-risk people, and conduct focused **human risk factor surveys and serosurveys to produce statistically significant findings for henipaviruses, CoVs and FVs.** In Aim 2, we will use combined biological sampling and risk factor surveillance in targeted populations within the community to 1) test the hypothesis that occupational (i.e. wildlife hunting) risk factors correlate with seropositivity to henipaviruses, FVs and CoVs; 2) assess possible health effects of infection in people; and 3) where recent

illness is reported, obtain biological samples for PCR testing and potential viral isolation and characterization. Obtaining this information could be a significant step in understanding the likelihood of recent 'hidden' spillover events and their public health impacts, as well as the risk of future emergence of viral disease.

**2.2.c. Risk factors for illness:** Our preliminary data in Thailand, Malaysia and other SE Asian countries revealed that frequent contact with wild (e.g. bats, rodents, NHPs) and domestic animals (e.g. poultry, swine) among local communities was associated with a high percentage of self-reported severe/acute respiratory illness (SARI/ARI) and Influenza-like illness (ILI) symptoms (**Section 3.2.b**). In addition, people involved in crop production, hunting and butchering of wildlife reported statistically significantly higher SARI and ILI symptoms (Li *et al.*, in prep.). **These preliminary data suggest a target population and sites for current proposal with the correct targets for serological surveillance and risk factor surveys in Aim 2 to produce statistically significant findings.** Coupled with better serological tools from our team (**Section 2.2.d**), we will be able to identify the likely routes of exposure to known or novel coronaviruses, henipaviruses, and FVs in the study region, as well as build data on the illnesses they cause in people.

**2.2.d. Serological platform development:** Most emerging viruses produced a short-lived viremia in people so that large sample sizes are required to provide enough PCR-positive individuals to analyze infection patterns. For Aim 2, we will focus on serological sampling in the community, because antibodies are typically long-lived and can be used to assess prior virus exposure or infection with much smaller sample sizes (123). Most serological assays target a single protein, and for emerging viruses, it's often unclear which viral antigen will be immunodominant during human infection, and therefore which to target in developing serological assays. Co-Is Wang, Anderson (Duke-NUS) and Broder, Laing (USUS) have developed a series of approaches to deal with this problem, and which will be used in testing human biological samples in Aims 2 and 3. Henipaviruses, FV and CoVs express envelope receptor-binding proteins that are the target of protective antibody responses. Co-I Broder has led efforts to express and purify henipavirus native-like virus surface proteins for immunoassay application (166, 167), developing monoclonal antibodies (168, 169) and as subunit vaccines (170, 171), has developed a novel, multiplex microsphere immunoassay (MMIA) allowing serum samples to be simultaneously tested for antibodies reactive with henipaviruses, FVs and CoVs. This MMIA uses a Luminex-based multiplex platform and custom designed virus receptor-binding proteins expressed in a mammalian cell-culture system and purified as native-like oligomeric proteins. These oligomeric antigens retain post-translational modifications and quaternary structures, allowing capture of conformational-dependent antibodies raised during a natural infection, which represent the majority of the protective humoral response. The known diversity of henipaviruses includes five presently described viruses, NiV, HeV, CedV, GhV and MojV and this assay has been expanded to include all described species (**Fig. 11**). In the past, our collaborators have used NiV and HeV G protein antigens in a MMIA assay to identify a serological footprint of NiV-related African henipaviruses and exposure to virus(es) antigenically-related to NiV in livestock sampled in Bangladesh (78, 79). To strengthen serological data interpretation, the G protein from each virus is integrated into the MMIA so that virus-specific vs. henipavirus cross-reactive antibodies can be detected and address specificity of past virus exposure. Extensive cross-reactivity exists among ebolaviruses and between ebolaviruses and marburgviruses (172-174). We are validating the MMIA pan-FV assay for specificity, and as part of this, in collaboration with Duke-NUS, we have found serological evidence of past exposure to a filovirus(es) most antigenically-related to ebolaviruses (e.g. Ebola virus, Bundibugyo virus), but unreactive with Reston virus GP in three under-sampled fruit bat species, suggesting that novel FVs circulate within bat hosts in SE Asia (43). **This platform has now been set up for use in Malaysia and Thailand and will be available for use in this proposed work.** Co-Is Hughes, Broder, Laing have conducted initial screening of human, wildlife and livestock samples at high-risk interfaces in Malaysia, finding serological evidence of past exposure to viruses antigenically-related to NiV and EBOV in humans, bats and non-human primates (NHPs).

**Fig. 11:** Validation of multiplex microsphere immunoassay (MMIA) specificity and identification of immunologically cross-reactive viruses for A) NiV B) EBOV.

Co-Is Wang and Anderson (Duke-NUS) have developed a phage-display method to screen antibodies for all known and related bat-borne viruses, including henipaviruses, FVs and CoVs and have set up a similar Luminex-based assay. Additionally the Duke-NUS team has demonstrated capacity for rapid and cost-effective development of LIPS serological assays against novel viral agents (**Sections 2.6.a, 3.2.a**). These will be used for verification and expanded surveillance. For molecular investigation (Aim 2 & 3), we will combine targeted PCR with a discovery-driven enrichment NGS strategy to not only survey currently known viruses, but also to discover potential novel viruses. Both the phage-display serological and enrichment platforms can be rapidly updated to include new viruses identified.

**2.3 General Approach/Innovation: Our human sampling approach uses two approaches in Aims 1 & 2 (Fig. 12). In Aim 2 we will conduct community-based surveillance using a brief, focused questionnaire to**

identify the prevalence and frequency of risk-factors for viral spillover in tandem with collection of high quality biological samples to determine the seroprevalence of spillover viruses in at-risk human populations. We will use generalized linear models to analyze correlation between biological results and risk-factors for viral spillover. In Aim 3, we will conduct clinic-based syndromic surveillance and biological sampling at clinics/hospitals that are the catchment healthcare facilities for the communities sampled in Aim 2. Both community-based and clinic-based syndromic surveillance programs are cross sectional case-control studies designed with the sample sizes necessary to statistically quantify (with a power of 80%) risk factors and health impacts for viral spillover, linked to serological status and PCR prevalence in symptomatic patients. All human sampling conducted under Aims 2 and 3 will adhere to strict criteria for inclusion and recruitment and protection of human subjects from research risk (**see Human Subjects and Clinical Trials Information**).

**Fig. 12:** Human sampling approach. Aim 2 (left) focuses on serology in high-risk communities to identify evidence of population exposure to novel zoonotic viruses. Aim 3 (right) sets up clinical cohorts at hospitals serving these high-risk communities to conduct syndromic surveillance and identify the etiology of new viral syndromes

**2.4 Target population & sample sizes:** We will target populations in the same geographic regions as those identified in Aim 1 that harbor wildlife with high potential zoonotic viral diversity, that are EID hotspots, and that are well-connected through regional travel and trade hubs to the global travel network (**Fig 13**). Within each geographic region we will identify populations at four sub-sites, building on our preliminary data (Table 2). We will target specific communities based on our analysis of previously collected behavioral questionnaire data, and other publicly available data (e.g. wildlife hunting licenses sold in a region, number of guano caves accessed for fertilizer etc.) to identify key at-risk populations and occupations with high exposure to wildlife. We will conduct concurrent sampling trips at visits to sub-sites during which members of the community will be enrolled and wildlife surveillance activities conducted. Individuals living or working around wildlife habitats (e.g. bat caves/roosts), who hunt wildlife, work with wildlife or livestock, or slaughtering wildlife will be considered for enrollment. Participants will complete a consent form and questionnaire in addition to having biological samples collected. During these community trips after data collection the field research staff will conduct community meetings to help inform the public health risk of zoonoses. **Target populations:** Thailand (Co-I Wacharapluesadee): 100 subjects of healthy high-risk community from 2 study sites, Chonburi (NiV, other PMVs and CoVs found by PCR in bats in our previous work), and Ratchaburi (bat guano harvester villages where we found a MERSr-CoV in bat guano (50, 175) and serological evidence of α-CoVs, HKU1-CoV in people (175)). Peninsular Malaysia (Co-I Hughes, CM Ltd.): We will expand our sampling of the Orang Asli indigenous communities to include sub-sites in communities in Districts we have already sampled and

additional Districts in the States of Kelantan Perak, Pahang, and Kelantan all close to bat caves. Samples will be stored and tested at NPHL. Sarawak (Co-I Tan, Fac. Med. Hlth. Sci. UNIMAS): We will expand our sampling of the Bidayuh and Iban indigenous people to include the Dayak and Orang Ulu (“people of the interior”) because this group has a more intimate connection to remote wildlife-rich areas than the other two, albeit all are hunters. Human sampling will be led by UniMAS in collaboration with CM Ltd / EHA. Sabah: We will conduct sampling at the Madai bat and bird cave that has 200 permanent residents who harvest bird’s nests for soup, and >1,000 during the harvesting season and at Gomantong cave – one of the largest bat and cave swiftlet nesting sites in the world. Sabah: (Co-I Hughes): We will conduct sampling at the Madai bat and bird cave that has 200 permanent residents who harvest bird’s nests for soup, and >1,000 during the harvesting season and at Gomantong cave – one of the largest bat and cave swiftlet nesting sites in the world. Protocols follow those for Peninsular Malaysia Singapore: (Co-I Wang, Duke-NUS): Active human surveillance will be not be conducted in Singapore, but archived human specimens e.g. from our Melaka virus serosurvey (8), will be made available to conduct retrospective serosurveys for specific pathogens that are identified as high interest to the EIDRC, NIH, and EID-CC.

**Fig. 13:** Targeting high-risk sites for human zoonotic disease surveillance in Thailand and Malaysia. This map plots areas with high numbers of expected viruses in wildlife (3), greater spillover probability based on EID risk factors (2), and higher levels of connectivity (measured by road density data) that may facilitate person-person spread.

**Sample sizes:** From our previous work we conservatively anticipate that 10-30% of the community population will have had exposure to wildlife allowing us to capture highly exposed and non-exposure individuals at each site. Individuals living or working around wildlife habitats (e.g. bat caves/roosts), who hunt wildlife, work with wildlife or livestock farming, transportation, selling, or slaughtering wildlife in the surveyed areas will be targeted so that they make

up  $\geq 30\%$  of the sampled population in each community. We will stratify sampling to ensure appropriate representation of sex, demographic, and socio-economic factors at each community site. In each of our regions, we will conduct sampling at four sub-sites in populations with high prevalence of high occupational and environmental risk of exposure to wildlife populations, sampling 175 persons at each sub-site. We will target populations with, on average, 30% or higher prevalence of occupational or environmental exposures to wildlife based on data from previous studies. This design will give us >80% power to detect 5 percentage point differences in seroprevalence against any of our viral groups between baseline and high-risk subgroups. We conservatively assume 5% base seroprevalence, as well as assuming high spatio-temporal variance amongst sub-sites, with baseline varying 0-25% amongst sub-sites and the fraction of the population at risk varying from 20-40%. (Power calculation conducted by 500 simulations of a generalized linear mixed model (GLMM)). For community-based surveillance, we will enroll 700 individuals per study region, allowing us to make county/province-level comparisons of differing effects; the total sample will be 3,500 participants over 5 years.

**2.5 Data & sample collection:** Following enrollment, biological specimens (5mL will be drawn for whole blood and serum collection, samples will be aliquoted, at least one max 500  $\mu$ L of whole blood and two 500  $\mu$ L serum samples) will be collected by locally certified healthcare professional proficient in phlebotomy techniques and a short questionnaire will be administered by trained project staff that speak appropriate local language to all participants. Through the serological findings and the survey we will investigate the details of five risk factors related to high risk wildlife exposure, to maximize the power of the analyses, based on continuing analysis of our previous work, and will focus on: 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, in/around house; 3) proximity of residence or work place to environments of increased risks, e.g. nearby bat roosts; 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms in the past 12mo and lifetime. For participants who report the symptoms relating to 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; or 5) hemorrhagic fever within the last 10 days, an additional sample type will be collected, nasal or oropharyngeal swab (2x). Blood of participants whose serum tests positive for emerging viral pathogens will be taken and Peripheral Blood Mononuclear Cells (PBMCs) frozen for future use.

These will be used for future harvesting of polyclonal and monoclonal antibodies as potential therapeutics/diagnostics (**see Letter of Support NEIDL**).

**2.6: Laboratory analysis: 2.6.a Serological testing:** We will screen all human specimens for henipaviruses, FVs and CoVs using our novel, multiplex microsphere immunoassay (MMIA) (**Section 2.2.d**). We will use ELISA and serum neutralization tests (SNT) as confirmatory, where feasible and appropriate for the biocontainment level given sensitivity and specificity variation, and the need for live virus for SNTs (**See Select Agent Research**). Serologic evidence of local spillover will be used to prioritize zoonotic strains for recombinant virus recovery from full length sequences. Preliminary data suggest ELISA will be effective for some viral groups. We previously developed a SARSr-CoV specific ELISA for serosurveillance using the purified NP of a bat SARSr-CoV (Rp3). The specificity of this assay was evaluated using polyclonal antibodies against HKU1, OC43, 229E, NL63, MERS-CoV and EBOV and no significant cross-activity detected (16). **This suggests that if we can expand our NP serology tests to cover other bat CoVs, and that doing so may identify many more seropositive individuals.** For CoVs, we will therefore use two serological testing approaches: 1) testing human sera collected from both community- and clinic- based sampling for a panel of bat CoVs that will include SARS-CoV, MERS-CoV, SADS-CoV and a range of bat SARSr-CoVs (16); 2) testing for antibodies to common human CoVs (HCoV NL63, OC43 – **Section 2.8**). We will test panels of NP and G recombinant proteins to assess if this approach will act as a comparison to MMIA for FVs and PMVs.

**2.6.b RT-PCR testing.** Specimens from individuals in the community who reported being symptomatic within the last 10 days (**Section 2.5**) will be screened using RT-PCR initially for CoVs, PMVs, and FVs following published protocols (**Section 1.4.c**). Positive samples will be subjected to full genome sequencing and RT-PCR amplification of the glycoprotein genes. Samples from the clinic-based syndromic surveillance will also be tested using RT-PCR for Influenza A & B, HCoV NL63, OC43, HKU1, SARS-CoV & 229E, NiV, HeV, Ebola (WHO PCR protocol) based on the symptom as rule-outs.

**2.6.c Biological characterization of viruses identified:** Novel viruses identified in humans will be recovered by cultivation or viruses re-derived from full length genome sequences using reverse genetic approaches. Viruses will be characterized for growth in primary human cell lines and in mouse models, including the Collaborative Cross Mice or humanized mice expressing human receptors from related strains. The approaches are discussed in more detail under Aim 1.

**2.7 Epidemiological analysis:** We will conduct a cross sectional case-control study to identify risk factors for Henipavirus, FVs, and CoVs spillover. “Cases” are defined as participants whose samples tested positive for Henipavirus, FVs, or CoVs by serological tests. “Controls” will be selected from the pool of participants admitted to the studies and whose samples tested negative for Henipavirus, FVs, or CoVs. We will use nearest neighbor matching to pair cases demographically (e.g. age, sex, location) with controls at a 1-to-3 ratio or greater. We will use generalized linear models and least absolute shrinkage and selection operator (LASSO) regression analyses (176) to analyze correlation between biological results, serological/PCR status, and risk factors related to high risk wildlife exposure including: 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, in/around house; 3) home or work proximity to environments of increased risks, e.g. nearby bat roosts; 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms lifetime and past 12mo. Additionally, we will use this procedure to determine how clinical presentation differs between Henipavirus, FVs, or CoVs in exposed and unexposed participants, as well as in the time course of illness, severity of symptoms, and type of symptoms.

**2.8 Potential problems/alternative approaches: Rarity of spillover events** means it may be difficult to identify sufficient seropositives to statistically analyze human risk profiles. First, we will be targeting our community-based surveillance to subpopulations with high-levels of wildlife exposure, at sites selected for diverse and prevalent viruses to increase likelihood of finding positive individuals. Second, our serology testing will include a multi-plex panel of assays for a large diversity of viruses, increasing likelihood of positives. For example, in previous work our overall bat CoV PCR prevalence in the community was, 11.8%;  $\beta$ -CoV, 3.4%;  $\alpha$ -CoV, 9.1%). Thus, using this broad serological panel to screen individuals prone to contact with species of higher zoonotic risk increases the potential for detecting spillover with enough power for statistical analyses,

and will shed light on behaviors that predispose to spillover. Third, we will include common human CoVs, PMVs, and influenza viruses in our panel, so that even if low prevalence of wildlife viruses is found, we will be able to conduct a valuable cross-sectional study of the seroprevalence of more common human viruses. Finally, we will be able to assess relative measures of human-wildlife contact from our survey work. We will analyze intensity of contact with high-risk taxa against other risk factors to provide useful proxy information for spillover risk. **Serological testing may be difficult to interpret in the presence of known and novel viruses.** We will use the three-tiered serological testing system outline in **2.6.a** to try to identify exposure to these ‘novel’ viruses. However, we know exposure to a range of related viruses generates antisera that are cross-reactive with known, related virus antigens - a serious challenge to serological surveillance and diagnostics. Our collaborations have already demonstrated that SE Asia bat sera samples screened with our pan-filovirus MMIA have been exposed to an Ebola-like virus, that is antigenically-distinct from known Asiatic filoviruses, Reston virus and Měnglà virus (43). Using these three serological platforms we will address inherent challenges of indirect virus surveillance through antibody capture by testing multiple binding assay platforms and antigens, using positive control samples to establish serological profiles against known viruses that will aid in our interpretations of cross-reactive antisera responses likely representative of ‘novel’ viruses.

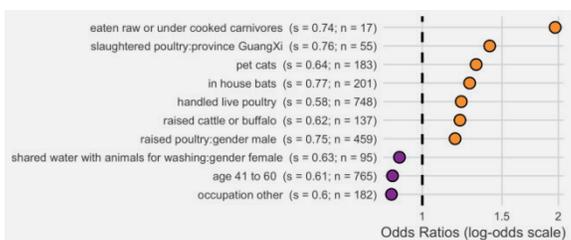

### **Aim 3: Identify and characterize viral etiology of ‘cryptic’ outbreaks in clinical cohorts.**

**3.1 Rationale/Innovation:** Our previous research (**Table 1**) and other data suggests that there are substantial numbers of outbreaks or clinical cases for which the etiologic agent is not diagnosed, e.g. (177, 178). To investigate this in SE. Asia, we have assembled a multi-disciplinary team that includes senior infectious disease doctors and clinicians and will work directly with local clinics and regional hospitals to identify the ‘cryptic’ outbreaks or cases that occur in the region. **In Aim 2, we will conduct serology in high zoonotic-risk communities to find evidence of prior exposure in people**, i.e. evidence of viral spillover into the community. In Aim 3 we identify members of these communities presenting at clinic with undiagnosed illness that may have high-impact zoonotic viral etiology. **Therefore, in Aim 3 we focus on PCR to identify the putative viruses that are replicating in these actively-infected patients (Fig. 12).** We will enroll, and collect high quality biological samples from patients who live in rural communities linked to Aim 2 and who present at regional clinics or hospitals with symptoms typical of high impact zoonotic viruses. We will collect detailed survey data to assess their contact type and frequency with wildlife and livestock and conduct molecular and serological diagnostic assays to test causal links between their syndromes and the known and novel viral agents identified in Aim 1. We will conduct molecular viral discovery assays on patients who present with symptoms indicative of a high-risk zoonotic virus. If novel pathogens are identified by PCR, we will attempt to isolate, obtain full genome sequence and/or biologically characterize the wildtype or molecularly re-derived pathogen, using the *in vitro* and *in vivo* strategy laid out in Aim 1.

**3.2 Preliminary data clinical surveillance: 3.2.a. Clinical surveys and outbreak investigations:** Our longterm collaboration in the region has included the following activities investigating clinical syndromes: **Peninsular Malaysia: At the time of writing, an outbreak of suspected undiagnosed viral illness in the indigenous Batek Orang Asli (“people of the forest”) community living at Gua Musang (“civet cat cave”) district, in Kelantan, Malaysia, close to Taman Negara – a National Park containing the oldest known rainforest. This community is one where we have conducted prior routine surveillance and biological sampling, demonstrating proof-of-concept that our two-pronged high-risk community/clinic approach will work.** Dozens of people are affected and the outbreak is currently being investigated by our group in collaboration with the Malaysian NPHL. The Orang Asli continue to practice traditional subsistence hunting of wild animals (bats, rodents, primates). These communities are remotely located, in heavily forested areas, with limited access to medical services. **This outbreak, and others that will continue to emerge just like it, underscore the critical need for our EIDRC - to improve the technological tools, training, and human capacity for rapid EID surveillance, diagnosis, and response at the frontlines of disease emergence in SE Asia. Investigating this outbreak is a key priority if EID-SEARCH is funded.** **Sabah:** Co-I Kamruddin (BMHRC) is leading an asymptomatic leptospirosis study on sanitation workers, an ILI study in a Kota Kinabalu clinic and diarrheal study in children under 5 yrs. Co-Is William, Tan and others have conducted clinical observational studies to determine the etiology of central nervous system infections and acute undifferentiated febrile illness in Sabah.

