Anti–S-IgG induced severe lung injury during acute SARS-CoV infection. In our previous study, i.n. inoculation of Chinese macaques with $SARS\text{-}CoV_{PUMC}$ (1×10^5 $TCID_{50}$) led to lower respiratory tract infection in all animals within 2 days (25). However, most of them rapidly cleared infection in the lungs, and all of the animals ($n = 8$) exhibited mild lung lesions before 3 dpi (25). Severe lung injury in SARS-CoV–infected Chinese macaques has not been detected until 7 dpi (26, 27). To determine the effect of anti-S antibody on the extent of SARS-CoV–mediated lung injury, we adoptively transferred 5 mg (low dose) and 200 mg (high dose) purified anti–S-IgG from ADS-MVA–vaccinated but unchallenged macaques into 2 groups of unvaccinated macaques ($n = 6$/group) via i.v. injection, and then i.n. challenged recipients with $SARS\text{-}CoV_{PUMC}$ (1×10^5 $TCID_{50}$) (Figure 2A). As controls, another 2 macaques were administered 200 mg of control IgG (C-IgG) derived from ADC-MVA–vaccinated macaques. We sacrificed half of the macaques in each group at 2 dpi to avoid potential disruption by virus infection–induced antibodies against nucleocapsid protein (N) and other viral proteins — and prior to when induction of ALI was typically observed. The remaining half of the macaques in each group was sacrificed at 21 dpi to evaluate long-term impact (Figure 2A). At day 2, sera from macaques that received low- or high-dose S-IgG showed neutralizing activity, with IC_{50} values ranging from 10–260 and 1,000–10,000, corresponding to the dose of sera transfer; macaques that received C-IgG failed to show neutralizing activity (Figure 2B and Supplemental Table 1). While NAb titers in the sera of macaques in the high-dose group declined steadily between 2 and 21 dpi, macaques in the low-dose and control groups displayed increased NAb titers over time (Figure 2B), suggesting active viral replication.