Co-Is William and consultant Yeo have collaborated with Co-I Wang to enroll 90 adult and over 100 pediatric participants with central nervous system infections, negative tests for malaria and dengue from 3 district hospitals in Sabah to determine the various etiologies. While a proportion tested positive for rickettsial agents, the majority had no clear diagnosis. Co-Is William, Rajahram, and Yeo have conducted clinical studies of over 200 inpatients with acute febrile illness with negative tests for malaria and dengue from 3 district hospitals in Sabah to determine the various etiologies. While a high proportion tested positive for rickettsial agents, the majority had no clear diagnosis. **Sarawak:** Co-I Siang (UNIMAS) is conducting a survey of high-risk female Kelabit indigenous people and has found 8% with HPV52 as the dominant strain. He is working on clinical cohorts of hand, foot and mouth disease and will recruit patients from that study in the current proposed work. Finally, Co-Is Siang, Kamruddin are conducting a long-term study of rotavirus and other viral etiologies of acute gastroenteritis in Kuching, Sarawak that will include swine herders and farmers. The Baric lab is a global leader in norovirus VLP diagnostic reagents to detect serologic evidence of norovirus gastroenteritis, as well as RT-PCR detection of novel noroviruses in humans, and has identified novel bat noroviruses, suggesting further opportunities for expansion of this work (142, 179-181). This work is particularly relevant in Malaysia because pig farms are shunned by the government and local villagers to they are placed far away from town centers, deep in the forest, and it is this scenario that led to the emergence of Nipah virus in 1998-9 (6, 22). **Thailand:** Co-Is Hemachudha, Wacharapluesdee (TRC-EID, Chulalongkorn Univ. Hosp.) work in coordination with the Thailand Ministry of Health to investigate outbreak etiology, including the first case of imported MERS-CoV in Thailand, **for which we produced sequence confirmation within 24 hours from acquiring the specimen.** Three imported MERS cases have been detected in Thailand since 2015, and all cases were confirmed at the TRC-EID. We worked during the Zika outbreak to identify > 500 PCR-positive Zika patients with sequence confirmation. We have also worked on returning and suspected Ebola travelers, syndromic surveillance for SARI, encephalitis, Hand Foot and Mouth disease in children and viral diarrhea. Consultant Hickey (US CDC, Thailand), screened specimens collected between 1998 and 2002 from a large cohort of children from Kamphaeng Phet Province to examine Dengue virus and JE epidemiology (182, 183). Among the 784/2,574 convalescent sera henipavirus-specific antibodies were detected in 13 serum samples (1.7% seroprevalence), suggesting prior exposure to endemic henipaviruses or a related PMV in rural Thailand. **Singapore:** Duke-NUS has worked with the Ministry of Health to investigate Zika cases (184), and other EIDs. With EHA and others, Duke-NUS has developed novel CoV assays for clinical surveillance, and for expedited analysis during outbreaks. Our pipeline of novel virus detection, reservoir host identification, serological assay development, and serological testing is as rapid as several months, with the development of novel serological assays from sequence data in 7 days (17). **For example, with the discovery of SADS-CoV, we identified and fully sequenced a new virus, screened archived wildlife specimens to identify the natural reservoir host species (*Rhinolophus* spp. bats), developed LIPS serological assays, and tested human and swine samples to assess seroprevalence in less than 3 months (17).**

**3.2.b Analysis of self-reported illness:** We have developed a standardized approach for analyzing data from study participants on self-reported symptoms related to target illnesses: fever with cough and shortness of breath or difficulty breathing (severe acute respiratory illness - SARI); fever with muscle aches (fevers of unknown origin (FUO)); and, cough or sore throat (influenza-like illness - ILI). For all of our prior human clinical surveillance in 20+ countries, including in Malaysia and Thailand, we used a least absolute shrinkage and selection operator (LASSO) regression to identify associations between participants who reported ILI and/or

SARI symptoms and demographics, occupation, and contact with animals in the last year. Results have clear biological relevance. For example, in Yunnan, China, factors strongly associated with prior disease involve animal hunting and consumption (Fig. 14). We will expand this approach for all clinical syndromes in Aim 3, and use targeted questions to assess patient's exposure to wildlife in terms that are relevant to each specific country.

**Fig. 14:** Factors associated with self-reported ILI & SARI in prior 12 months (s = bootstrap support; n = #+ve out of 1,585 respondents). **Orange circles** = odds ratios > 1 (+ve association); **purple** = odds ratios < 1 (-ve association).

**3.3 General Approach:** Our previous research suggests that there are substantial numbers of outbreak cases for which the etiologic agent has not been identified. To capture these, we will expand on our current syndromic surveillance to enroll, and collect high quality biological samples from patients who present at regional clinics and live in rural communities linked to Aim 2. Case definitions and enrollment criteria include: 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; 5) hemorrhagic fever; or 6) high fever/diarrhea with unusual presentation. We will collect survey data to assess contact with wildlife, and occupational and environmental exposures, conduct molecular and serological assays to test causal links between their syndromes and the known and novel viral agents identified in Aim 1. If novel pathogens are identified by PCR, we will attempt to isolate and biologically characterize the pathogen, using the collaborative cross to identify an appropriate animal model to conduct preliminary pathogenesis work. We will then use behavioral survey data, ecological and phylogeographic analyses to assess the likely reservoir hosts to inform intervention programs.

**3.4 Clinical cohorts. 3.4.a Cohort selection:** We will initiate active clinic-based syndromic surveillance at 2 town-level level clinics and 2 provincial-level hospitals in each Thailand, Peninsular Malaysia, Sabah and Sarawak. These serve as the catchment healthcare facilities for people in our community-based surveillance of Aim 2 and are inclusive of wildlife sampling sites in Aim 1. Patients  $\geq 12$  years old presenting at the health facility who meet the syndromic and clinical case definitions above will be recruited into the study after completing a consent form. We will aim to enroll 300 participants per hospital, with that we will have a 95% probability of detecting live virus in patients in each hospital assuming a population prevalence of 1%. This sampling effort will total of 4,800 individuals for clinical syndromic surveillance. We assume up to 40% loss from follow-up, therefore yielding 2880 participants that will be available for follow-up blood sampling (**Section 3.4.b**). While enrollment is limited by the number of patients that come to the healthcare facility presenting with relevant clinical symptoms, in our work in the PREDICT project we enrolled an average of 100 participants per year, so we are confident this is an achievable enrollment target. Study data will be pooled across country regions, as clinical patients are limited by the number of individuals presenting at hospitals. “Cases” will be determined as participants whose samples tested positive for either CoVs, henipavirus, or FVs, PCR tests. “Controls” will be selected from the pool of participants admitted to the studies and whose samples tested negative. We will use nearest neighbor matching to pair cases demographically (e.g. age, sex, location) with controls at a 1-to-3 ratio or greater. Sites: Thailand: We will work with two primary hospital, Phanat Nikhom Hosp., Chonburi district (Key Pers. Dr. P. Hemachudha) & Photharam Hosp., Ratchaburi Province, and a large tertiary hospital, King Chulalongkorn Memorial Hospital, Bangkok Thailand (Co-I Dr. T. Hemachudha). Peninsular Malaysia: **Focusing immediately on the current outbreak in Orang Asli, we will work closely with the Malaysian Ministry of Health to support their investigation, and with 6 Orang Asli clinics which focus solely on this indigenous community.** Co-I Sellaran (Lintang Clinic, Kuala Kangsar) refers patients to Sungai Siput Hospital and Gen. Hospital, Ipoh. Key Pers. I Lotfi (Pos Betau clinic, Kuala Lipis) will continue collaboration with Co-I Hughes in the communities at that site. Sarawak: Key Pers. Diyana (Director, Bario Clinic) refers patients to Miri Hospital (Co-I Utap) and serves people from the Kelabit, and nomadic tribes in the region, as well as populations within a number of large towns. Sabah: We will continue our collaboration with Queen Elizabeth Hospital, QEH (Key Pers. Lee, Rajahram) and Hospital University Malaysia Sabah, HUMS (Co-I Lasimbang, Director). Both clinics include our targeted sites for **Aim 2** in their catchment, and both have ongoing collaboration with the Borneo Medical Health Ctr (Co-I Kamruddin, Director). Singapore: Currently, there are no plans to conduct clinic surveillance based on budget constraints. However, in the event that that is an evolving need for clinic surveillance, enrollment, and sampling, we have close working relationships with all hospitals in the country, and the central infectious disease reference lab (key clinicians at which are aware of our proposal). This would allow us to rapidly on-board a hospital based site.

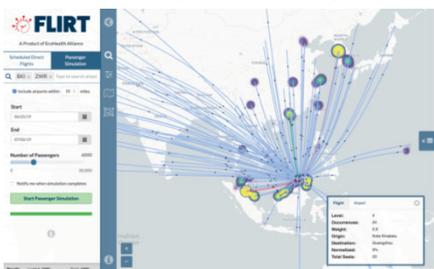

**3.4.b Clinic enrollment and follow-up:** We will recruit inpatients and outpatients to participate in the study after initial screening to determine if they meet our clinical case definitions. Once consented and enrolled, biological samples will be collected by trained and locally certified hospital staff and a questionnaire administered by trained hospital or research staff that speak appropriate local language. Every effort will be made to take samples concurrently when collecting samples for normative diagnostics. For both inpatients and outpatients, samples will be collected no more than 10 days of reported onset of illness to increase the chance

of PCR detection of viruses (185). Where possible, we will follow up 35 days after enrollment to collect an additional two 500  $\mu$ L serum samples conduct a standardized questionnaire supplement to collect additional data on the course of symptoms in the interim period. This gives adequate time for development of IgG, which occurs <28 days after onset of symptoms for SARS patients (186-188). Serum samples will be used to screen panels of high risk human and local zoonotic Filovirus, Henipavirus and Coronavirus strains as described in Aim 2. These samples may prove valuable to collaborators in that the PBMC could be used in production of therapeutic antibodies.

**3.4.c Sampling and clinical interview:** Biological specimens whole blood (5mL will be drawn for whole blood and serum collection, samples will be aliquoted, at least one max. 500  $\mu$ L whole blood; two 500  $\mu$ L serum samples) and two nasal or oropharyngeal swabs will be collected from all participants, and a questionnaire will be administered. We will investigate five risk factors, to maximize the power of the analyses, all related to high risk wildlife exposure, based on continuing analysis of our previous work, and will include: 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, in/around house; 3) proximity of residence or work place to environments of increased risks, e.g. nearby bat roosts; 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms in the past 12mo and lifetime. With additional consent considerations for participants enrolled from clinical settings, we will review clinical records to collect data on medical history, clinical syndromes, and patient etiology. Blood will be taken for future harvesting of Peripheral Blood Mononuclear Cells (PBMCs), as per **Section 2.5**.

**3.5 Sample testing:** The standard syndromic diagnostic PCR assays for common pathogens will be conducted and the results will be shared with the hospital with 48 hours. Specimens will be further tested for 3 viral families; CoV, PMV and filovirus by consensus PCR (**Section 1.4.c**). Necropsy samples from deceased patients will be further characterized by NGS if previous PCRs are negative and unable to identify the cause of infection. Co-Is Wang, Anderson will conduct a VirScan serological assay using paired serum samples at Duke-NUS that identifies antibodies with a four-fold rise in titer in the convalescent sample compared with the acute sample, thereby indicating a possible etiological agent. A PCR test with the specific primer from each virus antibody positive case will be further tested from acute specimens to confirm infection.

**3.6 Viral risk characterization and potential for pandemic spread:** We will use statistical models built from collated biological, ecological, and genetic data to assess the likelihood of pathogenicity for the range of diverse viruses we will characterize. The aim is to quickly identify and assess which viruses pose the most significant risk to human health and thus prioritize additional resources to more fully characterize, better understand pathogenicity, and invest in our animal model pipeline and ultimately therapeutic development for those pathogens. We will combine two independent but related statistical models to predict pathogen spillover risk and pathogenicity. First, we will expand a simple generalized additive modeling approach (3) to assess spillover risk probability to a new virus that is currently not known to infect people, when we have only limited genetic data from initial PCR screening and sequencing. Additional data from receptor binding protein homology and cell line infection experiments will be incorporated into the model framework as available. Second, given high likelihood to spillover and infect humans, or direct evidence of human infection from our clinical surveillance, we will then assess the likelihood of pathogenicity based on traits for phylogenetically related nearest neighbor viruses as a first approximation and incorporating more detailed data from genomic characterization and animal model experiments (Aim 1). Epidemiological trait data for ~300 viral species known to infect people (e.g. case fatality rate, global estimates of number of human cases per year or decade,  $R_0$ , infectious period, and primary symptoms) have been collated by recent studies and will be used as predictor variables (189). Thirdly, we will apply tools already developed, and being refined by EHA under DTRA and DHS supported research, to predict pandemic spread for viruses using global flight models, as well as additional datasets on human movement and connectivity across Southeast Asia (90, 91) (**Fig. 15**).

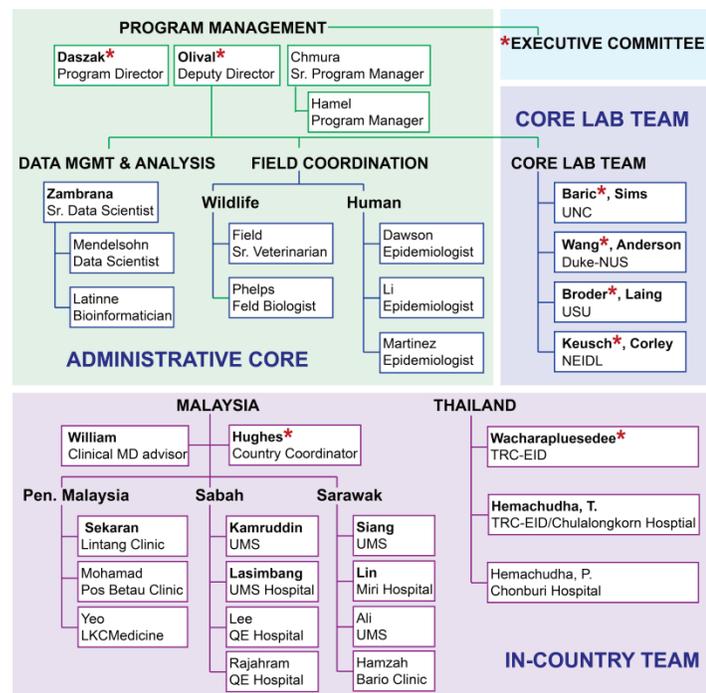

**Fig. 15:** Probability feed from EHA's Flight Risk Tracker tool (FLIRT). This image is of the likely pathways of spread and establishment for a Nipah-like virus emerging from Sabah, based on human movement and airline flight data (90, 91).

**3.7 Potential problems/alternative approaches: Patients visiting clinics may have cleared virus, but not yet developed IgG antibodies, reducing seropositive cases.** Our 35 day follow-up sampling should account for this because the maximum lag time between SARS infection and IgG development is ~28 days and Ebola virus infection and IgG approximately 20 days (185-188, 190). We also expect that patients in rural communities will only visit clinics when symptoms have progressed, likely coinciding with late illness and onset of IgG. We will also have data from our community study that can be analyzed in conjunction with, or in the absence of, clinical data from the hospital data to identify PCR- or seropositives. Finally, the risk of limited detection is outweighed by the potential public health importance of discovering active spillover of new henipaviruses, FVs or CoVs infection.

**4. Administrative Plan**

**4.1. Project management: 4.1.a. Administrative core:** The EID-SEARCH organizational partner roles are laid out by Specific Aim above (see Fig. 3). EcoHealth Alliance (EHA) will lead the administrative core of the EID-SEARCH, including: coordination and management of all human and animal research; communication with consortium partners, NIH, other EIDRCs, and the EIDRC-CC; data management and quality assurance; modeling and analysis; and compliance with all US, international, and institutional rules and regulations. The administration will be led by PI Daszak, who has >20 years' experience managing international research collaborations on emerging zoonoses, and has collaborated with all partners in the EIDRC consortium for 5-20 yrs on NIAID- and USAID-funded research (Fig. 16). He also has direct experience as one of two external reviewers of one of the CEIRS partners for NIAID (Program officer Diane Post). PI Daszak will be assisted by Deputy Lead, co-I Olival, who has overseen zoonotic disease research in Southeast Asia for >10 years and working directly with our partners in Thailand and Malaysia for 15 years. Senior program manager (Chmura) and full-time program assistant (Hamel) will provide administrative support. The EID-SEARCH data management, epidemiological analysis, and modeling activities will be led by co-Is Olival and Zambrana who have led all modeling and analytics on USAID USAID PREDICT for the last 10 years. They will oversee a programmer/data scientist (Mendelsohn), evolutionary biologist/bioinformatician (Latinne), and human epidemiologists (Dawson, Li, Martinez). Our human epidemiology team will work directly with country teams in Malaysia and Thailand to manage human surveillance, IRB applications and approvals, and ensure compliance with all human subjects work. EHA's senior veterinarian (Field) and wildlife field biologist (Phelps) have extensive experience working that bats, rodents, and primates in SE Asia and will coordinate all training and field research in Malaysia and Thailand and ensure compliance with IACUCs.

and full-time program assistant (Hamel) will provide administrative support. The EID-SEARCH data management, epidemiological analysis, and modeling activities will be led by co-Is Olival and Zambrana who have led all modeling and analytics on USAID USAID PREDICT for the last 10 years. They will oversee a programmer/data scientist (Mendelsohn), evolutionary biologist/bioinformatician (Latinne), and human epidemiologists (Dawson, Li, Martinez). Our human epidemiology team will work directly with country teams in Malaysia and Thailand to manage human surveillance, IRB applications and approvals, and ensure compliance with all human subjects work. EHA's senior veterinarian (Field) and wildlife field biologist (Phelps) have extensive experience working that bats, rodents, and primates in SE Asia and will coordinate all training and field research in Malaysia and Thailand and ensure compliance with IACUCs.

**Fig. 16: Administration and program management for the EID-SEARCH**

The EID-SEARCH core laboratory team includes global experts in virology, molecular pathogenesis, and the development of assays, reagents, and therapeutics for high consequence viral zoonoses (Co-Is Wang, Anderson at Duke-NUS; Baric, Sims at UNC; Broder, Laing at USU; Keusch, Corley at NEIDL). The core laboratory team will work with in-country diagnostic labs in Thailand (Wacharapluesedee, Hemachudha at the TRC-EID, Chulalongkorn University) and Malaysia (Hughes, Lee, CM Ltd.). Wacharapluesedee and Hughes will additionally serve as country coordinators for the EID-SEARCH, liaising directly with EHA on weekly conference calls, and working with in-country partners to ensure the smooth operation and coordination of clinical and community surveillance and wildlife research in Thailand and Malaysia, respectively. **A Core Executive Committee** comprising PI Daszak, Deputy Lead and Co-I Olival, and leads from each core partner and country: Co-Is Hughes, Wacharapluesedee, Baric, Wang, Broder, Keusch (or alternates), will conduct

regular conference calls and in-person meetings to facilitate rapid decision making within the EID-SEARCH. **This committee will also convene to manage EID-SEARCH response to outbreaks.**

**4.1.b Project Management in Thailand and Malaysia:** Wacharapluesedee and Hughes have collaborated directly with EHA for >15 years, including acting as country coordinators on the USAID PREDICT project for the last 10 years (project end date Sept. 2019). They maintain strong ties with Ministries of Health (MOH), Agriculture and Environment, multiple universities and research institutions, clinics, and hospitals, in their respective countries and across the region. The EID-SEARCH will use these connections to disseminate results, obtain permissions to conduct sampling, and also rapidly respond to and assist with outbreaks as they happen. Peninsular Malaysia, Sarawak, and Sabah are the three main Malaysian administrative regions, and effectively operate as three separate countries, with different regulations and government structures. We therefore provide specific details on the management of EID-SEARCH activities in each:

Coordination among Peninsular Malaysia, Sabah and Sarawak will be led by co-I Hughes (Conservation Medicine Ltd), and follow a successful model we implemented under USAID-PREDICT. **On Peninsular Malaysia** this project will be administered through the Zoonosis Technical Working Committee (ZTWC) established under the PREDICT project with a binding MOU among EHA, CM Ltd. and ZTWC, and including officers from MOH, Dept. of Veterinary Services, and PERHILITAN (the Govt. wildlife agency). EHA will communicate weekly with Co-I Hughes to coordinate and monitor implementation of research and reporting to ZTWC. Co-I Hughes will coordinate activities at all other Peninsular Malaysia institutions: NPHL, the National reference laboratory for diagnostic confirmation of pathogens, will manage molecular and serological screening (BioPlex) of Orang Asli samples, and serological screening of syndromic samples from Sabah and Sarawak; the PERHILITAN molecular zoonosis laboratory will store and conduct molecular and serological screening on wildlife samples; and Universiti Putra Malaysia (UPM) Faculty of Veterinary Medicine will conduct molecular and serological screening (BioPlex) of livestock samples, should these be required. **For Sabah & Sarawak**, work will be administered through the Sabah Zoonotic Diseases Committee (SZDC), a working technical committee comprising appointed and authorized officers from Sabah State Health Dept., Department of Veterinary Services, Sabah Wildlife Dept. (SWD), Universiti Malaysia Sabah (UMS) and EHA, all of which are also committed through a signed MOU. Co-I Hughes will oversee work at all other partners in Sabah, including: the Kota Kinabalu Public Health Lab (KKPHL) for molecular screening of syndromic samples from Sabah and Sarawak; the SWD Wildlife Health and Genetic and Forensics Lab for molecular screening of Sabah wildlife samples; The Borneo Medical Health Research Center (BMHRC) for screening some Sabah wildlife and livestock samples, if required, and human syndromic samples from Sabah and Sarawak. **In Thailand** all human community and wildlife research and testing will be coordinated by co-I Wacharapluesedee from the TRC-EID center. Clinical surveillance will be overseen by senior clinical physician and co-I T. Hemachudha.

**4.1.c. Approval and release of results:** In our experience, it is critical when working in resource-poor countries, on potentially important pathogens, to strictly adhere to protocols for release of results. EID-SEARCH will liaise with existing points of contact in the Ministries of Health, Environment, and Agriculture in each our administrative areas to approve and release project findings publicly. Results from human screening will be shared with participants when they become available, as per our IRB agreements ensuring no violations to anonymize data requirements (**see Protection of Human Subjects**).

**4.2. Flexibility to extend the EID-SEARCH to new sites as needed:** The EID-SEARCH consortium partners maintain extensive working relationships with leaders in EID outbreak control, clinical investigations and research at over 50 clinics, research institutes and public health laboratories across Southeast Asia. Due to space constraints, we haven't listed each of these, nor have we solicited >50 Letters of Support for this project. However, each core EID-SEARCH partner has contacted their networks and obtained permission for inclusion in the broader goals of the EIDRC. As examples of these contacts, our core partner, the Thai Red Cross Emerging Infectious Disease Health Science Centre (TRC-EID) at Chulalongkorn University, also serves as the WHO Collaborating Centre for Research and Training on Viral Zoonoses and has ongoing research collaborations across WHO SEARO countries including Bangladesh, Bhutan, Democratic People's Republic of Korea, India, Indonesia, Maldives, Myanmar, Nepal, Sri Lanka, (Thailand), Timor-Leste; and has recently served as a training hub for scientists from Malaysia, Myanmar, Laos, the Philippines, and China to learn methods of wildlife sampling and diagnostic screening. Our Thai clinicians (Co-I T. Hemachudha and KP P.

Hemachudha) provide regular case consultations and clinical trainings for doctors across SEARO countries, including with Yangon General Hospital and the National Health Lab in Myanmar, 2018. To maximize leverage of this broad network, EHA has budgeted for annual meetings in SE Asia, in addition to regular smaller network meetings, with our core team and key public health experts from network labs in each of the 10 SE Asian countries. Additionally, we will set up a listserv and an internal communication network to facilitate collaboration and information exchange, including on the first reports of new disease outbreaks. Our annual and smaller network meetings will critically allow face-to-face meetings of the EID-SEARCH that will foster greater sharing of information on novel research and diagnostic approaches, pathogens that are of key pandemic potential, regions or populations at high risk of spillover, and information from the greater network on likely outbreaks of novel disease. This platform will coordinate sample sharing and diagnostic platforms and help build a rapid response to outbreaks in the region, guided by the PI, Deputy and the Executive Committee.

**4.3. Outbreak response:** EHA collaboration with expert networks around the world allows us to mobilize and enhance effective One Health response to disease emergencies (191), ranging from real-time situation updates and risk analyses to on-the-ground investigations (192-194). We will adopt management tools from Emergency Operating Center (EOCs) (195) and Incident Management Systems (IMS) (196), to shift resources where necessary to help respond to novel zoonotic outbreak events and other public health emergencies. EHA has extensive experience working with governments in low and middle income countries (LMIC) applying these principles of epidemic preparedness during outbreak responses we've been involved with under the USAID-PREDICT project. For example, at the request of the government of Bangladesh, we provided technical field and laboratory support for Nipah virus and avian influenza outbreak investigations, assisting with wildlife sampling as part of the outbreak response alongside human and domestic animal sampling. In India, we provided technical assistance in response to the Nipah virus outbreak in Kerala in 2018. Last month in Indonesia we assisted the Ministry of Health's Center for Health Laboratory in Makassar to provide technical assistance in a mysterious outbreak in a small village in South Sulawesi that killed 4 villagers and infected 72. Our network partners include the key government and govt. approved laboratories that would be directly involved in public health emergency response in their respective countries. The serological and PCR platforms that EID-SEARCH develops will be made available to the main government outbreak investigation teams for clinical work and research during the outbreak. EID-SEARCH will also offer assistance training and conducting animal sampling during an outbreak, epidemiological analysis and modeling to help identify likely reservoirs or likely pathways to spread. Technical and material support for lab, field and analytical activities during an outbreak will be provided by EHA, UNC, USU, Duke-NUS, and NEIDL, as well as in-country partners. Any clinical samples, viral isolates and sequence data will be shared among partners to promote the rapid development of new diagnostic assays, reagents, and therapeutics that can be deployed to the region or other regions as part of the larger NIH EIDRC network.

Finally, while the initial pathogen focus of our group is on CoVs, PMVs and FVs, our broad collaborative group has multidisciplinary expertise on a number of virus-host systems. For example: PI Daszak was PI on a subaward from PI Laura Kramer's U01 on Poxviruses and Flaviviruses, managing a multidisciplinary research project on West Nile virus ecology. He was also co-I on a 5-year NSF-funded project to understand West Nile virus dynamics and risk in the USA (197-201); Co-I Baric is a global leader in Norovirus research leading to the development of vaccines and therapeutics (202-205); Co-I Wang has conducted significant work on bat immunology, therapeutic, and reagent development, as well as being involved in a range of outbreak investigations, viral discovery programs and other research on a wide diversity of viral groups (206-215). Additionally, the serological and PCR-based diagnostic platforms being developed by Co-Is Wang and Broder are adaptable to other viral targets. The modeling tools developed by Co-Is Olival and Zambrana-Torrel can be used to predict the emergence and spread of diverse viral targets, including influenza, antimicrobial resistance, and vector-borne diseases (216-221). Our clinicians working in Thailand and Malaysia have a wide range of infectious disease investigations to adapt to any outbreak situation.

**4.4. Communications:** EHA will coordinate communication among all co-Is and key personnel, including:

- Multiple meetings per week with PI, Deputy Lead, Senior Program Manager (on project and task status)
- Weekly web/phone meetings between Program Manager and subawardee admin. staff
- Monthly web/phone conferences between EHA PIs and all subawardee PIs.

- Monthly web conferences between key personnel (research presentations/coordination)
- In-person Annual meetings with partner leads, key personnel at EHA and two in-person partner meetings annually between subawardees.
- Annual in-person meeting among all key personnel

**4.5. Problem identification and resolution:** Regular planning, monitoring, and evaluation meetings will be the primary mechanisms for problem identification. Minor problems (e.g. delays in sample availability or test results) will be dealt with internally through appropriate action and resolution monitored by PI Daszak and co-PI Olival, and our Senior Program Manager. In the event of significant problems, such as prolonged poor productivity, inadequate scientific collaboration, or major disputes regarding research direction or resource allocation, EHA will assist with resolving the problem through negotiation with relevant co-PIs and consultation with the Executive Committee. Should a resolution not be forthcoming, consultation with the EIDRC-CC, additional external technical advisors, and NIH staff may be warranted.

**4.6. Adaptive management and risk mitigation:** Maintaining a timeline and meeting milestones will require strict and continuous oversight of all project phases, frequent and regularly scheduled communication, and the ability to make decisions and implement strategies. To maintain our timeline on all projects, including the EID-SEARCH, we use an adaptive management approach to continually evaluate these trade-offs, to make decisions about when iteration is appropriate and when it is necessary to move forward with current information. Our ethos is that regular, scheduled communication among all staff, partners and collaborators will go a long way towards mitigating risks, especially if the process is collaborative and transparent.

## 5. Data Management Plan

EHA will house the Data Management and Analysis (DMA) team for EID-SEARCH, led by Co-PIs Olival and Zambrana-Torreilo and include Key Personnel Latinne and Mendelsohn. EHA has served as the data and analysis hub for numerous multi-institutional, multi-sectoral, international disease research groups, including acting as Modeling and Analytics lead for the PREDICT project (122), the Western Asia Bat Research Network (222) and EHA's Rift Valley Fever Consortium. We will leverage our experience and infrastructure from those projects to benefit the EID-SEARCH. **5.1. Project Database:** We will create a dedicated, centralized EID-SEARCH database to ingest, store, link, and provide for analysis all data associated with the proposed study and other expanded projects associated with the research network. The database will be SQL-based and use encrypted, secure cloud hosting services and enable export to archival and platform-independent formats. It will ensure data and metadata compatibility between project components, track data versioning and annotations. The system will be designed to work with both with both paper- and tablet-based field data entry and with the Lockbox laboratory information management systems (**Section 5.2**) in place in individual partner labs. The database will use existing metadata standards, including NCBI standards for genetic and molecular data and Ecological Metadata Language (EML) for field and wildlife data, as well as other standards and formats designated by the EIDRC CC. This will enable rapid publication and deposition of data. Granular security and privacy controls will be applied so that specific expansion projects undertaken in the network may be managed while maintaining data confidentiality as needed.

**5.2. Biological Specimen Management:** Project laboratories will use the Lockbox Laboratory Information Management System (LIMS), to manage the security, traceability, and quality of biological specimens. The LIMS will support sample barcoding at creation, tracking through transport, storage/inventory, and use via portable scanners. Lockbox supports CLIA and ISO 17025 as well as direct export to NCBI formats such as Sequence Read Archive. We will use the Lockbox LIMS application programming interface (API) to link to the central project database and associated samples with field and ecological data. We note that the project focuses on highly pathogenic viruses, including select agents; Lockbox LIMS supports sample tracking and movement compliant with US Select Agent Regulations and US Department of Commerce Pathogen Import and Export Control Regulations, and includes all necessary encryption, security, and backup protocols.

**5.3. Training:** Members of the DMA team will team will develop documentation and provide training for field and laboratory teams at all partner institutions in data management, metadata standards and data hygiene best practices. The DMA team will act as trainers and consultants for partner institutions in experimental

design, power analysis, data analysis, and computational and reproducibility issues, and visit each partner institution and/or field team base for training workshops and analysis consultations.

**5.4. Data Identification and Privacy:** For human clinical data and questionnaires, data will be identified by a unique identification code assigned to each individual and only this, de-identified code will be accessible in the project database, and destroyed at the end of the project - as per details provided in the Clinical Management Plan and Protection of Human Subjects forms.

**5.5. Computing Resources:** EHA operates a cluster of high-performance servers for data analysis activities, as well as infrastructure to launch cloud-based computing environments (**see EHA Facilities**). Our servers host all necessary software for statistical and bioinformatics work that is available to the DMA and partners anywhere in the world. We use a mixture of cloud services (AWS, Azure, Backblaze, GitHub) to provide redundancy, backup, version control, and rapid post-disaster recovery, and will be available to all project partners for analysis and training.

**5.6. Data and Code Sharing:** See details provided in the **Resource Sharing Plan**.

## **6. Clinical Management Plan**

**6.1. Clinical site selection:** Our consortium partners have been conducting lab and human surveillance research, including during outbreaks, for >20 years and have developed strong relationships with local clinical facilities and processes in SE Asia and in LMIC globally. The plan for selection of clinical sites will begin in the same geographic regions as those identified in Aim 1 with high zoonotic viral diversity. Clinical sites will additionally serve as the catchment healthcare facilities for people in our community-based surveillance of Aim 2. We have already developed successful working relationships with the major healthcare facilities in Thailand and Malaysia and will use these established partners to rapidly gain appropriate permits and begin data collection quickly. Focusing on these EID hotspots in select biogeographic areas (see **Fig 13**) also reduces the number of additional sites needed to meet our goals within our geographic range. The capacity and capability requirements for clinical sites are fairly minimal, and include ability to enroll patients that meet the clinical case definitions of interest, collect and temporarily store biological samples, and follow standards for data management and subject protection with locked filing cabinets to store all paper records and an encrypted computer. We will be enrolling inpatient and outpatient participants within 10 days of the presentation of symptoms to increase the chance of PCR detection of viruses so we will not wait for advanced normative diagnostic tests, that are likely unavailable in the more remote sites, to be completed. We will work with clinical sites to determine the best process for project staff, in most cases supporting the time of currently hired staff at each site. We will recruit and train hospital staff in project-specific procedures including enrollment of patients, sample types to be collected, storage of samples, administration of the questionnaire, and data management plans. During the development and onboarding of new clinical sites we will assess the physical needs of the site and what supplies will be required for collection of data.

**6.2. Standardized approach, oversight, and implementation:** Management and oversight for all study sites will be undertaken by the local country coordinator with support from our Core Administrative team at EHA. Our research team has over 10 years of experience building capacity on human subjects' research and has developed training resources and materials for standardized implementation of community and clinical research and SOPs for screening, enrollment, and retention of participants. The country coordinator will conduct regular site visits to the clinical sites and annual visits to observe, monitor and evaluate the research process, and conduct follow-up training if required. Through our work with clinical sites under the USAID-PREDICT project we have developed culturally appropriate screening measures for clinical sites that do not disrupt the flow or quality of medical treatment received by the patient. This was done by working collectively with clinical staff to evaluate current procedures and patient flow at the site to determine the most efficient while minimal invasive inclusion of our study into the daily working of the clinical site. Most efficiently this was done by adding minimal basic screening questions to the current clinical intake forms, which allows the clinical research officer to quickly scan charts or logs for potential patients to enroll avoiding potential enrollees from being overlooked if staff are too busy or not on duty. Patients will be enrolled following established clinical criteria (**see Section 6.3**), samples collected and brief surveys conducted to assess the participants contact with wildlife through: 1) occupational exposures; 2) animal contact; and 3) the environment. With permission

from each clinic, and consent from participants, we will review clinical records to collect data on medical history, clinical syndromes, and patient etiology. Additionally, we will be following up with clinical participants to determine how clinical presentation differs between CoV, henipavirus, or FV in exposed and unexposed participants, as well as in the time course of illness, severity of symptoms, and type of symptoms. The country coordinator will be continually monitoring the project database to ensure we hit target sample sizes. While patient's enrollment is limited by the number of individuals presenting at hospitals, in previous research we enrolled an average of 105 patients per year, ranging from 77-244.

**6.3. Clinical cohort setup, recruitment, enrollment:** We will recruit inpatients and outpatients from clinical sites to participate in the study after initial screening to determine if they meet the clinical case definitions for 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; 5) hemorrhagic fever, of unknown etiology or severe diarrhea with unusual presentation for symptoms to increase the chance of PCR detection of viruses. Once enrolled, biological samples will be collected by trained hospital staff. When possible, samples will be taken concurrently with samples being collected for normative diagnostics. We will collect 5mL of blood for whole blood and serum collection, samples will be aliquoted, at least one max. 500  $\mu$ L whole blood; two 500  $\mu$ L serum samples and two nasal or oropharyngeal swabs will be collected. Controls who test positive for CoVs, FVs, or Henipaviruses will be selected from the pool of participants admitted to the studies and whose samples tested negative for coronaviruses, henipavirus, or filoviruses. We will follow up 35 days after enrollment to collect an additional 5mL blood draw for collection of two 500  $\mu$ L serum samples and a standardized questionnaire supplement to collect additional data on the course of symptoms in the interim period. Following up 35 days post initial collection gives adequate time for 1) development of IgG and IgM, which occurs <28 days after onset of symptoms to evaluate the immunological progression of disease and 2) further the risk assessment of the participants to monitor contact with wildlife, people, and to assess the likely reservoir hosts to collect information to inform potential intervention programs.

**6.4. Utilization of collected data:** Sampling of wildlife and the enrollment of community surveillance participants and a clinical cohort of participants give us the ability to assess the viruses that are circulating in each of the three populations in a similar geographic region. We will use phylogenetic analysis to compare the relationship between wildlife viruses found and viruses found in human participants. Additionally, the questionnaire data will allow us to assess relative measures of human-wildlife contact that we will analyze the intensity of contact with species known to be at a higher risk for spillover against other risk to provide useful proxy information for spillover risk. The clinical cohort will be split into cases and controls. "Cases" are defined as participants whose samples tested positive for either CoV, henipavirus, or FV via PCR tests. "Controls" will be selected from the pool of participants admitted to the studies and whose samples tested negative. We will use nearest neighbor matching to pair cases demographically (e.g. age, sex, location) with controls at a 1-to-3 ratio or greater. In clinical study, we will use this procedure to determine how clinical presentation differs between virus-exposed and -unexposed participants, as well as in the time course of illness, severity of symptoms, and type of symptoms. We will model the outcomes to analyze correlation between biological results and risk factors related to high risk wildlife exposure. With this collective data set we aim to quantify and detect novel viruses likely to spillover regularly to people, are often unreported or misdiagnosed as their clinical manifestations, and are unknown to detect cryptic outbreaks causing previously 'hidden' clinical syndromes in people. Our strategy for targeted surveillance and detection of spillover and illness in at-risk human populations can be used as an 'early warning system' to conduct public health interventions and disrupt disease emergence.

**6.5. Development of reagents of value to the community.** Members of the EID-SEARCH consortium have substantial experience producing reagents, assays, and other products that are used widely by the clinical and research community, and some of which are on a pathway to commercialization. These include: PIs Daszak and Co-I Olival have produced software for analyzing the spread of novel viral agents through air travel networks; Co-I Baric has collaborated with a Norovirus surveillance collaboration with surveillance cohort at CDC and has developed therapeutics that have reached phase 2 and 3 clinical trials, He is currently working with Takeda Sanofi Pasteur on a Dengue therapeutic and with NIH on a tetravalent vaccine; Co-I Broder

developed a Hendra virus subunit vaccine that was commercially produced by Zoetis for horses and is labeled for human use under compassionate circumstances during outbreak situations.

**6.6. Potential expansion:** Expansion of the research project to other clinical sites or research areas could happen as new information is gathered, either through our research, the EID-SEARCH information network, or an outbreak being identified in the region by other organizations. If expansion is required we would rapidly shift research activities towards the clinical or community sites where the outbreak is active, using the same process we used to set up initial research locations. First, by working with local stakeholders to create a working relationship and on-boarding new clinical research staff through advanced trainings of project aims, SOPs on data collection and storage, and ethical guidelines. The network of infectious disease researchers in the community and hospital settings would allow for an accelerated response to any potential infectious disease outbreaks as staff are well trained on ethical guidelines for working with human subjects, data and specimen collection, storage, and transpiration, project staff would be on the front lines ready for the call to action. Ideally, our testing for viruses in priority viral families may lead to the discovery cryptic outbreaks before it spreads in the general public. Biological results coupled with survey data on key risk factors will provide necessary information for granular understanding of disease spread.

## **7. Statistical Analysis Plan:**

**7.1. Framework:** Statistical analyses across the project will be conducted under a common Bayesian framework. These models provide a unified, probabilistic approach best-suited for estimating effect sizes in heterogeneous populations of human clinical and wildlife subjects in observational studies. Within this Bayesian framework, we will use generalized linear mixed models to estimate population prevalences and seroprevalences, and estimate the effects of demographic, occupational and environmental factors affecting these. We will use occupancy models (223) to estimate total viral species and strain diversity and completeness of sampling within the human and wildlife sub-populations, and discrete phylogeographic models to identify taxonomic and geographic centers of viral diversification. All statistical analyses will be performed reproducibly using scripted, programmatic workflows (e.g., the R and Stan languages) and maintained under source code version control (git). As with data management, the DMA team will act as trainers and consultants for exploratory data analysis, power analysis, and study design with project partners, and the EHA computing cluster will be available for partners undertaking additional or expansion studies. Power analyses, current and expansion, are performed via simulation approaches allowing planning for complex, hierarchical variation in study populations. Power analyses and specific analytical components of this study are detailed under each Specific Aim.

**7.2. Data Quality Control and Data Harmonization:** All data will be examined at entry by field and lab teams upon data entry, followed by examination by DMA team members at upload and integration, for complete de-identification, completeness, accuracy, and logical consistency. The DMA will provide field and lab teams with reports, produced automatically, of data summaries, including aggregates, distribution, detected outliers and possible mis-entries. On a regular basis (quarterly or as-needed during data collection), DMA team members will review reports with field and lab teams to identify errors and update collection and entry procedures as necessary.

**7.3. Statistical Considerations for Behavioral Questionnaires and Clinical Metadata:** The data collected from the questionnaire will be analyzed to assess the reported measures of contact for each risk group under study, related to 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, rodents, and primates in/around house and other livestock animals (e.g. farming, butchering, slaughtering); 3) proximity of residence or workplace to environments of increased risks (e.g. nearby bat roosts); 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms in the past 12 months and lifetime. Specific measures we are interested in are the proportion of respondents indicating they consume wildlife, where wildlife is obtained for consumption, have hunted wildlife, butchered or slaughtered live animals, seen wildlife in their homes, been bitten or scratched by animals, etc. Comparisons of measures of exposure contacts and types between men and women, children and adults, different study regions will be conducted in order to explore the occupational, environmental, and demographic factors (gender, age, socioeconomic status (SES)) that influence contact with animals and to determine who is

most at-risk. Statistical analysis will be employed to identify differences between groups with a 95% probability of detecting a difference. Measures of contact related to different activities within specific groups will be compared to determine the activities that put groups at most risk. As appropriate multivariate analysis (e.g. ordinary linear regression, logistic regression, non-normal distributions of outcome, least absolute shrinkage and selection operator (LASSO) regression, etc.) will be utilized to evaluate the relationship between the outcome variables, positive biological results (PCR or serology) key measures of contact and the factors that influence frequency and types of human-animal contact.

## 8. Project Milestones and Timelines

**8.1 Milestones: End of Year 1: Aim 1:** Sample targeting locations, species (for wildlife), sample size justifications completed for whole project and reported to in-country teams; Sample testing, viral isolation, NGS, glycoprotein sequencing begun for all archival and some newly-collected samples; *in vitro* work begun; host-pathogen dynamic analyses; animal model work begun. **Aim 2:** Target human community populations identified and sample sizes calculated for some sites in each country; Community data collection, serological testing and RT-PCR testing begun; first epidemiological analyses of data begin in last quarter. **Aim 3:** Clinical cohort selection underway; clinical enrollment, data collection and sample analysis begun. First Annual meeting in last quarter. First publications submitted by end of year, summary overview papers or reviews.

**End of Year 2:** **Aim 1:** No sample targeting or sample size justification analyses needed. All other aspects underway **Aim 2:** All aspects underway **Aim 3:** All sub-aims underway. Second Annual meeting in last quarter. Further 2 publications submitted by end of year, including first data papers.

**End of Year 3:** **Aim 1:** No sample targeting or sample size justification analyses needed. All other aspects underway **Aim 2:** All aspects underway **Aim 3:** All sub-aims underway. Third Annual meeting in last quarter. Further 3 publications submitted by end of year, largely data papers.

**End of Year 4:** **Aim 1:** No sample targeting or sample size justification analyses needed. All other aspects underway **Aim 2:** All aspects underway. Receptor binding work completed. **Aim 3:** No further cohort selection required; all other sub-aims underway. Fourth Annual meeting in last quarter. 3 further publications submitted, including first papers analyzing risk factors, pathogenic potential of novel viruses submitted.

**End of Year 5:** **Aim 1:** No sample targeting or sample size justification analyses needed. No receptor binding assays continuing. Serological and PCR testing completed end of 2<sup>nd</sup> quarter. Glycoprotein, *in vitro* and *in vivo* analyses, analysis of viral risk continue to end of project. **Aim 2:** No further community targeting or sample size work. Community data collection completed at end of 2<sup>nd</sup> quarter. All other aspects continue to end of project **Aim 3:** All sub-aims underway. Final Annual meeting in last quarter. Further 3 publications submitted.

### 8.2. Timeline:

ACTIVITIES	YEAR 1				YEAR 2				YEAR 3				YEAR 4				YEAR 5			
	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4	Q1	Q2	Q3	Q4
AIM 1	1.4.a. sampling targets	■	■	■	■															
	1.4.b. sample size justifications	■	■	■	■															
	1.4.c. sample collection & testing																			
	1.4.d. NGS

**Subject:** Re: EID-SEARCH v4

Hi Peter,

Built on top of Chris' suggestions. Included a prelimin data figure from Hughes et al, in prep. Double check that is ok with Tom?

Dear All,

Here's version 4. Apologies for the delay. It's in better shape now, but there are still lots of areas that need your attention. Please put in time today, and tomorrow to edit and firm up the text. I've put your names in some of the comment boxes where I need specific help but I also need you to read this critically now and edit and tighten it up. We have 30 pages of space, and our research plan is now 21 pages, so we need to lose maybe 3 or 4 pages. There are also some weak points, specifically on Filoviruses, on the details of where we'll do our clinical work, and on what we'll do with the animal models for henipias and filos.

Please get comments back with me before Wednesday 26<sup>th</sup> 4pm New York time, so that I have Wednesday evening and all day Thursday to incorporate them. In the meantime, I'll be working with folks here on better figures, and all the extra sections that come after the research plan. I'll need you all to help with those on Thursday while I'm finishing off the draft.

Thanks to all of you in advance and look forward to the next round.

Cheers,

Peter

**Subject:** EIDRC-SEA v.3  
**Importance:** High

Dear all,

Thanks to everyone for comments and text for the earlier draft at the beginning of the week. Kevin's spent the last couple of days pulling all the comments together into one draft and inserting his changes, and I've now attached a v3 of the draft. It's still rough, and now too long, but it's getting there. I wanted you to look at this rough version because I'm stuck in Liberia in meetings Friday, then flying back home Saturday. I'll continue editing this draft on the plane and will be working solely on this grant from home on Sunday, Monday, Tues, Wed, Thurs.

Please work on this rapidly if possible. If you can all push your comments through, using track changes, and get them back to me **by Sunday evening New York Time**, I will turn round a polished draft by Tuesday, giving us time for significant last go-over on Wed, Thurs. It's tight, but unfortunately, it is what it is, so please commit the time if you can!! As well as general edits (using track changes, with references in comment boxes), please do the following...

Linfa/Danielle – We especially need your input in section 1.1, 1.3, 1.4 and 2.5

Ralph/Amy - Please work your magic on this draft, inserting text, editing and reducing text, and making sure the technical details of the characterization are correct and fit the proposed work on CoVs, PMVs and Henipaviruses

Chris/Eric – Eric – congratulations on your (b) (6) and thanks for working on it at this time!  
Chris – please help and edit/finesse the language in the relevant sections for you

Tom – Your edits crossed over with Kevin's changes, so please insert all the bits that were new in the last version you sent to me, into this version. I think these are mainly the sections and comments from the other Malaysian colleagues, but please check and re-insert all key text. We especially need to be specific about which partner in Malaysia is doing what cohorts, and where, and about who's doing the testing

Thanks again all, and I'm looking forward to non-stop work on this as soon as I get on my flight in 24 hours...