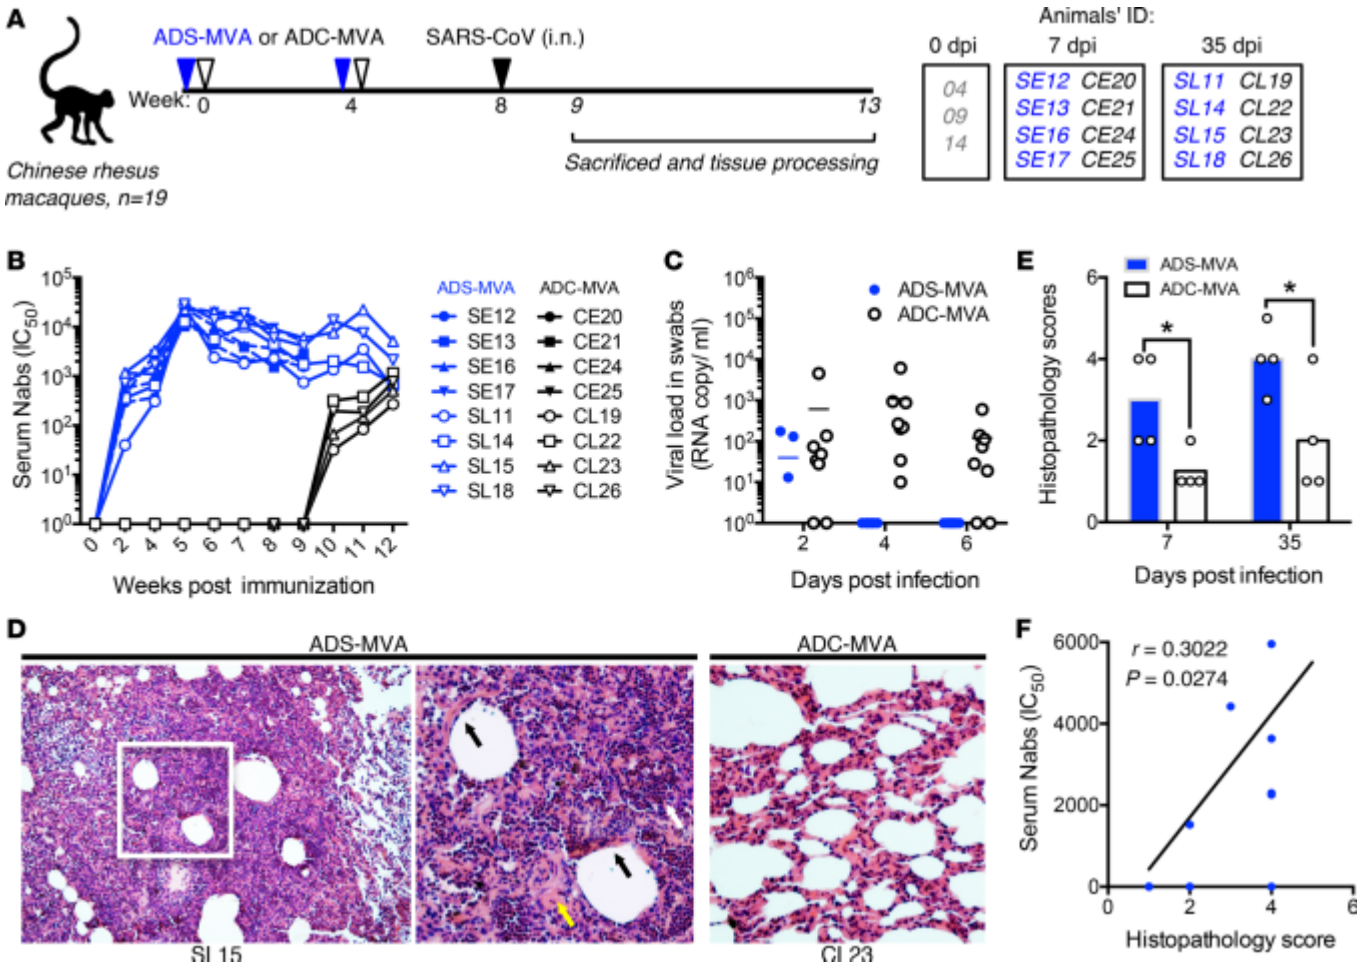

Figure 1. ADS-MVA–induced S-specific immune response enhanced pulmonary pathology in SARS-CoV–infected Chinese rhesus macaques. (**A**) imental design used to investigate the influence of S-specific immunity on SARS-CoV–induced lung injury. Two groups of Chinese rhesus macaques (*n* = 8/group) were subjected to i.m. injections of ADS-MVA or control vaccine ADC-MVA at weeks 0 and 4, followed by i.n. challenge with live pathogenic SARS-CoV_{PUMC} (1×10^5 $TCID_{50}$) at 4 weeks after the second vaccination. Four animals each were sacrificed at 1 and 5 weeks after inoculation. Three healthy macaques were included as controls. (**B**) Serum neutralizing activity. Sera collected from macaques were tested for a capacity to neutralize SARS-CoV pseudotype virus. (**C**) Detection of viral RNA in oral swabs. SARS-CoV RNA was detected by nested RT-PCR in the swabs at the indicated time points relative to infection. (**D**) Pathology changes of the lung tissue. Sections were stained with H&E. **D** shows symptom of acute DAD exhibited in 6 of 8 ADS-MVA–vaccinated macaques with extensive exudation (yellow arrow), hyaline membranes lining the alveolar walls (black arrows), and massive cell infiltration in alveolar cavities (white arrow). Left image shows a low magnification overview (100×). Middle image shows higher magnification of the boxed area in left image (200×). Right image shows minor inflammation observed in 7 macaques received ADC-MVA (*n* = 8) with slight alveolar septa broadening and sparse monocyte infiltration (original magnification, 100×). (**E**) Histopathological scores of the ADS-MVA group, including lung samples collected at both 7 and 35 dpi, were compared against the ADC-MVA control group. See Supplemental Figure 1 for the scoring index based on severity of lung histopathology. Data represent mean ± SEM values. Statistical analysis was undertaken using 2-tailed unpaired Student's *t* test. $^*P < 0.05$, *n* = 4. (**F**) Correlation of lung histopathological scores of all macaques with sera NAb titers at 0 dpi. Solid lines denote the relationship between histopathology scores and serum neutralizing activity. Statistical analysis was performed using Spearman's rank correlation test.