Cheers,

Peter

<EIDRC Southeast Asia v4.docx>

## II. Research Strategy:

**1. Significance:** Southeast Asia is a critical hotspot for emerging diseases due to its high biodiversity of wildlife and their viruses, and the presence of key ecological and socioeconomic drivers of emergence (**Fig. 1**) (1). These include dense human populations living in networks of rural and urban communities, with strong cultural and occupational connection to wildlife and livestock farming and trading, and intimate connection to global travel networks (2). The region is undergoing rapid environmental and demographic change, both of which increase the risk of disease emergence and spread. Pathogens that emerge in this region often spread and sometimes enter the USA (e.g. prior influenza pandemics, SARS) and threaten global health security.

**Fig. 1:** Southeast Asia, and in particular, parts of Thailand and Malaysia are hotspots of risk for disease emergence (**left**), and predicted high diversity of 'missing' or as-yet undiscovered viruses, yellow = highest diversity (**left**). From (1-3).

Not surprisingly novel viruses, including near-neighbors of known agents, have emerged in the region leading to often unusual clinical

presentations (**Table 1**). This adds to a significant background burden of repeated Dengue virus outbreaks in the region (20), and over 30 known *Flavivirus* species circulating throughout S. and SE Asia (21). The events in Table 1 are dominated by three viral families: coronaviruses (CoVs), paramyxoviruses (PMVs - particularly henipaviruses) and filoviruses (FVs), which are initial examples of our team's research focus and capabilities. These viral groups have led to globally important emerging zoonoses (4, 5, 22-31), causing tens of thousands of deaths, and costing billions of dollars (32-34). Furthermore, near-neighbors of known pathogens in these families have been reported throughout the region, including by members of our consortium: henipaviruses in bats in Thailand, Cambodia, Philippines, Laos, Indonesia, China, Malaysia, Bangladesh and India (35-41); a novel henipavirus, Mòjiāng virus, in wild rats in Yunnan (14); serological evidence of FVs in bats in Bangladesh (42) and Singapore (43); Nipah- and Ebola-like viruses in *Hipposideros*, *Cynopterus* and *Rhinolophus* species in Malaysia (Hughes *et al.*, in prep.); evidence of novel FVs in bats in China (44-46), including Měnglà virus

Viral agent	Site, date	Impact	Novelty of event	Ref.
Nipah virus	Malaysia, Singapore 1998-9	~246 human cases, ~40% fatal	2 <sup>nd</sup> emergence of a zoonotic henipavirus, 1 <sup>st</sup> large outbreak	(4-6)
Melaka & Kampar virus	Malaysia 2006	SARI in family group, individual	1 <sup>st</sup> disease due to bat-origin reoviruses, also Singapore, Vietnam etc.	(7-10)
Reston filovirus	Philippines 2008	Seropositive people killed pigs,	No prior FVs in pigs	(11)
Thrombocytopenia Syndrome virus	E. Asia 2009	100s of deaths in people	Novel tick-borne zoonosis with large caseload	(12)

that appears capable of infecting human cells (47); novel PMVs in bats and rodents consumed as bushmeat in Vietnam (48); a lineage C  $\beta$ -CoV in bats in China using the same cell receptor as MERS-CoV to infect human cells *in vitro* (49); MERSr-CoVs in bat guano harvested as fertilizer in Thailand (50), and directly in bats (Wacharapluesadee *et al.*, in prep.); 172

**Table 1:** Recent emergence events in SE Asia indicating potential for novel pathways of emergence, or unusual presentations for known or

related viruses.

novel  $\beta$ -CoVs (52 novel SARSr-CoVs) and a new  $\beta$ -CoV clade (“lineage E”) in bats in S. China that occur throughout the region (24, 49, 51, 52); 9 novel wildlife-origin CoVs and 27 PMVs in Thailand, and 9 novel CoVs in Malaysia reported by us from USAID-PREDICT funding (51, 53). These discoveries underscore the clear and present danger of zoonotic events in the region. The wide diversity of potentially pathogenic viral strains also has significant potential use in broadly active vaccine, immunotherapeutic and drug development (49).

Most high-impact zoonotic viruses originate in wildlife reservoirs, sometimes spilling over first into livestock ‘amplifier’ hosts, or directly into localized human populations with high levels of animal contact (**Fig. 2**). Efforts to prevent emerging zoonoses have targeted these high-risk populations in regions prone to disease emergence (31, 54). However, these regions tend to be in the developing world, where nations often lack the resources to investigate novel zoonotic events, or wildlife reservoirs of zoonoses, and prioritize more immediate public health concerns such as Dengue virus or NTDs (20). Zoonotic disease surveillance and control is also hampered by inadequate information on basic disease ecology (e.g. range of wildlife reservoirs, risk factors for spillover) and pathogen biology (viral diversity, pathogenesis), and by logistical challenges sharing novel diagnostics, animal models, samples and reagents at sites where outbreaks begin (55). Countermeasure and vaccine development is challenged by the small number of isolates available, and the presence of closely-related strains, some with evidence of transmission to people but with unknown pathogenicity. For example, using NIH and other funding, we found serological evidence of exposure to African henipaviruses in 3-4% of a sample of people in Cameroon, with a significant risk factor being butchering of bats; and serological responses to bat SARSr-CoVs in 6/209 (2.87%) and bat HKU10-CoV in 2/412 (0.5%) people living close to a bat cave in Yunnan, all novel viruses with unknown clinical impact (16, 56). We discovered two novel bat-borne reoviruses, Melaka and Pulau viruses, and showed that 14/109 (13%) of people living in close proximity to bat roosts on Tioman Island, Malaysia were exposed to these viruses (7) as well as 12/856 (1.4%) of a random sample screened in Singapore (8). Previous studies in the Philippines found farmers and butchers who had contact with sick pigs tested positive for Reston ebolavirus antibodies but had not experienced illness (11), and it was our team that discovered Philippine bats as natural reservoir hosts for Reston virus (57). In preliminary screening in Malaysia with funding from DTRA we found serological evidence of exposure to henipaviruses (Hendra, Nipah and Cedar) in 14 bats and 6 human samples, and Ebola (Zaire and Sudan)-related viruses in 11 bats, 2 non-human primates (NHP) and 3 human samples (Hughes, in prep.).

Even when spillover leads to outbreaks of illness and mortality, they are often unreported, undiagnosed or misdiagnosed. We initiated targeted syndromic surveillance of encephalitis patients in Bangladesh clinics and showed that Nipah virus (NiV) causes repeated annual outbreaks with an overall mortality rate of ~70% (58). NiV has been reported in people in West Bengal, India, which borders Bangladesh (28), in bats in Central North India (59), and now in people in Kerala, South India in 2018 and 2019, raising the specter of future spillover at other sites in the region (18, 60).

**Fig. 2: Our Early Warning Approach:** Most zoonotic viruses emerge from wildlife hosts, sometimes via livestock (**lower panel**), to cause small scale outbreaks (green) or larger chains (red) of human-to-human transmission (**middle**). In some cases, these spread more widely via air travel (**upper**). Our EIDRC proposal targets each stage: SA1 examines the diversity and spillover potential of viral threats in targeted SE Asian wildlife; **SA2** seeks evidence of their spillover into focused high-risk human populations; **SA3** identifies their capacity to cause illness and to spread more widely. Figure from (54).

Under a current NIAID R01, we have shown that we can use analytical approaches to target surveillance of wildlife and people and identify likely sites of spillover. We used phylogenetic analysis of bat hosts and their CoVs to identify a key cave complex in SW Yunnan Province that harbors all the genetic elements of SARS-CoV (61), as well as a series of SARSr-CoVs that can infect human cells *in vitro*, cause SARS-like clinical signs in humanized mice, and evade vaccine treatment and therapeutics (24, 49, 51, 52, 62-64). We conducted risk factor surveys and biological sampling of human populations living close to this cave and found serological evidence of spillover in people highly exposed to wildlife (16). **This work provides proof-of-**

**concept for an early warning approach that we will expand in this EIDRC to target other viral groups in one of the world's most high-risk EID hotspots.**

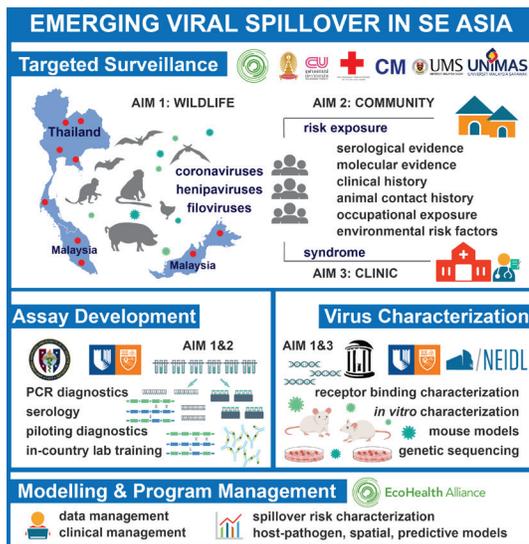

The overall premise of this EIDRC proposal is that there is substantial evidence that: 1) diverse CoVs, henipaviruses and FVs related to known human pathogens are circulating in wildlife reservoirs in Southeast Asia; 2) these viruses likely spillover regularly to people, are often unreported or misdiagnosed, and their clinical manifestations and potential to cause pandemics are unknown and underestimated; and 3) our strategy for targeted surveillance and detection of spillover and illness in at-risk human populations can be used as an 'early warning system' to conduct public health interventions and disrupt disease emergence. To scale-up this approach, we propose to launch EID-SEARCH (the **E**merging **I**nfectious **D**iseases - **S**outh **E**ast **A**sia **R**esearch **C**ollaboration **H**ub), to better understand, and respond to, the risk of zoonotic viral emergence in Southeast Asia. We will initially focus on the diversity of known and novel CoVs, henipaviruses, and FVs in wildlife reservoirs. We will use this work to build our center's interactive network throughout the region, bridge barriers, provide early focal point for basic and translational studies, develop sample handling and storage routines, communication networks, cohort management, infrastructure development, and cross-training in surveillance and novel diagnostic platforms. We will develop and transfer technology to test these viruses' capacity to infect human cells and mouse models, develop new specific and sensitive serological and molecular diagnostic tools, conduct surveillance of human communities with high risk of exposure to wildlife, and clinical cohorts to identify evidence of spillover of viruses causing previously 'cryptic' clinical syndromes in people. We will test the capacity of novel viruses to infect human cells and/or mouse models, and thus assess potential for spillover and spread which will feed into our risk models. Our group also has extensive experience in other viruses, including vector-borne flaviviruses, and alphaviruses, and will use this experience to provide robust long-term surveillance, diagnostics, and basic science opportunities. While the current proposal focuses its basic and applied research agendas on this group of viral EID, we note that the EID-SEARCH is poised to rapidly respond to any outbreak. **Thus, FVs, henipaviruses and CoVs are examples of sentinel surveillance systems in place that illustrate EID-SEARCH's capacity to identify and initiate a rapid response targeting any novel microbial pathogen that emerges in this region.**

**2. Innovation:** Previous work by our consortium has developed strategies to target surveillance in wildlife and people to better anticipate and identify early spillover events and pre-empt outbreaks of emerging viruses. In the EID-SEARCH we scale up this approach in a central research "hub" made up of leading laboratories, clinics and surveillance sites in three critically high-risk EID hotspot countries in SE Asia. EID-SEARCH's reach is expanded through its regional network of collaborators that covers nearly all of the greater SE Asia region. The innovation of the EID-SEARCH is in: 1) its multidisciplinary approach that combines modeling to target geographic and taxonomic sampling targets with on-the-ground zoonotic disease surveillance in human and wildlife populations; 2) the biological characterization approach that identifies how likely viruses are to be able to infect people, and enables evaluation of existing countermeasure technologies; an approach that is grounded in our successful work on SARSr-CoVs; and 3) the strategic sampling of both high-risk communities with extensive animal contact at the front-lines of viral spillover and syndromic clinical cohorts that present with signs of novel viral emergence, to identify risk of viral spillover in an early warning system approach (**Fig. 2**). **In Aim 1, we will target viruses in archived and newly collected wildlife samples, and characterize their risk of spillover to people.** We will use spatial and phylogeographic analyses to identify the geography and species of wildlife to test samples from, and to further characterize viruses we have recently discovered. We will use *in silico* methods (novel ecological-phylogenetic risk ranking and mapping of receptor binding domains), cell culture, and animal models to assess their potential for spillover into high-risk human populations. **In Aim 2, we will conduct targeted cross-sectional serological surveys of human communities with high levels of animal contact to find evidence of viral spillover, and identify occupational and other risk factors for zoonotic virus transmission.** We will use serological tests targeting viruses identified in Aim 1 to identify the baseline spillover of known or novel CoVs, henipaviruses and FVs in these populations. Serological findings will be analyzed together with subject metadata (including a simple animal-contact survey, location data, viral sequence/isolates etc.) to identify zoonotic risk factors and routes of exposure from specific wildlife or vector species. **In Aim 3, we will use syndromic surveillance of clinical human cohorts to identify evidence of viral etiology for otherwise 'cryptic' outbreaks.** We will enroll and

collect biological samples from patients in local clinics and hospitals who present with syndromes previously linked to known viral agents and live within communities at high risk for disease emergence. We will conduct molecular and follow-up serological diagnostic assays to identify likely viral etiology of syndromes that may represent otherwise cryptic events. Where viruses are identified, we will attempt to isolate or molecularly re-derive them, and use survey data, ecological and phylogenetic analysis to identify likely reservoir hosts and inform intervention programs. Our US partner BSL-4 laboratory, NEIDL, will attempt isolation and characterization of viruses requiring BSL-4 of containment (e.g. novel filoviruses, close relatives of Hev/NiV).

**3. Approach: 3.1. Research team:** The EID-SEARCH builds on long-term collaboration among world leaders in emerging virus research with proven experience collaborating internationally on field, lab and human surveillance research (**Fig. 3**). Over the past two decades, our consortium partners have conducted high profile research on EIDs within the region and globally, including identifying the wildlife reservoirs for NiV and Hendra virus (HeV), MERS- and SARS-CoVs (24, 27, 59, 61, 65-67), discovering SADS-CoV (17), and developing an array of serological, molecular, *in vitro* and *in vivo* approaches to characterizing high-risk CoVs, henipaviruses, and FVs (62-64, 68-81). Our team has substantial experience conducting human surveillance in the community and during outbreaks (Sections 2.2.a., 2.2.b., 2.2.c, 3.2.a, 3.2.b), including: USAID-PREDICT, and DTRA-funded viral surveillance of indigenous communities in Peninsular Malaysia and syndromic surveillance of hospital patients in Sabah (Co-I Hughes); collection of >2,000 serum samples from healthy blood donors and sanitation workers, febrile and influenza like illness (ILI), and diarrheal stool samples from children under 5 years of age across Borneo Malaysia (Co-I Kamruddin); collaboration on the MONKEYBAR project with the

London School of Hygiene and Tropical Medicine to analyze risk and prevalence of the zoonotic malaria *Plasmodium knowlesi* through case control and cross-sectional studies in Sabah villagers (n=~800, 10,000 resp.) and clinical observational studies to determine the etiology of central nervous system infections and acute undifferentiated febrile illness in Sabah. (Co-Is William, Rajahram, Yeo); and community-based surveillance of hundreds of bat-exposed villagers in Thailand (Co-Is Wacharapluesedee, Hemachudha). As a proof-of-concept of how our team can rapidly scale up resources for diagnostics and surveillance in the face of a new EID, in 2016, we discovered a novel bat-origin HKU-2 CoV (82, 83) killing >20,000 pigs in S. China, designed PCR and serological assays, surveyed pig farmers for evidence of exposure, and conducted experimental infections, pathogenesis and molecular studies, **all in the span of 3 months** (17, 84).

**Fig. 3:** EID-SEARCH scope, core institutions, and roles.

The administration of this center (**Section 4.1.**) will be centralized at EcoHealth Alliance (EHA) led by PI Daszak, who has >20 years' experience managing international research collaborations on emerging zoonoses, and has collaborated with all partners in the EIDRC consortium for 5-20 yrs on NIAID- and USAID-funded research. He will oversee all activities in this EIDRC, supported by Deputy lead, Dr. Olival – who has managed human and wildlife disease surveillance projects in SE Asia for >10 years, and a **Core Executive Committee (Section 4.1.a)**. Co-Is Olival and Zambrana are leaders infectious disease analytics, and head the modeling and analytics work for USAID-PREDICT. Co-Is Wang, Baric, Broder, Anderson, and Laing have developed a unique array of *in vitro* cell culture, serological and molecular reagents to identify and characterize emerging viruses in people and animals (henipaviruses and other PMVs, CoVs, FVs and many others). Co-Is Wacharapluesedee, Hemachudha, and Hughes and collaborators have coordinated clinical and community surveillance of people, and of wildlife and livestock within Thailand and Malaysia for the past 15 years, in collaboration with Ministries of Health, Agriculture and Environment. Finally, this consortium has extensive external funding from NIH, DoD, USAID, DHS and other USG agencies supporting laboratory, analytical and field studies directly related to the current proposal, and will bring substantial leverage to our EIDRC.

**3.2. Geographical focus:** The three core (hub) countries for this proposed EIDRC are Thailand, Malaysia and Singapore, three contiguous EID hotspot countries that stretch through one of the most significant foci of EID origins globally. Our proposed work includes sampling wildlife and people in Thailand, Peninsular Malaysia, Sarawak and Sabah, and thus contains overlapping wildlife biogeography with India, Bangladesh, Myanmar, SW China, Laos, Cambodia, Vietnam, Philippines, and Indonesia. It encompasses diverse cultural and socioeconomic backgrounds which have correspondingly diverse and intensive interactions with wildlife reservoirs and the global travel network. We have already begun sampling of wildlife hunters, livestock workers, wildlife farmers and market workers, rural villagers living close to high risk wildlife species, people otherwise highly exposed to animals in these countries, and clinical cohorts, as part of current/prior NIH, DTRA, and USAID funding. Our core member's extensive network of collaborators in clinics, research institutes and public health laboratories in almost every other Southeast Asian country positions the EID-SEARCH within a much larger catchment area for emerging zoonoses and will allow us to rapidly scale up to include additional sites in response to an outbreak or shift in research priorities. We will conduct regular meetings with key research, public health and community leaders, including >50 leading laboratories/institutions in 10 countries (Section 4.2) to maintain these collaborative relationships with the core members of our consortium (Fig. 4).

We will use these, and our annual meetings, to share information on novel research and diagnostic approaches, pathogens that are of key pandemic potential, regions or populations at high risk of spillover, and information from the greater network on likely outbreaks of novel disease. This platform will coordinate sample sharing and diagnostic platforms and help build a rapid response to outbreaks across the region.

**Fig.4 :** Map of Southeast Asia indicating three hub countries for this proposed EIDRC (**Red**: Thailand, Singapore, Malaysia) and countries in which Key Personnel have existing collaborating partners via other funded work (**Green**), indicating that EID-SEARCH provides access to key collaborators and sites throughout the region.

**3.3. Capacity for linkage with other NIAID studies, and scaling up to respond to outbreaks:** EID-SEARCH US-based partners include senior scientists with significant experience on NIAID-funded projects, extensive collaborations with other NIAID-funded scientists, and previous experience working with NIAID leadership through workshops, review of programs (e.g. PI Daszak's role in NIAID CEIRS external review), and work on study sections. These contacts ensure that the EID-SEARCH senior leadership will be ready and able to rapidly set up data, sample and reagent/assay sharing protocols with NIAID researchers, the other EIDRCs, the EIDRC CC and other NIAID research centers. EID-SEARCH in-country partners include senior medical doctors and infectious disease specialists at national and regional hospitals in each country and administrative state in this proposal. On news of potential outbreaks, **EID-SEARCH will rapidly mobilize its core staff and their extensive collaborative network across almost all SE Asian countries (Fig. 4) (Sections 4.1.a, 4.2. 4.3)**. The core analytical approach can be used to rapidly identify sampling sites and targets to harvest vectors, vector borne arboviruses, birds and mammalian species that harbor most other viral threats. Through existing projects such as the USAID PREDICT Project and DTRA-funded biosurveillance projects, EHA is currently partnered with hospitals and researchers across South and Western Asia, West and Central Africa, and Latin America. Our partners already have capacity to conduct human and wildlife sampling and testing for novel viral agents, so expanding in geography or scale is readily achievable given sufficient resources.

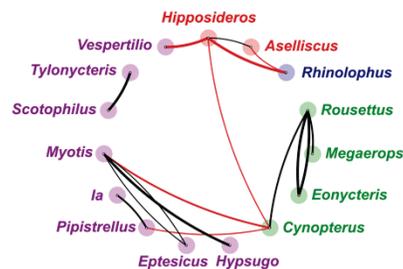

**Aim 1: Identify, characterize and rank spillover risk of high zoonotic potential viruses from wildlife.**

**1.1 Rationale/Innovation:** The vast majority of emerging zoonotic pathogens are linked directly or indirectly to wildlife host, particularly from important mammalian groups like bats, rodents and NHPs (3). Our previous work on wildlife origin viruses demonstrates that zoonotic viral emergence tends to occur in specific regions with high diversity of wildlife that harbor viruses of zoonotic potential, and human populations that have close contact to these wildlife (Fig. 1) (2, 3). In Aim 1 (see Fig. 9 for overview), we will strategically conduct EID surveillance by applying risk analytics to prioritize the regions, wildlife species, and human populations that

have a particularly high risk of viral spillover. We will target high-risk zoonotic host reservoirs (bats, rodents and NHPs) in these regions and apply novel predictive models to estimate viral diversity and host range to identify wildlife species that have been ignored or under-sampled by previous zoonotic disease surveillance efforts. We will strategically collect specimens from these species and screen them, together with some of the tens of thousands of recently collected samples we have archived, for known and novel agents. We will begin screening using conserved PCR assays to identify known and novel viruses in high risk RNA viral families, *Coronaviridae*, *Paramyxoviridae*, and *Filoviridae*. We will expand to other groups of pathogens, including arboviruses, pending available resources and priorities established with the EIDRC coordinating center (EIDRC-CC) and other regional EIDRCs. Using risk ranking algorithms and a series of ecological and virological risk factors, we will triage the wildlife viruses we discover for further genomic characterization and viral isolation. On this subset of viruses, we will then use *in vitro* and *in vivo* approaches (viral rescue, cell lines, gene edited humanized transgenic mice and the collaborative cross genetic reference mouse population) previously developed and widely used by our team to predict capacity of novel viruses to infect people and spillover (63, 85-88). These high-risk viruses and their close relatives will be targets for human community serosurveys and clinical sampling in Aims 2 and 3, respectively.

**1.2 Preliminary data: 1.2.a. Geographic targeting:** EHA has led the field in analyzing where the highest risk of zoonotic spillover is across the globe, identifying SE Asia as a major EID hotspot (1, 2). These hotspots are sites where high wildlife biodiversity, human population density and rapid ecologic change collide (**Fig 1**). Using host and ICTV viral data for all known mammalian viruses, and generalized additive models to correct for sampling bias, we are able to predict the relative number of yet-to-be-described viruses that a species harbors (3). This demonstrates substantial undiscovered viral diversity in mammals across Southeast Asia, and particularly in regions of Thailand, Singapore and Malaysia (**Fig. 1**). Separately, we found that factors driving spillover (host diversity, climate) differ from those driving spread in human populations (population density, bushmeat hunting, livestock production) (89). We therefore analyze capacity for viral spread as a separate risk factor, using our unique demographic and air travel and flight data modeling software (90, 91). In the current proposed work, we will use all the above approaches to target wildlife sampling (archival and new field collections) in Aim 1, to inform sites for human sampling in Aim 2, and to assess risk of spread in Aim 3.

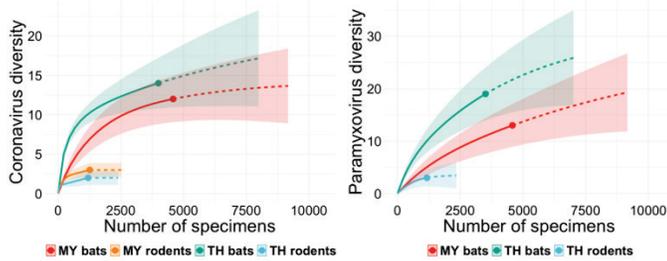

**1.2.b. Reservoir host species targeting:** Our analysis of all known mammalian host-viral associations demonstrates that bats, rodents and NHPs represent the three most important reservoirs for zoonoses, responsible for the highest proportion of known and predicted viral diversity of zoonotic potential (3). Thus, the bulk of our proposed wildlife sampling and testing will consist of these three taxa with a focus on bats, because this group is the known or hypothesized reservoir for the majority of high-impact zoonotic CoVs, PMVs and FVs (50, 92-94). Bats have the highest proportion of predicted zoonotic viruses in any mammalian group (2), and are exceedingly diverse in Southeast Asia (~500 species). To further prioritize taxonomic sampling targets within these diverse geographic hotspots, we used a novel Bayesian phylogeographic algorithm to identify host genera and species that are the most important centers of evolutionary diversity for a given viral group, e.g. bat genera for  $\beta$ -CoVs (**Fig. 5**) (51). This approach will be extended to other mammal taxa and viral families of interest, allowing us to identify the reservoir hosts of specific zoonotic viral groups, where viral diversity is likely highest.

**Fig 5:** Preliminary analysis of sequence data collected under prior NIH funding, identifying SE Asian bat genera with the highest  $\beta$ -CoV evolutionary diversity. We will apply this Bayesian discrete phylogeographic model to identify taxonomic and geographic centers of viral diversification and sharing for relevant PMV, CoV, FV and other virus clades. Line thickness proportional to probability of virus sharing between two genera. Inter-family switches in red.

Finally, we have designed a strategy to estimate sampling gaps, using a viral 'mark-recapture' approach we previously published (95, 96) (**Fig. 6**). Using prior data for bat, rodent and NHP viral discovery vs. sampling rates, we can identify the likely total viral diversity for specific host groups in a region, and use this to estimate sample sizes to discovering the majority of unknown viruses within a specific family or genus. **In the current**

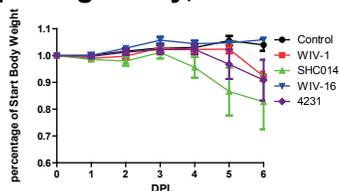

**proposal**, we will use these analyses to estimate geographic and species-specific sampling targets **to more effectively identify new strains to support experimental infection studies and risk assessment.**

**Fig. 6:** Estimated CoV (**left**) and PMV (**right**) diversity in bats and rodents from Thailand and Malaysia, using data from PCR screening and RdRp sequences from >10,000 specimens in bats and 4,500 in rodents. Bats have 4X more viral species than rodents, controlling for sampling effort. We estimate that additional collection of 5k-9k bat specimens and testing of our archived bat and rodent specimens alone will identify >80% of remaining CoV and PMV viral species in these key reservoirs, yielding >800 unique viral strains.

**1.2.c. Sample testing to identify known and novel viruses:** We have conducted extensive wildlife surveillance for novel viruses across Southeast Asia in prior NIAID funded work and as part of the USAID PREDICT project. Under the 10-year PREDICT program globally, we identified 912 novel and 210 known viruses, more than the total number of viruses previously recognized in mammals by the ICTV (97). This work included collecting nearly 300,000 individual mammal samples from 14 EHA-led PREDICT countries, and PCR-screening of more than 60,000 individual specimens (53). In southern China alone, we identified 178  $\beta$ -CoVs, of which 172 were novel, discovered a new  $\beta$ -CoV clade, “lineage E” (41), diverse HKU3r-CoVs (179 sequences) within a 'sister' clade to the SARS-CoV lineage, and a new bat-origin SADS-CoV, responsible for killing >25,000 pigs in Guangdong Province (17). We have collected 28,957 samples from bats, rodents and NHPs in Thailand and 47,178 in Malaysia, **but have only tested a minority of these using PCR.** We have identified 100 novel viruses in Thailand and 77 in Malaysia. **Furthermore, we have only sequenced a small segment of one gene for all novel viruses found. We have archived duplicate samples which are now available for use in this project**, including fecal, oral, urogenital, serum samples, and biopsies from bats, rodents, and NHPs. In the current proposed work, we will attempt to sequence, isolate and characterize those viruses that our analyses below suggest are most likely to be able to infect humans.

**1.2.d. In vitro & in vivo characterization of viral potential for human infection:** Using Coronaviridae as an example, we have conducted *in vitro* and *in vivo* experiments to characterize the pathogenic potential of novel SARSr-CoVs from bats. We isolated three SARSr-CoVs from bat feces: WIV1, WIV16 and Rs4874, with Spike (S) protein sequences that diverged from SARS-CoV by 3-7% (24, 61, 98). We conducted full-length genome sequencing of 12 other novel SARSr-CoVs, some highly similar to outbreak SARS-CoV in the most variable genes (61). Using our reverse genetics system we constructed chimeric viruses and rederived full length recombinant SARSr-CoV from in silico sequence. All 3 SARSr-CoV full length isolates and the two chimeric viruses replicated efficiently in Vero E6 cells and in HeLa cells expressing hACE2, civet and bat ACE2, but not in those without ACE2 (24, 61, 98). We used the SARS-CoV reverse genetics system (72) to generate a chimeric virus with a mouse-adapted SARS-CoV backbone expressing SHC014 S protein with 10% sequence divergence from SARS-CoV S. This and the other full length and chimera viruses replicated in primary human airway epithelium, using the human ACE2 receptor to enter into cells (62). Thus, **SARSr-CoVs with diverse variants of SL-CoV S protein without deletions in their RBD can use human ACE2 as receptor for cell entry.** The Baric lab has a well-established hACE2 and DPP4 transgenic mouse model that **we used to assess the capacity of novel SARSr-CoVs and MERS-CoV to infect humans and cause disease (85, 99).** Infection of bat SARSr-SHC014 or WIV1 caused SARS-like clinical signs in the transgenic hACE2 mouse model **that weren't reduced by immune-therapeutic monoclonals that attenuate SARS-CoV pathogenicity, nor after challenge following vaccination against SARS-CoV (62) (Fig. 7).** We repeated

this virus characterization approach with chimeras using HKU3r-CoV S proteins that are ~25% divergent from SARS-CoV S, **and found that they are unable to use the ACE2 receptor.** Additionally, we were unable to culture HKU3r-CoVs in Vero E6, or human cell lines.

**Fig. 7:** Body weight change in hACE2 transgenic mice after SARSr-CoV infection, demonstrating that bat-origin SARSr-CoVs cause similar clinical signs to outbreak SARS-CoV strain (4231) (62, 63).

A similar approach to the above pipeline for CoVs will be applied to novel henipaviruses we discover during our research. The broad mammalian tropism of HeV and NiV (68) is likely mediated by their usage of highly conserved ephrin ligands for cell entry (19, 100). A third isolated henipavirus, Cedar virus does not cause pathogenesis in animal models. **Co-Is Broder and Laing** have developed a reverse genetics system and rescued a recombinant CedV to test ephrin receptor usage/tropism and pathogenicity during henipavirus infections (77). CedV is unable to use the Ephrin-B3 receptor (77, 101) which is found in spinal cord and may underlie NiV encephalitis (102) and that pathogenesis also involves virulence factors V and W proteins. The putative henipaviruses, Ghana virus and Mòjiāng virus, predict V and W protein expression, with GhV able to bind to ephrin-B2, but not -B2 (103), and the receptor for MoJV remains unknown (104) but is likely ephrin-B2 (105). Our group has also used similar methods to test the hypothesis that novel Filoviruses discovered in wildlife are able to infect people. NiV, EBOV and MERS-CoV all infect primary microvascular endothelial cells, which are available at Co-I Baric's lab for EID-SEARCH collaborators (71, 106). Primary human lung endothelial cells are highly susceptible to Ebolavirus infection (107), and Huh7 cells can be used to isolate virus from clinical samples (108) offering advantages for reverse genetic recovery of novel FVs (109). The three filovirus genera, *Ebolavirus*, *Marburgvirus* and *Cuevavirus*, use Niemann–Pick type C1 (NPC1) protein as cell entry receptor (110). For novel filoviruses, cell culture would be carried out under BSL-4, however they can readily be characterized following identification of their encoded GP sequences which can be pseudotyped into recombinant GP-bearing vesicular stomatitis virus (VSV) pseudovirions (111). These pseudovirions can be safely used to characterize the tropism and entry filoviruses mediated by GP without a need for BSL4 containment. **Co-Is Wang and Anderson** used cells originating from various mammalian species to determine spillover and/or zoonotic potential of MLAV, a newly discovered Asian filovirus (47). Despite the low amino acid sequence identity (22–39%) of the glycoprotein with other filoviruses, MLAV is capable of using NPC1 as entry receptor. Cells from humans, monkeys, dogs, hamsters and bats were able to be infected with a MLAV pseudovirus, implying a broad species cell tropism with a high risk of interspecies spillover transmission.

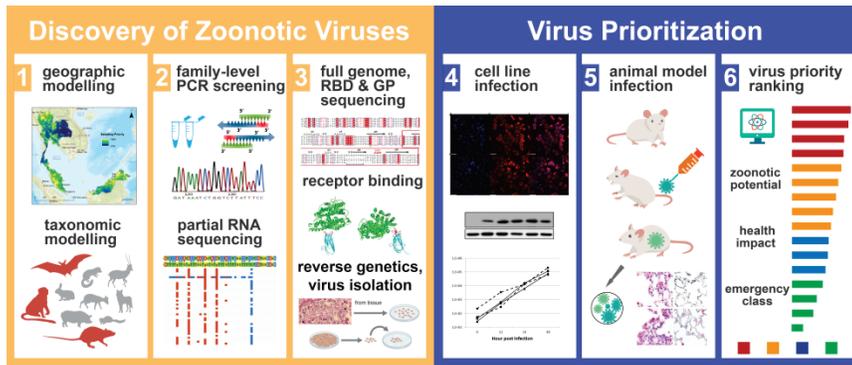

**Mouse models.** For novel viruses across all families, we will use the UNC collaborative cross mouse that captures 90% of the diversity within all mouse groups to assess the most suitable model for further experiments (112). We have used this model for CoV, FV (Ebola), Flaviviruses, and alphaviruses infections. Clinical signs such as weight loss, hemorrhage, encephalitis, and, acute or chronic arthritis were recapitulated in these mice following SARS, EBOV, West Nile virus and Chikungunya infections, respectively (86-88, 113-116). Note that CC OR3015 shows hemorrhagic disease phenotypes after EBOV infection (**Fig. 8**). **Bat Models.** Duke-NUS has developed two models for bat *in vivo* studies: a colony of *Eonycteris spelaea* (cave dwelling small fruit bat) and a bat mouse model, which contains the bat immune system in an immunodeficient mouse (117). In a proof of concept study, **Co-Is Wang and Anderson** infected *E. spelaea* bats with MERS-CoV to demonstrate their susceptibility and suitability for infection with a bat borne virus under BSL3 containment. These bats and the bat mouse model will serve to complement and expand studies from the UNC collaborative cross mouse, pending further funding from EIDRC CC.

Recombinant viruses, transgenic mouse models and experimental recombinant protein constructs described above will be made available to the EID-SEARCH consortium and other EIDRCs following standard procedures (**see Resource Sharing Plan**).

**Fig. 8:** EBOV Infection in Collaborative Cross Mouse. **Panel A/B:** Wt EBOV in two different CC lines demonstrate different disease patterns. **Panel C/D:** Hemorrhagic phenotypes on d. 6 (arrow) in spleen and liver, resp. From (86).

**1.3. General Approach:** We will conduct analyses to geographically- and taxonomically-target testing of samples from wild mammals that are most likely to harbor known high-profile zoonotic pathogens, or close relatives with potential to infect people. This includes selecting from tens of thousands of samples collected on recent projects and stored in freezers in our laboratories, and new sampling of wildlife in high risk locales. We will use viral family level PCR assays to identify and partially characterize viruses, then follow up sequencing of relevant receptor binding proteins to assess homology and predict binding affinity, then attempt to isolate and

biologically characterize viruses that phylogenetic and other data suggest have high spillover and pandemic potential. We will follow this with *in vitro* binding assays and cell culture experiments, and *in vivo* animal model infections to assess their potential to infect people and cause disease (**Fig. 9**). EHA will lead the study design, targeted sampling, and data analysis; Co-Is Hughes and Wacharapluesadee will lead field sampling and in-country testing; Duke-NUS, UNC, USUS will lead the serological and PCR diagnostic development and the *in vitro* and *in vivo* analyses, as well as cross-training and tech transfer to the hub labs in Thailand and Malaysia. This will include via support of one Malaysian Ph.D student, Mei-Ho Lee (CM Ltd.) who has worked with the EID-SEARCH collaborators for 9 years. The focus of her study will be infection potential of novel CoVs and PMVs already found in bats in Malaysia under preliminary data for this proposal.

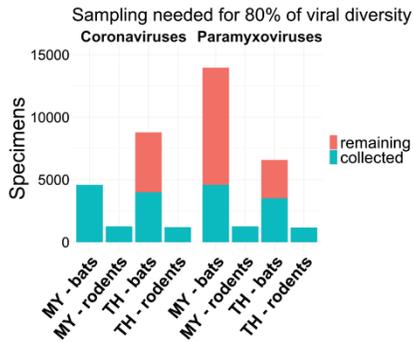

**Fig. 9:** Aim 1 will use analytical tools to target selection of archived and newly collected samples, conduct PCR and sequencing of novel viruses, recover by reverse genetics, and assess zoonotic potential using *in vitro* and *in vivo* models and analyses.

**1.4 Wildlife samples: 1.4.a. Geographic and taxonomic targeting for newly collected wildlife samples:** We will prioritize sites within each country that rank highest for both the risk of zoonotic

disease emergence (2) and the predicted number of 'missing' zoonotic viruses (3). Our preliminary analysis (**Fig. 1**) suggests priority areas include: the Kra Isthmus (S. Thailand) and adjacent forests in N. Peninsular Malaysia, NW Thailand (near the Myanmar-Laos border), and lowland rainforests of Sarawak and Sabah. In each of these 'hottest of the hotspots' regions, we will identify 2-4 distinct sampling sites based on the geographic distribution of key hosts we prioritize for additional wildlife sampling. We will priority rank bat, rodent, and NHP species using host trait-based models (3). We will also identify species predicted to be centers of evolutionary diversity for CoVs, PMVs, and FVs using ancestral host reconstruction of available sequence data and Bayesian discrete phylogeographic models (118-120). We will leverage our strong collaborations with wildlife experts in Malaysia and Thailand, including many of whom are based at our core partner institutions, to ground-truth geographic and taxonomic model outputs with local expert knowledge to ensure the sampling plan is realistic based on current species distributions, population size estimates, seasonality, and accessibility to sites. Most zoonotic viruses are naturally carried by multiple wildlife host species, and there are strong, predictable relations between host phylogeny and viral taxonomy (3). We will use a combined network analysis and phylogeographic model to rapidly predict and prioritize new (unsampled) hosts for important, novel viruses we discover during our research. We have shown this relatively simple model (using just wildlife species range overlap and phylogenetic similarity between host species) is both generalizable to estimate host range for all mammalian and avian viruses *and* robust – accurately predicting hosts 98% of the time when cross-validated using data from known viruses (121).

**1.4.b. Sample size justifications for testing new and archived wildlife specimens:** We calculate initial sample sizes targets using our preliminary data on average PCR prevalence from screening tens of thousands of bat, rodent and NHP specimens for CoV and PMVs based on previous studies in Malaysia and Thailand. We will refine these sample size targets, in real-time, over the course of our project using viral discovery curve analyses (**Fig. 6**) to either scale-up or scale-back new sampling and testing of archived specimens for each species depending on viral capture rates. We will only collect additional specimens projected from each prioritized taxa to achieve statistically robust sample sizes and to complement our archived specimens. For example, *Rousettus* spp. bats, known FV reservoirs, were not adequately sampled under PREDICT research in Thailand. Preliminary analysis indicates that, for all viral target families, we will require ~14,000 new samples to identify 80% of remaining viral species diversity in our study region, ~5,000 samples from Thailand and ~9,000 samples from Malaysia (**Fig. 10**). Viral strain diversity from a sampling effort this size is expected to number in the hundreds of strains. For example, given ~6% prevalence of CoVs in bat species previously sampled under the PREDICT project, a target of 14,000 individuals would yield ~800 PCR positive individuals,

representing, an estimated ~600 novel sequences/strains. Similarly, for PMVs, which have an average PCR detection prevalence of ~1.5%, sampling of 14,000 individuals would yield ~200 positives and an estimated 150 unique strains. Filovirus estimates are not feasible yet due to the small number of positive samples in prior

studies, but will be estimated as the project begins. From each mammal, we will collect serum, whole blood, throat swabs, urine and fecal samples or rectal swab using our previously-validated nondestructive methods. We will sample sites at different time-points throughout each year, and sample an equal number of males and females to account for seasonal or sex-specific differences viral shedding (**See Vertebrate Animals**) (122, 123). Dead or animals euthanized due to injury will be necropsied.

**Fig. 10:** Stacked bar plot showing number of currently-archived specimens (blue) and new specimens required (orange) to discover 80% of predicted number of CoVs and PMV species from high-risk bat and rodent taxa in Malaysia and Thailand.

**1.4.c. Sample collection, testing, viral isolation:** Wildlife will be captured and sampled using previously published techniques, by personnel wearing appropriate personal protective equipment (Tyvek suits or dedicated long external clothing, double nitrile gloves, leather gloves, an N95 or p100 respirator, and safety glasses) (53, 93, 95, 96, 122, 124). All samples will be placed in a vapor phase liquid nitrogen dry shipper immediately upon collection, and then transferred to a -80C freezer once back in the lab, until testing. Viral RNA will be extracted from bat fecal pellets/anal swabs. RNA will be aliquoted, and stored at -80C. PCR screening will be performed with pan-coronavirus (125, 126), filovirus (127) and paramyxovirus primers (128), in addition to virus specific primers where additional sensitivity is warranted in key viral reservoirs, i.e. Nipah virus or MERS virus specific primers (129, 130). PCR products will be gel purified and sequenced. We will attempt isolation on samples that contain viruses of interest (determined in **Aim 1.5 below**), using Vero cells and primary cell culture from the wildlife taxonomic order (bat, rodent and NHP cell lines). Over 70 bat cell lines are maintained at Duke-NUS from five different bat species. These include primary lung, brain, bone marrow, heart, kidney, intestine, liver, lymph node, muscle, spleen, PBMC and ovary/testes from *Eonycteris spelaea*, *Cynopterus bracyhotis*, *Rhinolophus Lepidus*, *Myotis muricola* and *Pteropus alecto* bats. In addition we have 8 immortalized cell lines, including those derived from lungs, therefore suitable for the isolation of respiratory viruses.

**1.4.d. Moving beyond RNA viruses:** To detect pathogens from other families, such as non-RNA viruses, we will combine conserved PCR assays with NGS. We will perform either unbiased NGS, or use a pan-viral enrichment library to sequence full-length genomes (131). We will conduct this work via EID-CC research projects or as part of outbreak detection/investigation in the region from DNA viruses or other agents.

**1.4.e. Sequencing Spike Glycoproteins:** Based on earlier studies, our working hypothesis is that zoonotic CoVs, FVs and henipaviruses encode receptor binding glycoproteins that elicit efficient infection of primary or continuous human cell lines (e.g., lung, liver, etc.) (16, 61, 62). Characterization these for SARSr-CoVs suggest that viruses up to 10%, but not 25%, different in the spike glycoprotein use human and bat ACE2 receptors for docking and entry. Uneven sampling gaps (e.g., no strains were found with 10-25% spike variation) prevent a thorough understanding of the transition point where the most divergent strains lose human ACE2 receptor usage. Our viral discovery curves (**Fig. 6**) suggest further sampling will reveal a rich diversity of as-yet-undiscovered SARSr-CoVs and strains of other viruses that fill in the phylogenetic tree between currently-described viruses. In this aim we will use phylogenetic and viral discovery analysis to specifically target bat species and regions that are under-sampled to allow sufficient power to identify and characterize missing strain diversity for potential zoonoses. We will sequence the S proteins of novel SARSr-CoVs to prioritize viruses for experimental work in Aim 3 to test this hypothesis. Likewise, we will test the hypothesis that phylogenetic related zoonotic receptor binding protein genes of MERS-related, Ebola-related and NiV/HeV-related viruses will also program efficient entry via human and ortholog receptors. For all novel virus strains, we will sequence the complete entry spike genes by amplifying overlapping fragments using degenerate primers as shown previously (24, 61). **Reverse Genetics:** Full-length genomes of selected CoVs, FVs or henipaviruses (representative across subclades) will be sequenced using NEBNext Ultra II DNA Library

Prep Kit for Illumina and sequenced on a MiSeq sequencer. PCR or Minlon sequencing will be performed to fill gaps in the genome. The full length spike gene sequences, including the amount of variation in the receptor binding residues that bind the appropriate human receptor will be used to select strains for Aim 3 experiments. We will sequence full length genomes of high risk strains that are antigenically distinct and escape SARS or MERS-CoV cross neutralization, synthetically reconstruct a small subset (1-2) and evaluate growth in Vero, BHK and Huh7 cells (63, 132). From full length sequences, synthetic clones will be ordered to recover recombinant viruses using reverse genetics as described by our groups (62, 63, 77, 109, 133, 134). Recombinant virus growth will be accessed in Vero, BHK, Huh7 and select bat cells and recovered viruses used for downstream studies. Virus strain prioritization is described below.