Indeed, SARS-CoV RNA was detected using real-time RT-PCR on oral swabs, and/or virus was recovered from lung tissue in both control animals and 5 of 6 animals (83%) in the low-dose group. Only 2 of 6 animals (33%) in the high-dose group were viral RNA^+ (Figure 2C and Supplemental Table 1), suggesting reduced viral production by high-dose S-IgG.

Consistent with the findings in the control ADC-MVA–vaccinated group, histopathological examination of the lungs indicated minor and moderate inflammation at day 2 and 21 in C-IgG recipients, respectively. In contrast, all S-IgG recipients exhibited symptoms of acute DAD with various degrees of exudation, hyaline membrane formation, and hemorrhage and inflammatory cells within alveolus at both day 2 and 21 (Figure 2, D and E, and Supplemental Table 2). Of note, despite the presence of high titer sera NAbs during the chronic stage of infection (Figure 1B and Figure 2B), only 1 of 5 C-IgG and control

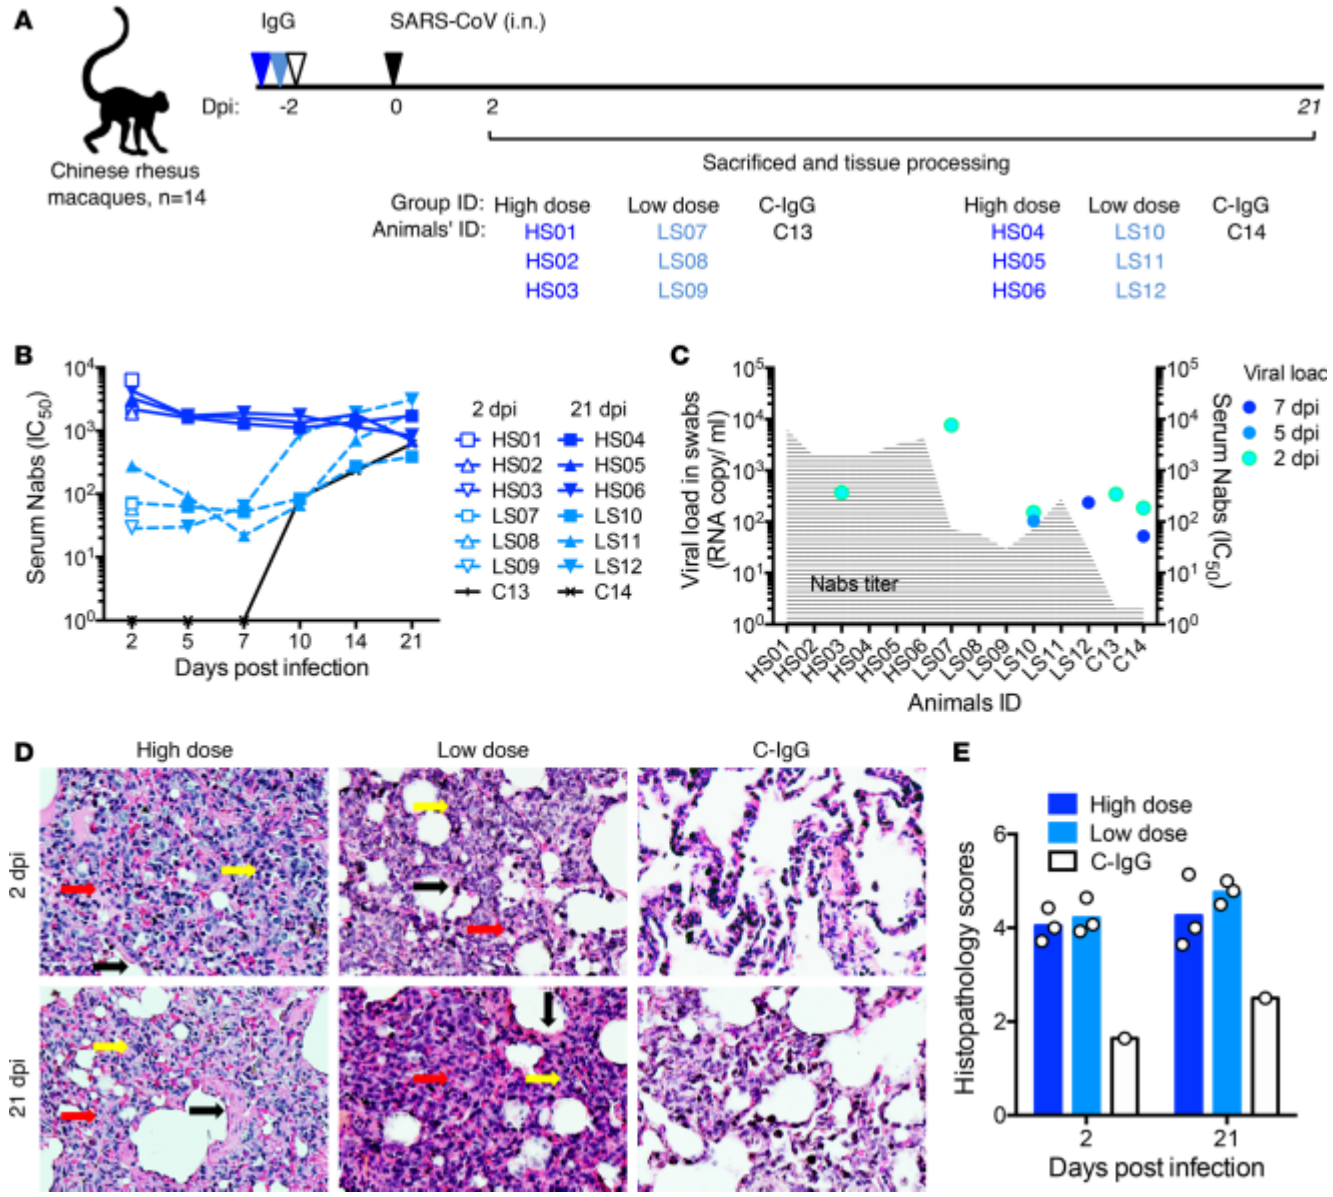

Figure 2. Anti-spike antibodies induced ALI in SARS-CoV–infected Chinese rhesus macaques. (**A**) Experimental design used to investigate the influence of S-IgG on SARS-CoV–induced lung injury. Two groups of Chinese rhesus macaques (*n* = 6/group) were subjected to i.v. injection of high-dose (200 mg) or low-dose (5 mg) purified S-IgG from ADS-MVA–vaccinated but unchallenged macaques. As controls, another 2 macaques were administered 200 mg of C-IgG derived from ADC-MVA–vaccinated macaques. After 