**1.5. Assessing risk for spillover. 1.5.a. Capacity to infect human cells:** We will use a series of cell cultures to assess the capacity of target viruses to enter human cells. For CoVs, FVs and henipaviruses, we will use primary human ciliated airway epithelial cells (HAE) and lung endothelial cell cultures derived from the lungs of de-identified transplant recipients. HAE are highly differentiated and grown on an air-liquid interface for several weeks prior to use (62, 63, 132). We will prepare HAE and lung endothelial cultures from three different patient codes in triplicate in collaboration with the tissue procurement facility at the Cystic Fibrosis Center at UNC. Cultures will be inoculated with chimeric bat SARSr-CoVs or novel FVs or henipaviruses to assess efficient replication. At 72 hpi, cultures will be fixed for immunofluorescent staining using antisera to the SARS-CoV conserved nucleocapsid protein (N) or to structural genes of the other viruses (64, 71). SARSr-CoVs that differ significantly in S protein sequence (11-24%) from epidemic SARS-CoV yet replicate *in vitro*, will also be evaluated for sensitivity to neutralization in Vero cells by PRNT50 assays using broadly SARS-CoV cross reactive human mAbs S227.14, S230.15, S215.17, and S109.8 (63, 135) or monoclonal antibodies targeting the Ebola or Marburg E glycoprotein (Available through BEI), or NiV/HeV glycoproteins (136). As controls or if antisera is not available, the S genes of novel SARSr-CoV or spike entry genes of other novel viruses under investigation will be inserted into VEE 3526 replicon vectors (VRP3526-S), packaged and used to vaccinate mice (137). Polyclonal sera against test bat-SARS virus or other spike genes will be harvested and tested for ability to cross neutralize SARS-CoV, GD03, WIV-1, SHC014, WIV-16, other novel SARSr-CoV and HKU3-SRBD by PRNT50 assay (63, 138, 139). Using PRNT50 titers with sera (n=4 each) among these viruses, antigenic cartography (140) will allow comparison of antigenic vs. phylogenetic distance, identifying the transition at which SARSr-CoV strains escape SARS-CoV based vaccines, informing immunotherapeutic and vaccine design strategies (141-143). Similar approaches will be applied to novel MERS-related viruses, other CoV, FVs or henipaviruses. While most wildlife-origin viruses with unknown transmission potential or pathogenicity in people uncategorized, we use BSL-3 for isolation as standard, and cell culture for potentially BSL-4 pathogens will be undertaken at collaborating institute NEIDL. To facilitate this, duplicate samples in culture medium from animals PCR +ve for FVs and very close relatives of NiV or HeV will be shipped to NEIDL (**See letter of support**) for culture, characterization and sharing with other approved agencies including NIH Rocky Mountain Laboratories where PI Daszak and Co-Is Baric have ongoing collaborations. Similarly, some duplicate samples of animals PCR +ve for CoVs will be shipped to UNC for further characterization by Co-I Baric. Where feasible and appropriate, training opportunities at NEIDL and UNC for in-country staff will be given, thereby enriching hands-on collaboration across sites.

**1.5.b. Host ACE2, DPPR, Niemann-Pick C1 (NPC1) and EphrinB2/EphrinB3 receptors:** We will sequence relevant host receptors for select mammalian wildlife species we find positive for strains of high-priority CoV clades, and all new henipaviruses and FVs. Of particular interest is homology across 18 bat and human orthologue ACE2 contact interface residues that engage the SARS RBD as a potential indicator of SARSr-CoV cross species transmission potential and growth in human cells (70). Likewise, variation in the NPC1 receptor has been shown to alter EBOV ability to infect in humans and bats, so this can be structurally mapped for prediction and downselection of strains (144). Signatures of positive selection in bat NPC1 were concentrated at the virus-receptor interface, with the strongest signal at the same residue that controls EBOV infection in *Eidolon helvum* cells. Thus NPC1 is a genetic determinant of FV susceptibility in bats, and some NPC1 variations likely reflect host adaptations to reduce FV replication and virulence (145). NiV and HeV use ephrin B2 or ephrin B3 as a receptor, and variation affects its ability to use human vs bat receptor molecules (103, 146).

**1.5.c. Host-virus evolution and predicting receptor binding:** We will use Bayesian and Maximum Likelihood phylogenetic analyses of RNA-dependent RNA polymerase (RdRp) sequences from PCR screening, receptor binding glycoproteins, and/or full genome sequence data (when available) to reconstruct the evolutionary history of the novel bat SARSr-CoVs, bat MERSr-CoV, FVs and henipaviruses that we identify. We will run co-phylogenetic analyses to map out instances of host-switching (147, 148) and ancestral state reconstruction analyses (Fig. 4) to identify the most important species for shaping evolutionary diversity for these viruses (51, 149), allowing for more targeted future surveillance and spillover mitigation interventions. For receptor binding glycoprotein sequence data from characterized viruses, we will apply codon usage analyses and codon adaptation indices, as used recently on henipaviruses (150), to assess the relative contributions of natural selection and mutation pressure in shaping host adaptation and host range.

**1.5.d. Viral strain prioritization:** Of the expected 100-200 novel SARSr-CoV strains, and approximately 600 total CoV strains, we will down-select to prioritize for further characterization based on S genes that are: i) different from SHC014, WIV1, SARS-CoV with diversity ranges of 10-25%; ii) have virus S RBD that could use human/bat receptors; iii) have recombinant chimeric spikes indicative of gene flow between clade I and II strains; iv) have bat ACE2 or DPP4 receptors that might select for spike RBDs that can use human receptors for entry (15/18 conserved residues in human/bat ACE2 molecules that bind SARSs-CoV S RBD domains are likely more efficient receptors than 3/18 conserved sites). Using structural models based on the SARS S glycoprotein, the extent and location of antigenic variation will be annotated onto the structure, further resolving the locations of highly evolving and conserved structural motifs/epitopes that function in protective immunity (135, 151-153). For novel henipaviruses, we will examine the receptor-binding proteins (e.g. envelope attachment (G) proteins) for sequence and structural homology with particular attention to conservation of amino acids that mediate ephrin receptor binding. We will prioritize strains that are predicted to interact with ephrin-B2 and expression V/W proteins to determine whether these viruses represent zoonotic threats. Using the recombinant Cedar virus (rCedV) platform, we will be able to rescue rCedV that express heterotypic G proteins to explore receptor utilization and tissue dissemination in animal models. We will assess ability to infect human cells using a continuous lung epithelial cell line, Calu3, which our group has previously used to generate data on NiV and HeV growth curves and a variety of host expression changes after infection (154). We will also use primary human airway cultures and microvascular endothelial cells to assess human infection for FVs, henipaviruses and MERSr- and SARSr-CoVs (155) (156). There is some evidence for NiV and HeV replication in mouse lung, low level titers in young animals, 10 fold higher titers in aged mice (157, 158). Thus it is likely these models could be improved in the collaborative cross mouse resource at UNC. We have identified CC lines that are highly vulnerable to wildtype SARS and others that develop hemorrhagic disease following mouse adapted Ebola infections (86-88).

**1.5.e. Animal models:** We will use transgenic mouse models and the UNC Collaborative Cross model to assess spillover potential of viruses. For work on CoVs, we will follow the protocols in the transgenic mouse model used by the Baric lab previously. Briefly, in the BSL3 lab, 10- to 20-week old hACE2 or hDPP4 transgenic mice will be intranasally inoculated with  $5 \times 10^4$  PFU of full length wildtype rbat CoV, or chimeric SARSr-CoV or MERSr-CoV encoding different bat CoV spike proteins respectively, then monitored daily for weight loss, morbidity, and clinical signs of disease. Mice will be euthanized at 2, 4, and 6 dpi (endpoint of 14 dpi), organs harvested and virus quantified by plaque assay or genome (mRNA1) RT-PCR. After 7 days in formalin, tissues for histopathology will be removed from the BSL3 and stained with H&E, and for immunohistochemistry using polyclonal antibodies against the N protein. We will conduct limited evaluation of existing countermeasures using therapeutic monoclonal antibodies *in vitro*. Existing SARSr-CoV or MERS-CoV mAbs (159, 160) will be diluted in DMEM starting at 1:20, and serial dilutions mixed with an equal volume of 50 PFU of chimeric bat SARSr-CoVs encoding different spike proteins and RFP indicator genes, then incubated on Vero E6 cells at 37°C for 1 h. Antibody neutralization titers will be evaluated by plaque quantification at 4-5dpi. In select instances, hACE2 transgenic mice will be injected with SARS-CoV mAbs, and infected with chimeric bat SARSr-CoVs. Clinical signs and morbidity will be assessed and tissue pathology examined and compared with mice without treatment of mAbs to determine the therapeutic effect on SARSr-CoV infection, and protection of SARSr-CoV by wildtype SARS-S based vaccines assessed as described (132, 161). We will sequence full length genomes of high risk strains that are antigenically distinct and escape SARS or MERS-

CoV cross neutralization, synthetically reconstruct a small subset (1-2), recover full length viruses and evaluate the ability of nucleoside analogues to inhibit growth in HAE cultures and/or *in vivo* (63, 132). For the Collaborative Cross model, we will infect six to eight mice from 6-8 Collaborative Cross mouse lines (10 weeks of age) with six test viruses/yr, intranasally or by subcutaneous infection with  $1 \times 10^4$  virus. Animals will be followed for weight loss, morbidity, mortality and other clinical disease symptoms (e.g., hunching, hindleg paralysis). One half the animals will be sacrificed at day 3 and day 7 pi. to evaluate virus growth in various organs, and organ pathology. In highly vulnerable lines, additional experiments will be performed using more animals, evaluating virus growth, clinical disease symptoms, respiratory pathology, tropism and organ pathology through day 28 pi. We anticipate that some CC lines will prove highly vulnerable to select wildtype viruses, because of host susceptibility combinations that promote severe disease outcomes.

**1.6. Potential problems/alternative approaches: Challenges with logistics or obtaining permission for wildlife sampling in sites we select.** We have a >20-year track record of successful field work in Malaysia, and >10 years in Thailand, and have strong established partnerships with local wildlife authorities and communities to ensure access. We have existing permissions in place which will be renewed at the start of this project. Due to the abundance of wildlife habitats in the region, if access to a site is withdrawn, we will rapidly identify a suitable, complementary site with similar bat species composition and abundance. Finally, we have already collected tens of thousands of wildlife samples from the region and will focus on these while waiting for permission. **We may not identify novel viruses in our sample wildlife species due to seasonality of viral shedding or other factors.** We have calculated sample sizes based on realistic detection rates from our extensive preliminary data, and are confident that we will detect and identify large numbers of potentially zoonotic pathogens, particularly for CoVs and PMVs. We acknowledge that FV strain diversity may be harder to capture, given relatively low seroprevalence in bat populations – suggesting lower levels of viral circulation (42, 43). However, our team was the first and only group to sequence FV RNA from Asian wildlife species (46, 47, 57), and we are confident that with our targeted sampling and testing strategy offers the best chance globally to identify additional strains of Ebola and related viruses. The sampling regions we have selected are subtropical, and our previous data, and even published studies in temperate regions (162), do not suggest a strong pattern of seasonality in CoV shedding, and where seasonal patterns do occur, i.e. for henipaviruses in Thailand (163), or can be predicted from wildlife serology data, we will be sure to conduct sampling at different timepoints throughout the year to account for this.

**Aim 2: Identify evidence and analyze risk factors for viral spillover in high-risk communities using novel serological assays.**

**2.1 Rationale/Innovation:** Rapid response requires early detection. Assessing the spillover of rare or novel zoonotic agents will require targeted surveillance of high-risk communities that interface frequently with wildlife that harbor high risk emerging viral strains. To enhance the low statistical probability of identifying these rare events, In Aim 2 we will target rural human communities inhabiting regions identified in Aim 1 as having high viral diversity in wildlife, that also engage in practices that increase the risk of spillover (e.g. hunting and butchering wildlife). We will initially identify 4 subsites in each of Thailand, Peninsular Malaysia, Sarawak, and Sabah for sampling. We will design and deploy human risk factor questionnaires, and specific and sensitive serological assays to identify the baseline frequency, and causes of, spillover of known and related novel viral pathogens in these populations. **We will use the results to test a key hypothesis: that hunting wildlife increases the risk of exposure to novel viruses, compared to the rest of the community.** The alternative hypothesis is that seroprevalence in the general community is not statistically different to those who hunt and butcher wildlife, because exposure to wildlife pathogens is largely through inhabiting a biodiverse landscape where wildlife make indirect contact with people (e.g. via fomites). For participants who report symptoms related to 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; 5) hemorrhagic fever; or 6) unusual presentation of high fever with severe diarrhea; all within the last 10 days, an additional sample type will be collected, two nasal or oropharyngeal swabs. Samples will be marked for additional PCR-based assays to identify presence of known and novel CoVs, henipaviruses and FVs, and for isolation and biological characterization of potential pathogens, using the approach laid out in Aim 1.

**2.2 Preliminary data on high-zoonotic risk human community surveillance: 2.2.a Biological sample collection in SE Asia:** Our long-term collaboration in the region has included qualitative and quantitative survey data, and collecting large archives of banked human sera and other biological samples from high zoonotic-risk populations. For example, under the USAID-PREDICT project, EHA has collected 1,400 and 678 specimens in Malaysia and Thailand respectively from people living in zoonotic disease interfaces, all of which will be available for retrospective serological testing by EID-SEARCH which we have ensured is compliant with our existing IRB. Our core group has collected and tested many thousand additional specimens from other important community cohorts (**Table 2**), and some of these will continue under EID-SEARCH (**Section 2.4**).

Country, site	Lead	# enrolled, focus	Findings
Peninsular Malaysia	Hughes	9,800+ samples, Orang Asli indigenous pop., for PCR/serol.	25+ novel CoVs, influenza, Nipah ab+ve, FV ab+ve
Malaysia Sabah	Kamruddin	1,283 for serology	40% JE, 5% ZIKV ab+ve
Malaysia Sabah	William	10,800 for zoonotic malaria study	High burden of macaque-origin malaria
Malaysia Sabah	Hughes	150 bat cave workers	Ongoing
Malaysia Sarawak	Siang	500 Bidayuh and Iban people	8% PCR prevalence HPV in women
Malaysia PREDICT	Hughes	1,400 high zoonotic-risk communities for viral PCR, serology	Ongoing. Multiple known and novel CoVs, PMVs, others.
Thailand	Wacharaplu-esadee	100s of bat guano harvesters/villagers	Novel HKU1-CoV assoc. clinical findings
Thailand PREDICT	Wacharaplu-esadee	678 high zoonotic-risk communities for viral PCR, serology	Ongoing. Multiple known and novel CoVs, PMVs, others.
Singapore	Wang	856, for Melaka virus	7-11% MELV ab+ve

**Table 2:** Biological sample collection from healthy populations conducted by members of **EID-SEARCH** in our hub countries.

Of particular interest is the access to indigenous communities in Peninsular Malaysia (Orang Asli) and Sarawak (Bidayuh, Iban people), and the bat guano harvesters in Thailand. These communities hunt, butcher and eat wildlife daily, and work in supremely high-risk zoonotic interfaces (e.g. bat caves). One of our indigenous community sites is experiencing an ongoing outbreak of unknown etiology that we are investigating currently (Section 3.2.a).

**2.2.b Human Contact Risk Factors:** EHA is the lead organization across all 27 USAID-PREDICT project countries for collecting data on, and analyzing the human aspects of, zoonotic spillover risk (164, 165). We conducted exploratory studies using standardized one-on-one semi-structured interviews and site observation data with people living in hotspot areas or engaged in high-zoonotic spillover risk activities, using these data to assess local social and cultural norms underlying wildlife contact (165). We then developed a risk factor survey to accompany human biological sampling to evaluate the type and frequency of animal contact, wildlife exposure in daily life, occupational risk in markets and long the wildlife value chain, and unusual illnesses reported over the past 12 months. We conducted cross-sectional studies in high risk populations in 27 countries, and study participants provided biological samples (oral/oropharyngeal swab, nasal/nasopharyngeal swab, urine sample/urogenital swab, fecal sample/rectal swab, whole blood, serum, plasma). For example, survey and biological samples were collected from: 1,585 participants from 7 sites in Yunnan, Guangxi, and Guangdong provinces, China; 1,400 participants from 4 sites in Malaysia; and 678 participants from 4 sites in Thailand. Samples were tested with novel serological assays and results analyzed against risk factors from survey data (16). In China, CoV-seropositive individuals were mostly farmers/peasants (8/9), living in Yunnan province (7/9), 41-60 yrs old (7/9), with domestic contact with rodents (6/9), that are male (6/9). Although these results are preliminary and don't provide detailed information on routes of exposure, they identify key subpopulations to target that would likely increase the opportunity for identifying evidence of spillover for other CoVs, PMVs and FVs. Data from PREDICT surveys have been used to help identify target populations in Aim 2, identify strategies to better target at-risk people, and conduct focused **human risk factor surveys and serosurveys to produce statistically significant findings for henipaviruses, CoVs and FVs.** In Aim 2, we will use combined biological sampling and risk factor surveillance in targeted populations within the community to 1) test the hypothesis that occupational (i.e. wildlife hunting) risk factors correlate with seropositivity to henipaviruses, FVs and CoVs; 2) assess possible health effects of infection in people; and 3) where recent

illness is reported, obtain biological samples for PCR testing and potential viral isolation and characterization. Obtaining this information could be a significant step in understanding the likelihood of recent 'hidden' spillover events and their public health impacts, as well as the risk of future emergence of viral disease.

**2.2.c. Risk factors for illness:** Our preliminary data in Thailand, Malaysia and other SE Asian countries revealed that frequent contact with wild (e.g. bats, rodents, NHPs) and domestic animals (e.g. poultry, swine) among local communities was associated with a high percentage of self-reported severe/acute respiratory illness (SARI/ARI) and Influenza-like illness (ILI) symptoms (**Section 3.2.b**). In addition, people involved in crop production, hunting and butchering of wildlife reported statistically significantly higher SARI and ILI symptoms (Li *et al.*, in prep.). **These preliminary data suggest a target population and sites for current proposal with the correct targets for serological surveillance and risk factor surveys in Aim 2 to produce statistically significant findings.** Coupled with better serological tools from our team (**Section 2.2.d**), we will be able to identify the likely routes of exposure to known or novel coronaviruses, henipaviruses, and FVs in the study region, as well as build data on the illnesses they cause in people.

**2.2.d. Serological platform development:** Most emerging viruses produced a short-lived viremia in people so that large sample sizes are required to provide enough PCR-positive individuals to analyze infection patterns. For Aim 2, we will focus on serological sampling in the community, because antibodies are typically long-lived and can be used to assess prior virus exposure or infection with much smaller sample sizes (123). Most serological assays target a single protein, and for emerging viruses, it's often unclear which viral antigen will be immunodominant during human infection, and therefore which to target in developing serological assays. Co-Is Wang, Anderson (Duke-NUS) and Broder, Laing (USUS) have developed a series of approaches to deal with this problem, and which will be used in testing human biological samples in Aims 2 and 3. Henipaviruses, FV and CoVs express envelope receptor-binding proteins that are the target of protective antibody responses. Co-I Broder has led efforts to express and purify henipavirus native-like virus surface proteins for immunoassay application (166, 167), developing monoclonal antibodies (168, 169) and as subunit vaccines (170, 171), has developed a novel, multiplex microsphere immunoassay (MMIA) allowing serum samples to be simultaneously tested for antibodies reactive with henipaviruses, FVs and CoVs. This MMIA uses a Luminex-based multiplex platform and custom designed virus receptor-binding proteins expressed in a mammalian cell-culture system and purified as native-like oligomeric proteins. These oligomeric antigens retain post-translational modifications and quaternary structures, allowing capture of conformational-dependent antibodies raised during a natural infection, which represent the majority of the protective humoral response. The known diversity of henipaviruses includes five presently described viruses, NiV, HeV, CedV, GhV and MojV and this assay has been expanded to include all described species (**Fig. 11**). In the past, our collaborators have used NiV and HeV G protein antigens in a MMIA assay to identify a serological footprint of NiV-related African henipaviruses and exposure to virus(es) antigenically-related to NiV in livestock sampled in Bangladesh (78, 79). To strengthen serological data interpretation, the G protein from each virus is integrated into the MMIA so that virus-specific vs. henipavirus cross-reactive antibodies can be detected and address specificity of past virus exposure. Extensive cross-reactivity exists among ebolaviruses and between ebolaviruses and marburgviruses (172-174). We are validating the MMIA pan-FV assay for specificity, and as part of this, in collaboration with Duke-NUS, we have found serological evidence of past exposure to a filovirus(es) most antigenically-related to ebolaviruses (e.g. Ebola virus, Bundibugyo virus), but unreactive with Reston virus GP in three under-sampled fruit bat species, suggesting that novel FVs circulate within bat hosts in SE Asia (43). **This platform has now been set up for use in Malaysia and Thailand and will be available for use in this proposed work.** Co-Is Hughes, Broder, Laing have conducted initial screening of human, wildlife and livestock samples at high-risk interfaces in Malaysia, finding serological evidence of past exposure to viruses antigenically-related to NiV and EBOV in humans, bats and non-human primates (NHPs).

**Fig. 11:** Validation of multiplex microsphere immunoassay (MMIA) specificity and identification of immunologically cross-reactive viruses for A) NiV B) EBOV.

Co-Is Wang and Anderson (Duke-NUS) have developed a phage-display method to screen antibodies for all known and related bat-borne viruses, including henipaviruses, FVs and CoVs and have set up a similar Luminex-based assay. Additionally the Duke-NUS team has demonstrated capacity for rapid and cost-effective development of LIPS serological assays against novel viral agents (**Sections 2.6.a, 3.2.a**). These will be used for verification and expanded surveillance. For molecular investigation (Aim 2 & 3), we will combine targeted PCR with a discovery-driven enrichment NGS strategy to not only survey currently known viruses, but also to discover potential novel viruses. Both the phage-display serological and enrichment platforms can be rapidly updated to include new viruses identified.

**2.3 General Approach/Innovation: Our human sampling approach uses two approaches in Aims 1 & 2 (Fig. 12). In Aim 2 we will conduct community-based surveillance using a brief, focused questionnaire to**

identify the prevalence and frequency of risk-factors for viral spillover in tandem with collection of high quality biological samples to determine the seroprevalence of spillover viruses in at-risk human populations. We will use generalized linear models to analyze correlation between biological results and risk-factors for viral spillover. In Aim 3, we will conduct clinic-based syndromic surveillance and biological sampling at clinics/hospitals that are the catchment healthcare facilities for the communities sampled in Aim 2. Both community-based and clinic-based syndromic surveillance programs are cross sectional case-control studies designed with the sample sizes necessary to statistically quantify (with a power of 80%) risk factors and health impacts for viral spillover, linked to serological status and PCR prevalence in symptomatic patients. All human sampling conducted under Aims 2 and 3 will adhere to strict criteria for inclusion and recruitment and protection of human subjects from research risk (**see Human Subjects and Clinical Trials Information**).