2 days, 3 groups of macaques were challenged i.n. with SARS-CoV (10^6 $TCID_{50}$). Half of the animals from each group were sacrificed at 2 and 21 dpi. Sera (**B**) from macaques at the indicated time points were tested for the capacity to neutralize SARS-CoV pseudotype virus. (**C**) Detection of viral RNA in oral swabs. SARS-CoV RNA was detected by nested RT-PCR in the swabs from one of the high-dose S-IgG–treated macaques (*n* = 6), 3 low-dose S-IgG–treated macaques (*n* = 6), and 2 C-IgG–treated macaques (*n* = 2) at the indicated time points. Left *y* axis shows the viral RNA copy number per milliliter swab. Right *y* axis shows the serum NAb titers of each macaque at 2 dpi, which are highlighted by shaded area. (**D**) Pathology changes of the lung tissue (200×). Sections from macaques were stained with H&E. Images show symptom of acute DAD exhibited in macaques received high-dose and low-dose S-IgG (*n* = 2) with extensive exudation (red arrows), hyaline membranes (black arrows), and massive cell infiltration (yellow arrows) at 2 and 21 dpi. Right panel shows minor and moderate inflammation in the macaques received C-IgG with slight alveolar septa broadening and sparse monocyte infiltration at 2 and 21 dpi. (**E**) Histological scores of the high-dose and low-dose S-IgG groups, including lung samples collected at both 2 and 21 dpi, were compared against the C-IgG group. See Supplemental Figure 1 for the scoring index based on severity of lung histopathology.