**Fig. 12:** Human sampling approach. Aim 2 (left) focuses on serology in high-risk communities to identify evidence of population exposure to novel zoonotic viruses. Aim 3 (right) sets up clinical cohorts at hospitals serving these high-risk communities to conduct syndromic surveillance and identify the etiology of new viral syndromes

**2.4 Target population & sample sizes:** We will target populations in the same geographic regions as those identified in Aim 1 that harbor wildlife with high potential zoonotic viral diversity, that are EID hotspots, and that are well-connected through regional travel and trade hubs to the global travel network (**Fig 13**). Within each geographic region we will identify populations at four sub-sites, building on our preliminary data (Table 2). We will target specific communities based on our analysis of previously collected behavioral questionnaire data, and other publicly available data (e.g. wildlife hunting licenses sold in a region, number of guano caves accessed for fertilizer etc.) to identify key at-risk populations and occupations with high exposure to wildlife. We will conduct concurrent sampling trips at visits to sub-sites during which members of the community will be enrolled and wildlife surveillance activities conducted. Individuals living or working around wildlife habitats (e.g. bat caves/roosts), who hunt wildlife, work with wildlife or livestock, or slaughtering wildlife will be considered for enrollment. Participants will complete a consent form and questionnaire in addition to having biological samples collected. During these community trips after data collection the field research staff will conduct community meetings to help inform the public health risk of zoonoses. **Target populations:** Thailand (Co-I Wacharapluesadee): 100 subjects of healthy high-risk community from 2 study sites, Chonburi (NiV, other PMVs and CoVs found by PCR in bats in our previous work), and Ratchaburi (bat guano harvester villages where we found a MERSr-CoV in bat guano (50, 175) and serological evidence of α-CoVs, HKU1-CoV in people (175)). Peninsular Malaysia (Co-I Hughes, CM Ltd.): We will expand our sampling of the Orang Asli indigenous communities to include sub-sites in communities in Districts we have already sampled and

additional Districts in the States of Kelantan Perak, Pahang, and Kelantan all close to bat caves. Samples will be stored and tested at NPHL. Sarawak (Co-I Tan, Fac. Med. Hlth. Sci. UNIMAS): We will expand our sampling of the Bidayuh and Iban indigenous people to include the Dayak and Orang Ulu (“people of the interior”) because this group has a more intimate connection to remote wildlife-rich areas than the other two, albeit all are hunters. Human sampling will be led by UniMAS in collaboration with CM Ltd / EHA. Sabah: We will conduct sampling at the Madai bat and bird cave that has 200 permanent residents who harvest bird’s nests for soup, and >1,000 during the harvesting season and at Gomantong cave – one of the largest bat and cave swiftlet nesting sites in the world. Sabah: (Co-I Hughes): We will conduct sampling at the Madai bat and bird cave that has 200 permanent residents who harvest bird’s nests for soup, and >1,000 during the harvesting season and at Gomantong cave – one of the largest bat and cave swiftlet nesting sites in the world. Protocols follow those for Peninsular Malaysia Singapore: (Co-I Wang, Duke-NUS): Active human surveillance will be not be conducted in Singapore, but archived human specimens e.g. from our Melaka virus serosurvey (8), will be made available to conduct retrospective serosurveys for specific pathogens that are identified as high interest to the EIDRC, NIH, and EID-CC.

**Fig. 13:** Targeting high-risk sites for human zoonotic disease surveillance in Thailand and Malaysia. This map plots areas with high numbers of expected viruses in wildlife (3), greater spillover probability based on EID risk factors (2), and higher levels of connectivity (measured by road density data) that may facilitate person-person spread.

**Sample sizes:** From our previous work we conservatively anticipate that 10-30% of the community population will have had exposure to wildlife allowing us to capture highly exposed and non-exposure individuals at each site. Individuals living or working around wildlife habitats (e.g. bat caves/roosts), who hunt wildlife, work with wildlife or livestock farming, transportation, selling, or slaughtering wildlife in the surveyed areas will be targeted so that they make

up  $\geq 30\%$  of the sampled population in each community. We will stratify sampling to ensure appropriate representation of sex, demographic, and socio-economic factors at each community site. In each of our regions, we will conduct sampling at four sub-sites in populations with high prevalence of high occupational and environmental risk of exposure to wildlife populations, sampling 175 persons at each sub-site. We will target populations with, on average, 30% or higher prevalence of occupational or environmental exposures to wildlife based on data from previous studies. This design will give us >80% power to detect 5 percentage point differences in seroprevalence against any of our viral groups between baseline and high-risk subgroups. We conservatively assume 5% base seroprevalence, as well as assuming high spatio-temporal variance amongst sub-sites, with baseline varying 0-25% amongst sub-sites and the fraction of the population at risk varying from 20-40%. (Power calculation conducted by 500 simulations of a generalized linear mixed model (GLMM)). For community-based surveillance, we will enroll 700 individuals per study region, allowing us to make county/province-level comparisons of differing effects; the total sample will be 3,500 participants over 5 years.

**2.5 Data & sample collection:** Following enrollment, biological specimens (5mL will be drawn for whole blood and serum collection, samples will be aliquoted, at least one max 500  $\mu$ L of whole blood and two 500  $\mu$ L serum samples) will be collected by locally certified healthcare professional proficient in phlebotomy techniques and a short questionnaire will be administered by trained project staff that speak appropriate local language to all participants. Through the serological findings and the survey we will investigate the details of five risk factors related to high risk wildlife exposure, to maximize the power of the analyses, based on continuing analysis of our previous work, and will focus on: 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, in/around house; 3) proximity of residence or work place to environments of increased risks, e.g. nearby bat roosts; 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms in the past 12mo and lifetime. For participants who report the symptoms relating to 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; or 5) hemorrhagic fever within the last 10 days, an additional sample type will be collected, nasal or oropharyngeal swab (2x). Blood of participants whose serum tests positive for emerging viral pathogens will be taken and Peripheral Blood Mononuclear Cells (PBMCs) frozen for future use.

These will be used for future harvesting of polyclonal and monoclonal antibodies as potential therapeutics/diagnostics (**see Letter of Support NEIDL**).

**2.6: Laboratory analysis: 2.6.a Serological testing:** We will screen all human specimens for henipaviruses, FVs and CoVs using our novel, multiplex microsphere immunoassay (MMIA) (**Section 2.2.d**). We will use ELISA and serum neutralization tests (SNT) as confirmatory, where feasible and appropriate for the biocontainment level given sensitivity and specificity variation, and the need for live virus for SNTs (**See Select Agent Research**). Serologic evidence of local spillover will be used to prioritize zoonotic strains for recombinant virus recovery from full length sequences. Preliminary data suggest ELISA will be effective for some viral groups. We previously developed a SARSr-CoV specific ELISA for serosurveillance using the purified NP of a bat SARSr-CoV (Rp3). The specificity of this assay was evaluated using polyclonal antibodies against HKU1, OC43, 229E, NL63, MERS-CoV and EBOV and no significant cross-activity detected (16). **This suggests that if we can expand our NP serology tests to cover other bat CoVs, and that doing so may identify many more seropositive individuals.** For CoVs, we will therefore use two serological testing approaches: 1) testing human sera collected from both community- and clinic- based sampling for a panel of bat CoVs that will include SARS-CoV, MERS-CoV, SADS-CoV and a range of bat SARSr-CoVs (16); 2) testing for antibodies to common human CoVs (HCoV NL63, OC43 – **Section 2.8**). We will test panels of NP and G recombinant proteins to assess if this approach will act as a comparison to MMIA for FVs and PMVs.

**2.6.b RT-PCR testing.** Specimens from individuals in the community who reported being symptomatic within the last 10 days (**Section 2.5**) will be screened using RT-PCR initially for CoVs, PMVs, and FVs following published protocols (**Section 1.4.c**). Positive samples will be subjected to full genome sequencing and RT-PCR amplification of the glycoprotein genes. Samples from the clinic-based syndromic surveillance will also be tested using RT-PCR for Influenza A & B, HCoV NL63, OC43, HKU1, SARS-CoV & 229E, NiV, HeV, Ebola (WHO PCR protocol) based on the symptom as rule-outs.

**2.6.c Biological characterization of viruses identified:** Novel viruses identified in humans will be recovered by cultivation or viruses re-derived from full length genome sequences using reverse genetic approaches. Viruses will be characterized for growth in primary human cell lines and in mouse models, including the Collaborative Cross Mice or humanized mice expressing human receptors from related strains. The approaches are discussed in more detail under Aim 1.

**2.7 Epidemiological analysis:** We will conduct a cross sectional case-control study to identify risk factors for Henipavirus, FVs, and CoVs spillover. “Cases” are defined as participants whose samples tested positive for Henipavirus, FVs, or CoVs by serological tests. “Controls” will be selected from the pool of participants admitted to the studies and whose samples tested negative for Henipavirus, FVs, or CoVs. We will use nearest neighbor matching to pair cases demographically (e.g. age, sex, location) with controls at a 1-to-3 ratio or greater. We will use generalized linear models and least absolute shrinkage and selection operator (LASSO) regression analyses (176) to analyze correlation between biological results, serological/PCR status, and risk factors related to high risk wildlife exposure including: 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, in/around house; 3) home or work proximity to environments of increased risks, e.g. nearby bat roosts; 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms lifetime and past 12mo. Additionally, we will use this procedure to determine how clinical presentation differs between Henipavirus, FVs, or CoVs in exposed and unexposed participants, as well as in the time course of illness, severity of symptoms, and type of symptoms.

**2.8 Potential problems/alternative approaches: Rarity of spillover events** means it may be difficult to identify sufficient seropositives to statistically analyze human risk profiles. First, we will be targeting our community-based surveillance to subpopulations with high-levels of wildlife exposure, at sites selected for diverse and prevalent viruses to increase likelihood of finding positive individuals. Second, our serology testing will include a multi-plex panel of assays for a large diversity of viruses, increasing likelihood of positives. For example, in previous work our overall bat CoV PCR prevalence in the community was, 11.8%;  $\beta$ -CoV, 3.4%;  $\alpha$ -CoV, 9.1%). Thus, using this broad serological panel to screen individuals prone to contact with species of higher zoonotic risk increases the potential for detecting spillover with enough power for statistical analyses,

and will shed light on behaviors that predispose to spillover. Third, we will include common human CoVs, PMVs, and influenza viruses in our panel, so that even if low prevalence of wildlife viruses is found, we will be able to conduct a valuable cross-sectional study of the seroprevalence of more common human viruses. Finally, we will be able to assess relative measures of human-wildlife contact from our survey work. We will analyze intensity of contact with high-risk taxa against other risk factors to provide useful proxy information for spillover risk. **Serological testing may be difficult to interpret in the presence of known and novel viruses.** We will use the three-tiered serological testing system outline in **2.6.a** to try to identify exposure to these ‘novel’ viruses. However, we know exposure to a range of related viruses generates antisera that are cross-reactive with known, related virus antigens - a serious challenge to serological surveillance and diagnostics. Our collaborations have already demonstrated that SE Asia bat sera samples screened with our pan-filovirus MMIA have been exposed to an Ebola-like virus, that is antigenically-distinct from known Asiatic filoviruses, Reston virus and Měnglà virus (43). Using these three serological platforms we will address inherent challenges of indirect virus surveillance through antibody capture by testing multiple binding assay platforms and antigens, using positive control samples to establish serological profiles against known viruses that will aid in our interpretations of cross-reactive antisera responses likely representative of ‘novel’ viruses.

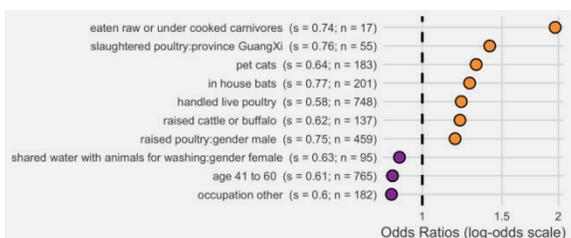

### **Aim 3: Identify and characterize viral etiology of ‘cryptic’ outbreaks in clinical cohorts.**

**3.1 Rationale/Innovation:** Our previous research (**Table 1**) and other data suggests that there are substantial numbers of outbreaks or clinical cases for which the etiologic agent is not diagnosed, e.g. (177, 178). To investigate this in SE. Asia, we have assembled a multi-disciplinary team that includes senior infectious disease doctors and clinicians and will work directly with local clinics and regional hospitals to identify the ‘cryptic’ outbreaks or cases that occur in the region. **In Aim 2, we will conduct serology in high zoonotic-risk communities to find evidence of prior exposure in people**, i.e. evidence of viral spillover into the community. In Aim 3 we identify members of these communities presenting at clinic with undiagnosed illness that may have high-impact zoonotic viral etiology. **Therefore, in Aim 3 we focus on PCR to identify the putative viruses that are replicating in these actively-infected patients (Fig. 12).** We will enroll, and collect high quality biological samples from patients who live in rural communities linked to Aim 2 and who present at regional clinics or hospitals with symptoms typical of high impact zoonotic viruses. We will collect detailed survey data to assess their contact type and frequency with wildlife and livestock and conduct molecular and serological diagnostic assays to test causal links between their syndromes and the known and novel viral agents identified in Aim 1. We will conduct molecular viral discovery assays on patients who present with symptoms indicative of a high-risk zoonotic virus. If novel pathogens are identified by PCR, we will attempt to isolate, obtain full genome sequence and/or biologically characterize the wildtype or molecularly re-derived pathogen, using the *in vitro* and *in vivo* strategy laid out in Aim 1.

**3.2 Preliminary data clinical surveillance: 3.2.a. Clinical surveys and outbreak investigations:** Our longterm collaboration in the region has included the following activities investigating clinical syndromes: **Peninsular Malaysia: At the time of writing, an outbreak of suspected undiagnosed viral illness in the indigenous Batek Orang Asli (“people of the forest”) community living at Gua Musang (“civet cat cave”) district, in Kelantan, Malaysia, close to Taman Negara – a National Park containing the oldest known rainforest. This community is one where we have conducted prior routine surveillance and biological sampling, demonstrating proof-of-concept that our two-pronged high-risk community/clinic approach will work.** Dozens of people are affected and the outbreak is currently being investigated by our group in collaboration with the Malaysian NPHL. The Orang Asli continue to practice traditional subsistence hunting of wild animals (bats, rodents, primates). These communities are remotely located, in heavily forested areas, with limited access to medical services. **This outbreak, and others that will continue to emerge just like it, underscore the critical need for our EIDRC - to improve the technological tools, training, and human capacity for rapid EID surveillance, diagnosis, and response at the frontlines of disease emergence in SE Asia. Investigating this outbreak is a key priority if EID-SEARCH is funded.** **Sabah:** Co-I Kamruddin (BMHRC) is leading an asymptomatic leptospirosis study on sanitation workers, an ILI study in a Kota Kinabalu clinic and diarrheal study in children under 5 yrs. Co-Is William, Tan and others have conducted clinical observational studies to determine the etiology of central nervous system infections and acute undifferentiated febrile illness in Sabah.

Co-Is William and consultant Yeo have collaborated with Co-I Wang to enroll 90 adult and over 100 pediatric participants with central nervous system infections, negative tests for malaria and dengue from 3 district hospitals in Sabah to determine the various etiologies. While a proportion tested positive for rickettsial agents, the majority had no clear diagnosis. Co-Is William, Rajahram, and Yeo have conducted clinical studies of over 200 inpatients with acute febrile illness with negative tests for malaria and dengue from 3 district hospitals in Sabah to determine the various etiologies. While a high proportion tested positive for rickettsial agents, the majority had no clear diagnosis. **Sarawak:** Co-I Siang (UNIMAS) is conducting a survey of high-risk female Kelabit indigenous people and has found 8% with HPV52 as the dominant strain. He is working on clinical cohorts of hand, foot and mouth disease and will recruit patients from that study in the current proposed work. Finally, Co-Is Siang, Kamruddin are conducting a long-term study of rotavirus and other viral etiologies of acute gastroenteritis in Kuching, Sarawak that will include swine herders and farmers. The Baric lab is a global leader in norovirus VLP diagnostic reagents to detect serologic evidence of norovirus gastroenteritis, as well as RT-PCR detection of novel noroviruses in humans, and has identified novel bat noroviruses, suggesting further opportunities for expansion of this work (142, 179-181). This work is particularly relevant in Malaysia because pig farms are shunned by the government and local villagers to they are placed far away from town centers, deep in the forest, and it is this scenario that led to the emergence of Nipah virus in 1998-9 (6, 22). **Thailand:** Co-Is Hemachudha, Wacharapluesdee (TRC-EID, Chulalongkorn Univ. Hosp.) work in coordination with the Thailand Ministry of Health to investigate outbreak etiology, including the first case of imported MERS-CoV in Thailand, **for which we produced sequence confirmation within 24 hours from acquiring the specimen.** Three imported MERS cases have been detected in Thailand since 2015, and all cases were confirmed at the TRC-EID. We worked during the Zika outbreak to identify > 500 PCR-positive Zika patients with sequence confirmation. We have also worked on returning and suspected Ebola travelers, syndromic surveillance for SARI, encephalitis, Hand Foot and Mouth disease in children and viral diarrhea. Consultant Hickey (US CDC, Thailand), screened specimens collected between 1998 and 2002 from a large cohort of children from Kamphaeng Phet Province to examine Dengue virus and JE epidemiology (182, 183). Among the 784/2,574 convalescent sera henipavirus-specific antibodies were detected in 13 serum samples (1.7% seroprevalence), suggesting prior exposure to endemic henipaviruses or a related PMV in rural Thailand. **Singapore:** Duke-NUS has worked with the Ministry of Health to investigate Zika cases (184), and other EIDs. With EHA and others, Duke-NUS has developed novel CoV assays for clinical surveillance, and for expedited analysis during outbreaks. Our pipeline of novel virus detection, reservoir host identification, serological assay development, and serological testing is as rapid as several months, with the development of novel serological assays from sequence data in 7 days (17). **For example, with the discovery of SADS-CoV, we identified and fully sequenced a new virus, screened archived wildlife specimens to identify the natural reservoir host species (*Rhinolophus* spp. bats), developed LIPS serological assays, and tested human and swine samples to assess seroprevalence in less than 3 months (17).**

**3.2.b Analysis of self-reported illness:** We have developed a standardized approach for analyzing data from study participants on self-reported symptoms related to target illnesses: fever with cough and shortness of breath or difficulty breathing (severe acute respiratory illness - SARI); fever with muscle aches (fevers of unknown origin (FUO)); and, cough or sore throat (influenza-like illness - ILI). For all of our prior human clinical surveillance in 20+ countries, including in Malaysia and Thailand, we used a least absolute shrinkage and selection operator (LASSO) regression to identify associations between participants who reported ILI and/or

SARI symptoms and demographics, occupation, and contact with animals in the last year. Results have clear biological relevance. For example, in Yunnan, China, factors strongly associated with prior disease involve animal hunting and consumption (Fig. 14). We will expand this approach for all clinical syndromes in Aim 3, and use targeted questions to assess patient's exposure to wildlife in terms that are relevant to each specific country.

**Fig. 14:** Factors associated with self-reported ILI & SARI in prior 12 months (s = bootstrap support; n = #+ve out of 1,585 respondents). **Orange circles** = odds ratios > 1 (+ve association); **purple** = odds ratios < 1 (-ve association).

**3.3 General Approach:** Our previous research suggests that there are substantial numbers of outbreak cases for which the etiologic agent has not been identified. To capture these, we will expand on our current syndromic surveillance to enroll, and collect high quality biological samples from patients who present at regional clinics and live in rural communities linked to Aim 2. Case definitions and enrollment criteria include: 1) severe/acute respiratory illness (SARI/ARI); 2) Influenza-like illness (ILI); 3) fever of unknown origin (FUO); 4) encephalitis; 5) hemorrhagic fever; or 6) high fever/diarrhea with unusual presentation. We will collect survey data to assess contact with wildlife, and occupational and environmental exposures, conduct molecular and serological assays to test causal links between their syndromes and the known and novel viral agents identified in Aim 1. If novel pathogens are identified by PCR, we will attempt to isolate and biologically characterize the pathogen, using the collaborative cross to identify an appropriate animal model to conduct preliminary pathogenesis work. We will then use behavioral survey data, ecological and phylogeographic analyses to assess the likely reservoir hosts to inform intervention programs.

**3.4 Clinical cohorts. 3.4.a Cohort selection:** We will initiate active clinic-based syndromic surveillance at 2 town-level level clinics and 2 provincial-level hospitals in each Thailand, Peninsular Malaysia, Sabah and Sarawak. These serve as the catchment healthcare facilities for people in our community-based surveillance of Aim 2 and are inclusive of wildlife sampling sites in Aim 1. Patients  $\geq 12$  years old presenting at the health facility who meet the syndromic and clinical case definitions above will be recruited into the study after completing a consent form. We will aim to enroll 300 participants per hospital, with that we will have a 95% probability of detecting live virus in patients in each hospital assuming a population prevalence of 1%. This sampling effort will total of 4,800 individuals for clinical syndromic surveillance. We assume up to 40% loss from follow-up, therefore yielding 2880 participants that will be available for follow-up blood sampling (**Section 3.4.b**). While enrollment is limited by the number of patients that come to the healthcare facility presenting with relevant clinical symptoms, in our work in the PREDICT project we enrolled an average of 100 participants per year, so we are confident this is an achievable enrollment target. Study data will be pooled across country regions, as clinical patients are limited by the number of individuals presenting at hospitals. “Cases” will be determined as participants whose samples tested positive for either CoVs, henipavirus, or FVs, PCR tests. “Controls” will be selected from the pool of participants admitted to the studies and whose samples tested negative. We will use nearest neighbor matching to pair cases demographically (e.g. age, sex, location) with controls at a 1-to-3 ratio or greater. Sites: Thailand: We will work with two primary hospital, Phanat Nikhom Hosp., Chonburi district (Key Pers. Dr. P. Hemachudha) & Photharam Hosp., Ratchaburi Province, and a large tertiary hospital, King Chulalongkorn Memorial Hospital, Bangkok Thailand (Co-I Dr. T. Hemachudha). Peninsular Malaysia: **Focusing immediately on the current outbreak in Orang Asli, we will work closely with the Malaysian Ministry of Health to support their investigation, and with 6 Orang Asli clinics which focus solely on this indigenous community.** Co-I Sellaran (Lintang Clinic, Kuala Kangsar) refers patients to Sungai Siput Hospital and Gen. Hospital, Ipoh. Key Pers. I Lotfi (Pos Betau clinic, Kuala Lipis) will continue collaboration with Co-I Hughes in the communities at that site. Sarawak: Key Pers. Diyana (Director, Bario Clinic) refers patients to Miri Hospital (Co-I Utap) and serves people from the Kelabit, and nomadic tribes in the region, as well as populations within a number of large towns. Sabah: We will continue our collaboration with Queen Elizabeth Hospital, QEH (Key Pers. Lee, Rajahram) and Hospital University Malaysia Sabah, HUMS (Co-I Lasimbang, Director). Both clinics include our targeted sites for **Aim 2** in their catchment, and both have ongoing collaboration with the Borneo Medical Health Ctr (Co-I Kamruddin, Director). Singapore: Currently, there are no plans to conduct clinic surveillance based on budget constraints. However, in the event that that is an evolving need for clinic surveillance, enrollment, and sampling, we have close working relationships with all hospitals in the country, and the central infectious disease reference lab (key clinicians at which are aware of our proposal). This would allow us to rapidly on-board a hospital based site.