ADC-MVA vaccine recipients showed acute DAD (Figure 1E and Figure 2E), indicating a time-restricted role for S-IgG, which mostly causes severe ALI in acutely infected macaques. Therefore, we conclude that, despite viral suppression, the presence of S-IgG at the acute stage of SARS-CoV infection caused severe ALI that persists until late stages.

S-IgG failed to prevent SARS-CoV lower respiratory tract infection and amplified IMM infiltration and accumulation in the lungs. To determine the potential cause of S-IgG–enhanced ALI, we measured viral infection and monocytes/macrophages infiltration in the lungs and serum cytokine profile at 2 dpi. We previously found that pulmonary infection of Chinese macaques could be rapidly controlled. Viral RNA$^+$ cells were detectable in the lungs of only 2 of 4 animals at 2 dpi, although all of them were viral nucleoprotein-positive (NP$^+$) in the lungs and the hilar lymph nodes (LNs), where the lymphatics of the lungs drain (25). Therefore, we measured viral RNA$^+$ cells by in situ hybridization (ISH), as well as NP signals in the lungs and the hilar LNs by IHC staining to evaluate the actual pulmonary infection of each macaque. Consistent with the results by viral isolation (Supplemental Table 1), viral RNA was detected in pneumocytes of 1 macaque in the high-dose (HS02, 33%), 2 macaques in the low-dose (LS01, LS02; 66%), and the C-IgG–treated macaque (Figure 3A and Supplemental Table 3), suggesting reduced productive infection by S-IgG. However, an NP antibody identified positive signals in the lungs and hilar LNs of all S-IgG and C-IgG recipients (7 of 7 macaques) but not healthy controls (Figure 3B and Supplemental Table 3), suggesting that S-IgG failed to prevent SARS-CoV entry, and SARS-CoV established lower respiratory tract infection in all of the challenged animals.

Consistent with previous findings in SARS-CoV–inoculated naive Chinese macaques (n = 4) (25), double-immunostaining with the NP antibody and antibodies specific to the stages of macrophage differentiation and inflammation (MAC387, CD68, CD163) revealed significant infiltration of IMMs in the lungs of C-IgG recipients, consisting of newly infiltrated (MAC387$^+$) and inflammatory (CD163$^+$) monocytes/macrophages (Figure 3C and Supplemental Figure 3). The CD163$^+$ cells greatly exceeded the CD68$^+$ population and typically gathered around NP$^+$ cells to form cell clusters (Figure 3C), showing an association between viral infection and IMM infiltration in these macaques.

Compared with C-IgG recipients, more robust signals for MAC387 and CD163 were identified in the lungs of S-IgG recipients (Figure 3C and Supplemental Figure 3), suggesting enhanced IMM infiltration by S-IgG. MAC387$^+$ and CD163$^+$ monocytes/macrophages not only gathered around NP$^+$ cells, but also formed clusters in tissues with little NP signal (Figure 3C), suggesting that infection-induced recruitment from circulation continued after viral clearance and accumulated at the inflamed site. Moreover, more-concentrated CD68$^+$ signals were found, indicating altered macrophages functional response by S-IgG treatment (Figure 3C). Consistently, elevated serum levels of IL-8 were observed in macaques treated with high-dose S-IgG at 2 dpi (Supplemental Figure 3), and the IL-8 levels are strongly correlated with anti–SARS-CoV NAb titers (Supplemental Figure 3). IL-8 is a macrophage-derived inflammatory cytokine important in initiating ALI. These results, therefore, suggest that S-IgG likely altered macrophage functional response in the lungs during acute infection, resulted in increase in IL-8 production, and enhanced ALI and IMM infiltration and accumulation.

Alveolar monocytes/macrophages assumed wound-healing function as early as 2 dpi in macaques not treated with S-IgG. Macrophage activation is dynamic and plastic. Different monocyte/macrophage activation statues have different specialized and critically timed roles, taking part in either the initiation and maintenance or resolution of inflammation (9). A well-organized wound-healing response leads to timely resolution of inflammation, whereas disturbance in wound-healing response results in persistent inflammation and injury. To understand the S-IgG–caused excessive inflammation, we further defined macrophage heterogeneity and activation statues in the lung lesions of C-IgG (n = 1) and S-IgG recipients (n = 3) at 2 dpi. Three healthy macaques and 4 naive Chinese macaques challenged with the same dose of SARS-CoV$_{PUMC}$ and scarified at 2 dpi from a previous study were included as controls (25).

By combining 5 macrophages markers (MAC387, CD68, CD163, HAM56, and CD206) (28–30), 2 subpopulations of resident macrophages were shown in the lungs of Chinese rhesus macaques at steady state as previously described (29). They are interstitial macrophages (IMs; MAC387$^+$HAM56$^-$CD206$^-$) (Figure 4A) and resident alveolar macrophages (AMs; CD68$^+$ HAM56$^-$) expressing low levels of CD163 and CD206, a marker specific to the macrophage wound-healing response, corresponding to their intrinsic antiinflammatory function (Figure 4B) (29). In lung lesions of both C-IgG–treated and naive macaque groups challenged with SARS-CoV$_{PUMC}$, IMMs were further characterized and divided into 2 subpopulations. One subpopulation was the recently recruited MAC387$^+$HAM56$^-$CD68$^-$ monocytes (Figure 4C) (29), which is like IM but is larger in size and primarily coexpressed CD163 (Supplemental Figure 4). The other subpopulation was single CD163$^+$ inflammatory macrophages that had differentiated from newly recruited MAC387$^+$ monocytes/macrophages (Figure 4D and Supplemental Figure 4) (29). Importantly, resident

AMs (CD68$^+$) differentiated into HAM56$^+$ cells, with a slight increase in numbers and increased size, with stronger CD163 and — more importantly — CD206 staining, suggesting that they are alternatively activated (Figure 4D). Strikingly, elevated levels of TGF-β expression were detected in all MAC387$^+$ — and most enlarged CD163$^+$ — as well as CD68$^+$ macrophages in the lungs of both C-IgG–treated and unvaccinated macaques compared with healthy controls (Figure 4, G–I), indicating that many IMMs and activated resident AMs have assumed a wound-healing function in infected lungs within 2 days of infection.

S-IgG treatment skewed wound-healing macrophage response in the lungs during acute SARS-CoV infection. Compared with the macaques not treated with S-IgG, the number of IMMs (MAC387$^+$ and CD163$^+$HAM56$^-$) significantly increased in S-IgG recipients (Figure 4, E and F). Moreover, many recently recruited MAC387$^+$HAM56$^-$ monocytes/macrophages did not coexpress CD163 (Supplemental Figure 4), representing the newest recruited blood monocytes, as a result of enhanced monocytes infiltration by S-IgG. Importantly, the majority of CD163$^+$HAM56$^-$ IMMs coexpressed CD68 (Supplemental Figure 4), suggesting a change of function of this subpopulation by S-IgG. Moreover, resident macrophages (CD68$^+$HAM56$^+$) in the lungs of S-IgG recipients no longer express CD206, which — being surrounded by many CD163$^+$ IMMs (Figure 4F) — suggests a loss of wound-healing function and a role in recruiting blood monocytes. Consistently, S-IgG–treated macaques displayed a loss of TGF-β and high expression of IL-6 in all macrophage subpopulations (Figure 4, G, H, and J). IL-6 favors macrophage accumulation at the site of injury and is important for the development of persistent inflammation and ALI (31, 32). Therefore, we conclude that, while AMs underwent phenotypic and functional changes in acutely infected lungs, many monocytes/macrophages assumed a wound-healing function for inflammation resolution, but the presence of S-IgG skewed the wound-healing response, leading to uncontrolled inflammation and tissue injury.