**3.4.b Clinic enrollment and follow-up:** We will recruit inpatients and outpatients to participate in the study after initial screening to determine if they meet our clinical case definitions. Once consented and enrolled, biological samples will be collected by trained and locally certified hospital staff and a questionnaire administered by trained hospital or research staff that speak appropriate local language. Every effort will be made to take samples concurrently when collecting samples for normative diagnostics. For both inpatients and outpatients, samples will be collected no more than 10 days of reported onset of illness to increase the chance

of PCR detection of viruses (185). Where possible, we will follow up 35 days after enrollment to collect an additional two 500 µL serum samples conduct a standardized questionnaire supplement to collect additional data on the course of symptoms in the interim period. This gives adequate time for development of IgG, which occurs <28 days after onset of symptoms for SARS patients (186-188). Serum samples will be used to screen panels of high risk human and local zoonotic Filovirus, Henipavirus and Coronavirus strains as described in Aim 2. These samples may prove valuable to collaborators in that the PBMC could be used in production of therapeutic antibodies.

**3.4.c Sampling and clinical interview:** Biological specimens whole blood (5mL will be drawn for whole blood and serum collection, samples will be aliquoted, at least one max. 500 µL whole blood; two 500 µL serum samples) and two nasal or oropharyngeal swabs will be collected from all participants, and a questionnaire will be administered. We will investigate five risk factors, to maximize the power of the analyses, all related to high risk wildlife exposure, based on continuing analysis of our previous work, and will include: 1) occupation and occupational exposures; 2) observed or reported interactions with priority wildlife, especially bats, in/around house; 3) proximity of residence or work place to environments of increased risks, e.g. nearby bat roosts; 4) working or regular visitor to animal markets; 5) self-reported ILI/SARI clinical diagnosis or symptoms in the past 12mo and lifetime. With additional consent considerations for participants enrolled from clinical settings, we will review clinical records to collect data on medical history, clinical syndromes, and patient etiology. Blood will be taken for future harvesting of Peripheral Blood Mononuclear Cells (PBMCs), as per **Section 2.5**.

**3.5 Sample testing:** The standard syndromic diagnostic PCR assays for common pathogens will be conducted and the results will be shared with the hospital with 48 hours. Specimens will be further tested for 3 viral families; CoV, PMV and filovirus by consensus PCR (**Section 1.4.c**). Necropsy samples from deceased patients will be further characterized by NGS if previous PCRs are negative and unable to identify the cause of infection. Co-Is Wang, Anderson will conduct a VirScan serological assay using paired serum samples at Duke-NUS that identifies antibodies with a four-fold rise in titer in the convalescent sample compared with the acute sample, thereby indicating a possible etiological agent. A PCR test with the specific primer from each virus antibody positive case will be further tested from acute specimens to confirm infection.

**3.6 Viral risk characterization and potential for pandemic spread:** We will use statistical models built from collated biological, ecological, and genetic data to assess the likelihood of pathogenicity for the range of diverse viruses we will characterize. The aim is to quickly identify and assess which viruses pose the most significant risk to human health and thus prioritize additional resources to more fully characterize, better understand pathogenicity, and invest in our animal model pipeline and ultimately therapeutic development for those pathogens. We will combine two independent but related statistical models to predict pathogen spillover risk and pathogenicity. First, we will expand a simple generalized additive modeling approach (3) to assess spillover risk probability to a new virus that is currently not known to infect people, when we have only limited genetic data from initial PCR screening and sequencing. Additional data from receptor binding protein homology and cell line infection experiments will be incorporated into the model framework as available. Second, given high likelihood to spillover and infect humans, or direct evidence of human infection from our clinical surveillance, we will then assess the likelihood of pathogenicity based on traits for phylogenetically related nearest neighbor viruses as a first approximation and incorporating more detailed data from genomic characterization and animal model experiments (Aim 1). Epidemiological trait data for ~300 viral species known to infect people (e.g. case fatality rate, global estimates of number of human cases per year or decade,  $R_0$ , infectious period, and primary symptoms) have been collated by recent studies and will be used as predictor variables (189). Thirdly, we will apply tools already developed, and being refined by EHA under DTRA and DHS supported research, to predict pandemic spread for viruses using global flight models, as well as additional datasets on human movement and connectivity across Southeast Asia (90, 91) (**Fig. 15**).

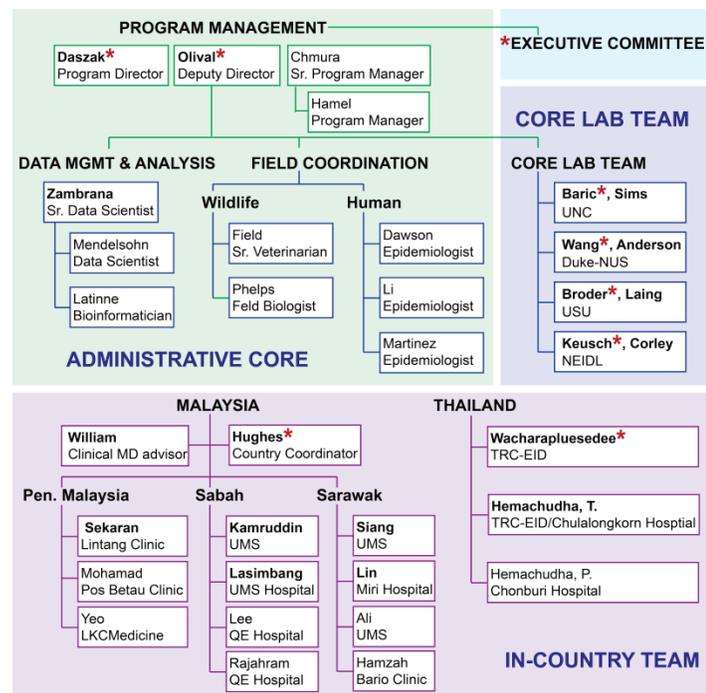

**Fig. 15:** Probability feed from EHA's Flight Risk Tracker tool (FLIRT). This image is of the likely pathways of spread and establishment for a Nipah-like virus emerging from Sabah, based on human movement and airline flight data (90, 91).

**3.7 Potential problems/alternative approaches: Patients visiting clinics may have cleared virus, but not yet developed IgG antibodies, reducing seropositive cases.** Our 35 day follow-up sampling should account for this because the maximum lag time between SARS infection and IgG development is ~28 days and Ebola virus infection and IgG approximately 20 days (185-188, 190). We also expect that patients in rural communities will only visit clinics when symptoms have progressed, likely coinciding with late illness and onset of IgG. We will also have data from our community study that can be analyzed in conjunction with, or in the absence of, clinical data from the hospital data to identify PCR- or seropositives. Finally, the risk of limited detection is outweighed by the potential public health importance of discovering active spillover of new henipaviruses, FVs or CoVs infection.

**4. Administrative Plan**

**4.1. Project management: 4.1.a. Administrative core:** The EID-SEARCH organizational partner roles are laid out by Specific Aim above (see Fig. 3). EcoHealth Alliance (EHA) will lead the administrative core of the EID-SEARCH, including: coordination and management of all human and animal research; communication with consortium partners, NIH, other EIDRCs, and the EIDRC-CC; data management and quality assurance; modeling and analysis; and compliance with all US, international, and institutional rules and regulations. The administration will be led by PI Daszak, who has >20 years' experience managing international research collaborations on emerging zoonoses, and has collaborated with all partners in the EIDRC consortium for 5-20 yrs on NIAID- and USAID-funded research (Fig. 16). He also has direct experience as one of two external reviewers of one of the CEIRS partners for NIAID (Program officer Diane Post). PI Daszak will be assisted by Deputy Lead, co-I Olival, who has overseen zoonotic disease research in Southeast Asia for >10 years and working directly with our partners in Thailand and Malaysia for 15 years. Senior program manager (Chmura) and full-time program assistant (Hamel) will provide administrative support. The EID-SEARCH data management, epidemiological analysis, and modeling activities will be led by co-Is Olival and Zambrana who have led all modeling and analytics on USAID USAID PREDICT for the last 10 years. They will oversee a programmer/data scientist (Mendelsohn), evolutionary biologist/bioinformatician (Latinne), and human epidemiologists (Dawson, Li, Martinez). Our human epidemiology team will work directly with country teams in Malaysia and Thailand to manage human surveillance, IRB applications and approvals, and ensure compliance with all human subjects work. EHA's senior veterinarian (Field) and wildlife field biologist (Phelps) have extensive experience working that bats, rodents, and primates in SE Asia and will coordinate all training and field research in Malaysia and Thailand and ensure compliance with IACUCs.

and full-time program assistant (Hamel) will provide administrative support. The EID-SEARCH data management, epidemiological analysis, and modeling activities will be led by co-Is Olival and Zambrana who have led all modeling and analytics on USAID USAID PREDICT for the last 10 years. They will oversee a programmer/data scientist (Mendelsohn), evolutionary biologist/bioinformatician (Latinne), and human epidemiologists (Dawson, Li, Martinez). Our human epidemiology team will work directly with country teams in Malaysia and Thailand to manage human surveillance, IRB applications and approvals, and ensure compliance with all human subjects work. EHA's senior veterinarian (Field) and wildlife field biologist (Phelps) have extensive experience working that bats, rodents, and primates in SE Asia and will coordinate all training and field research in Malaysia and Thailand and ensure compliance with IACUCs.

**Fig. 16: Administration and program management for the EID-SEARCH**

The EID-SEARCH core laboratory team includes global experts in virology, molecular pathogenesis, and the development of assays, reagents, and therapeutics for high consequence viral zoonoses (Co-Is Wang, Anderson at Duke-NUS; Baric, Sims at UNC; Broder, Laing at USU; Keusch, Corley at NEIDL). The core laboratory team will work with in-country diagnostic labs in Thailand (Wacharapluesedee, Hemachudha at the TRC-EID, Chulalongkorn University) and Malaysia (Hughes, Lee, CM Ltd.). Wacharapluesedee and Hughes will additionally serve as country coordinators for the EID-SEARCH, liaising directly with EHA on weekly conference calls, and working with in-country partners to ensure the smooth operation and coordination of clinical and community surveillance and wildlife research in Thailand and Malaysia, respectively. **A Core Executive Committee** comprising PI Daszak, Deputy Lead and Co-I Olival, and leads from each core partner and country: Co-Is Hughes, Wacharapluesedee, Baric, Wang, Broder, Keusch (or alternates), will conduct

regular conference calls and in-person meetings to facilitate rapid decision making within the EID-SEARCH. **This committee will also convene to manage EID-SEARCH response to outbreaks.**

**4.1.b Project Management in Thailand and Malaysia:** Wacharapluesedee and Hughes have collaborated directly with EHA for >15 years, including acting as country coordinators on the USAID PREDICT project for the last 10 years (project end date Sept. 2019). They maintain strong ties with Ministries of Health (MOH), Agriculture and Environment, multiple universities and research institutions, clinics, and hospitals, in their respective countries and across the region. The EID-SEARCH will use these connections to disseminate results, obtain permissions to conduct sampling, and also rapidly respond to and assist with outbreaks as they happen. Peninsular Malaysia, Sarawak, and Sabah are the three main Malaysian administrative regions, and effectively operate as three separate countries, with different regulations and government structures. We therefore provide specific details on the management of EID-SEARCH activities in each:

Coordination among Peninsular Malaysia, Sabah and Sarawak will be led by co-I Hughes (Conservation Medicine Ltd), and follow a successful model we implemented under USAID-PREDICT. **On Peninsular Malaysia** this project will be administered through the Zoonosis Technical Working Committee (ZTWC) established under the PREDICT project with a binding MOU among EHA, CM Ltd. and ZTWC, and including officers from MOH, Dept. of Veterinary Services, and PERHILITAN (the Govt. wildlife agency). EHA will communicate weekly with Co-I Hughes to coordinate and monitor implementation of research and reporting to ZTWC. Co-I Hughes will coordinate activities at all other Peninsular Malaysia institutions: NPHL, the National reference laboratory for diagnostic confirmation of pathogens, will manage molecular and serological screening (BioPlex) of Orang Asli samples, and serological screening of syndromic samples from Sabah and Sarawak; the PERHILITAN molecular zoonosis laboratory will store and conduct molecular and serological screening on wildlife samples; and Universiti Putra Malaysia (UPM) Faculty of Veterinary Medicine will conduct molecular and serological screening (BioPlex) of livestock samples, should these be required. **For Sabah & Sarawak**, work will be administered through the Sabah Zoonotic Diseases Committee (SZDC), a working technical committee comprising appointed and authorized officers from Sabah State Health Dept., Department of Veterinary Services, Sabah Wildlife Dept. (SWD), Universiti Malaysia Sabah (UMS) and EHA, all of which are also committed through a signed MOU. Co-I Hughes will oversee work at all other partners in Sabah, including: the Kota Kinabalu Public Health Lab (KKPHL) for molecular screening of syndromic samples from Sabah and Sarawak; the SWD Wildlife Health and Genetic and Forensics Lab for molecular screening of Sabah wildlife samples; The Borneo Medical Health Research Center (BMHRC) for screening some Sabah wildlife and livestock samples, if required, and human syndromic samples from Sabah and Sarawak. **In Thailand** all human community and wildlife research and testing will be coordinated by co-I Wacharapluesedee from the TRC-EID center. Clinical surveillance will be overseen by senior clinical physician and co-I T. Hemachudha.

**4.1.c. Approval and release of results:** In our experience, it is critical when working in resource-poor countries, on potentially important pathogens, to strictly adhere to protocols for release of results. EID-SEARCH will liaise with existing points of contact in the Ministries of Health, Environment, and Agriculture in each our administrative areas to approve and release project findings publicly. Results from human screening will be shared with participants when they become available, as per our IRB agreements ensuring no violations to anonymize data requirements (**see Protection of Human Subjects**).

**4.2. Flexibility to extend the EID-SEARCH to new sites as needed:** The EID-SEARCH consortium partners maintain extensive working relationships with leaders in EID outbreak control, clinical investigations and research at over 50 clinics, research institutes and public health laboratories across Southeast Asia. Due to space constraints, we haven't listed each of these, nor have we solicited >50 Letters of Support for this project. However, each core EID-SEARCH partner has contacted their networks and obtained permission for inclusion in the broader goals of the EIDRC. As examples of these contacts, our core partner, the Thai Red Cross Emerging Infectious Disease Health Science Centre (TRC-EID) at Chulalongkorn University, also serves as the WHO Collaborating Centre for Research and Training on Viral Zoonoses and has ongoing research collaborations across WHO SEARO countries including Bangladesh, Bhutan, Democratic People's Republic of Korea, India, Indonesia, Maldives, Myanmar, Nepal, Sri Lanka, (Thailand), Timor-Leste; and has recently served as a training hub for scientists from Malaysia, Myanmar, Laos, the Philippines, and China to learn methods of wildlife sampling and diagnostic screening. Our Thai clinicians (Co-I T. Hemachudha and KP P.

Hemachudha) provide regular case consultations and clinical trainings for doctors across SEARO countries, including with Yangon General Hospital and the National Health Lab in Myanmar, 2018. To maximize leverage of this broad network, EHA has budgeted for annual meetings in SE Asia, in addition to regular smaller network meetings, with our core team and key public health experts from network labs in each of the 10 SE Asian countries. Additionally, we will set up a listserv and an internal communication network to facilitate collaboration and information exchange, including on the first reports of new disease outbreaks. Our annual and smaller network meetings will critically allow face-to-face meetings of the EID-SEARCH that will foster greater sharing of information on novel research and diagnostic approaches, pathogens that are of key pandemic potential, regions or populations at high risk of spillover, and information from the greater network on likely outbreaks of novel disease. This platform will coordinate sample sharing and diagnostic platforms and help build a rapid response to outbreaks in the region, guided by the PI, Deputy and the Executive Committee.

**4.3. Outbreak response:** EHA collaboration with expert networks around the world allows us to mobilize and enhance effective One Health response to disease emergencies (191), ranging from real-time situation updates and risk analyses to on-the-ground investigations (192-194). We will adopt management tools from Emergency Operating Center (EOCs) (195) and Incident Management Systems (IMS) (196), to shift resources where necessary to help respond to novel zoonotic outbreak events and other public health emergencies. EHA has extensive experience working with governments in low and middle income countries (LMIC) applying these principles of epidemic preparedness during outbreak responses we've been involved with under the USAID-PREDICT project. For example, at the request of the government of Bangladesh, we provided technical field and laboratory support for Nipah virus and avian influenza outbreak investigations, assisting with wildlife sampling as part of the outbreak response alongside human and domestic animal sampling. In India, we provided technical assistance in response to the Nipah virus outbreak in Kerala in 2018. Last month in Indonesia we assisted the Ministry of Health's Center for Health Laboratory in Makassar to provide technical assistance in a mysterious outbreak in a small village in South Sulawesi that killed 4 villagers and infected 72. Our network partners include the key government and govt. approved laboratories that would be directly involved in public health emergency response in their respective countries. The serological and PCR platforms that EID-SEARCH develops will be made available to the main government outbreak investigation teams for clinical work and research during the outbreak. EID-SEARCH will also offer assistance training and conducting animal sampling during an outbreak, epidemiological analysis and modeling to help identify likely reservoirs or likely pathways to spread. Technical and material support for lab, field and analytical activities during an outbreak will be provided by EHA, UNC, USU, Duke-NUS, and NEIDL, as well as in-country partners. Any clinical samples, viral isolates and sequence data will be shared among partners to promote the rapid development of new diagnostic assays, reagents, and therapeutics that can be deployed to the region or other regions as part of the larger NIH EIDRC network.

Finally, while the initial pathogen focus of our group is on CoVs, PMVs and FVs, our broad collaborative group has multidisciplinary expertise on a number of virus-host systems. For example: PI Daszak was PI on a subaward from PI Laura Kramer's U01 on Poxviruses and Flaviviruses, managing a multidisciplinary research project on West Nile virus ecology. He was also co-I on a 5-year NSF-funded project to understand West Nile virus dynamics and risk in the USA (197-201); Co-I Baric is a global leader in Norovirus research leading to the development of vaccines and therapeutics (202-205); Co-I Wang has conducted significant work on bat immunology, therapeutic, and reagent development, as well as being involved in a range of outbreak investigations, viral discovery programs and other research on a wide diversity of viral groups (206-215). Additionally, the serological and PCR-based diagnostic platforms being developed by Co-Is Wang and Broder are adaptable to other viral targets. The modeling tools developed by Co-Is Olival and Zambrana-Torrel can be used to predict the emergence and spread of diverse viral targets, including influenza, antimicrobial resistance, and vector-borne diseases (216-221). Our clinicians working in Thailand and Malaysia have a wide range of infectious disease investigations to adapt to any outbreak situation.

**4.4. Communications:** EHA will coordinate communication among all co-Is and key personnel, including:

- Multiple meetings per week with PI, Deputy Lead, Senior Program Manager (on project and task status)
- Weekly web/phone meetings between Program Manager and subawardee admin. staff
- Monthly web/phone conferences between EHA PIs and all subawardee PIs.

- Monthly web conferences between key personnel (research presentations/coordination)
- In-person Annual meetings with partner leads, key personnel at EHA and two in-person partner meetings annually between subawardees.
- Annual in-person meeting among all key personnel

**4.5. Problem identification and resolution:** Regular planning, monitoring, and evaluation meetings will be the primary mechanisms for problem identification. Minor problems (e.g. delays in sample availability or test results) will be dealt with internally through appropriate action and resolution monitored by PI Daszak and co-PI Olival, and our Senior Program Manager. In the event of significant problems, such as prolonged poor productivity, inadequate scientific collaboration, or major disputes regarding research direction or resource allocation, EHA will assist with resolving the problem through negotiation with relevant co-PIs and consultation with the Executive Committee. Should a resolution not be forthcoming, consultation with the EIDRC-CC, additional external technical advisors, and NIH staff may be warranted.

**4.6. Adaptive management and risk mitigation:** Maintaining a timeline and meeting milestones will require strict and continuous oversight of all project phases, frequent and regularly scheduled communication, and the ability to make decisions and implement strategies. To maintain our timeline on all projects, including the EID-SEARCH, we use an adaptive management approach to continually evaluate these trade-offs, to make decisions about when iteration is appropriate and when it is necessary to move forward with current information. Our ethos is that regular, scheduled communication among all staff, partners and collaborators will go a long way towards mitigating risks, especially if the process is collaborative and transparent.

## 5. Data Management Plan

EHA will house the Data Management and Analysis (DMA) team for EID-SEARCH, led by Co-PIs Olival and Zambrana-Torreilo and include Key Personnel Latinne and Mendelsohn. EHA has served as the data and analysis hub for numerous multi-institutional, multi-sectoral, international disease research groups, including acting as Modeling and Analytics lead for the PREDICT project (122), the Western Asia Bat Research Network (222) and EHA's Rift Valley Fever Consortium. We will leverage our experience and infrastructure from those projects to benefit the EID-SEARCH. **5.1. Project Database:** We will create a dedicated, centralized EID-SEARCH database to ingest, store, link, and provide for analysis all data associated with the proposed study and other expanded projects associated with the research network. The database will be SQL-based and use encrypted, secure cloud hosting services and enable export to archival and platform-independent formats. It will ensure data and metadata compatibility between project components, track data versioning and annotations. The system will be designed to work with both with both paper- and tablet-based field data entry and with the Lockbox laboratory information management systems (**Section 5.2**) in place in individual partner labs. The database will use existing metadata standards, including NCBI standards for genetic and molecular data and Ecological Metadata Language (EML) for field and wildlife data, as well as other standards and formats designated by the EIDRC CC. This will enable rapid publication and deposition of data. Granular security and privacy controls will be applied so that specific expansion projects undertaken in the network may be managed while maintaining data confidentiality as needed.

**5.2. Biological Specimen Management:** Project laboratories will use the Lockbox Laboratory Information Management System (LIMS), to manage the security, traceability, and quality of biological specimens. The LIMS will support sample barcoding at creation, tracking through transport, storage/inventory, and use via portable scanners. Lockbox supports CLIA and ISO 17025 as well as direct export to NCBI formats such as Sequence Read Archive. We will use the Lockbox LIMS application programming interface (API) to link to the central project database and associated samples with field and ecological data. We note that the project focuses on highly pathogenic viruses, including select agents; Lockbox LIMS supports sample tracking and movement compliant with US Select Agent Regulations and US Department of Commerce Pathogen Import and Export Control Regulations, and includes all necessary encryption, security, and backup protocols.

**5.3. Training:** Members of the DMA team will team will develop documentation and provide training for field and laboratory teams at all partner institutions in data management, metadata standards and data hygiene best practices. The DMA team will act as trainers and consultants for partner institutions in experimental

design, power analysis, data analysis, and computational and reproducibility issues, and visit each partner institution and/or field team base for training workshops and analysis consultations.

**5.4. Data Identification and Privacy:** For human clinical data and questionnaires, data will be identified by a unique identification code assigned to each individual and only this, de-identified code will be accessible in the project database, and destroyed at the end of the project - as per details provided in the Clinical Management Plan and Protection of Human Subjects forms.

**5.5. Computing Resources:** EHA operates a cluster of high-performance servers for data analysis activities, as well as infrastructure to launch cloud-based computing environments (**see EHA Facilities**). Our servers host all necessary software for statistical and bioinformatics work that is available to the DMA and partners anywhere in the world. We use a mixture of cloud services (AWS, Azure, Backblaze, GitHub) to provide redundancy, backup, version control, and rapid post-disaster recovery, and will be available to all project partners for analysis and training.

**5.6. Data and Code Sharing:** See details provided in the **Resource Sharing Plan**.

## **6. Clinical Management Plan**