Onset of an antibody response prior to viral clearance is associated with abrogated wound-healing responses and increased IMM lung infiltration in unvaccinated Chinese rhesus macaques. To understand the mechanism underlying the time-restricted role of S-IgG in promoting ALI, we conducted a temporal analysis of the productive viral infection, antibody response, and macrophage functional changes in unvaccinated Chinese macaques during the first week of infection. Naive macaques were challenged i.n. with 1×10^6 $TCID_{50}$ $SARS\text{-}CoV_{PUMC}$ and sacrificed at 2, 3, and 7 dpi (4 macaques/group) (Figure 5A) (25). Successful lower respiratory tract infection was confirmed by detection of viral NP using IHC staining in the lungs of all macaques (25). Viral RNA$^+$ alveolar pneumocytes were primarily found at 2 dpi (2 of 4 macaques), and infrequently at 3 dpi (0 of 4 macaques; Figure 5B and Supplemental Table 4) (25). At 7 dpi, viral RNA was detectable in the lungs of 2 macaques, AD0516 and AD0518, suggesting productive infection there (Figure 5, B and C). Only few scattered NP$^+$ cells were found in AD0517 (Figure 5D). Neither NP nor viral RNA was found in the lungs or swabs of AD0515, suggesting clearance of productive viral pulmonary infection in this macaque (Figure 5D and Supplemental Table 4). Serum NAb was not observed at 2 and 3 dpi until 7 dpi in 2 of 4 macaques, AD0515 and AD0516 (Supplemental Table 4 and Figure 5E).

In agreement with the findings in the C-IgG group, temporal analysis of macrophage heterogeneity revealed significantly increased number of IMMs (CD163$^+$CD206$^-$) in viral RNA$^+$ lungs at 2 dpi (Figure 5F, right image). The IMMs diminished at 3 dpi (4 of 4 macaques) (Figure 5G) and became nearly completely absent at 7 dpi in macaques without productive pulmonary viral infection (2 of 4 macaques, AD0515 and AD0517) (Figure 5H), indicating that inflammatory response resolved with 7 days following the control of productive infection. Critically, wound-healing macrophages (CD163$^+$CD206$^+$ and CD163$^+$TGF-β$^+$) were observed in the lungs of all macaques at 2 dpi, despite productive pulmonary viral infection in macaques AD0506 and AD0508 (Figure 5F). In contrast, macaque AD0516, with serum NAbs and productive virus infection in the lungs, displayed a significantly enhanced proinflammatory macrophage response and reduced inflammatory-resolving macrophages (Figure 5I), which was not observed in macaques with productive viral infection but undetectable NAb responses (AD0518) or in macaques with detectable NAbs but undetectable viral replication (AD0515) (Figure 5D and Supplemental Table 4). Therefore, persistent viral replication and concomitant NAb detection is associated with increased IMM lung infiltration and reduced wound-healing macrophage numbers.

S-IgG modifies functional response of alternatively but not classically activated macrophages to SARS-CoV infection. To determine whether S-IgG skews wound-healing response through modifying wound-healing macrophage functional response during SARS-CoV infection, we treated in vitro–polarized alternatively activated human monocyte–derived macrophages (MDM) for 20 hours with SARS-CoV pseudovirus and heat-inactivated sera of high-dose S-IgG–treated macaques (S-IgG sera) collected at 2 dpi. We

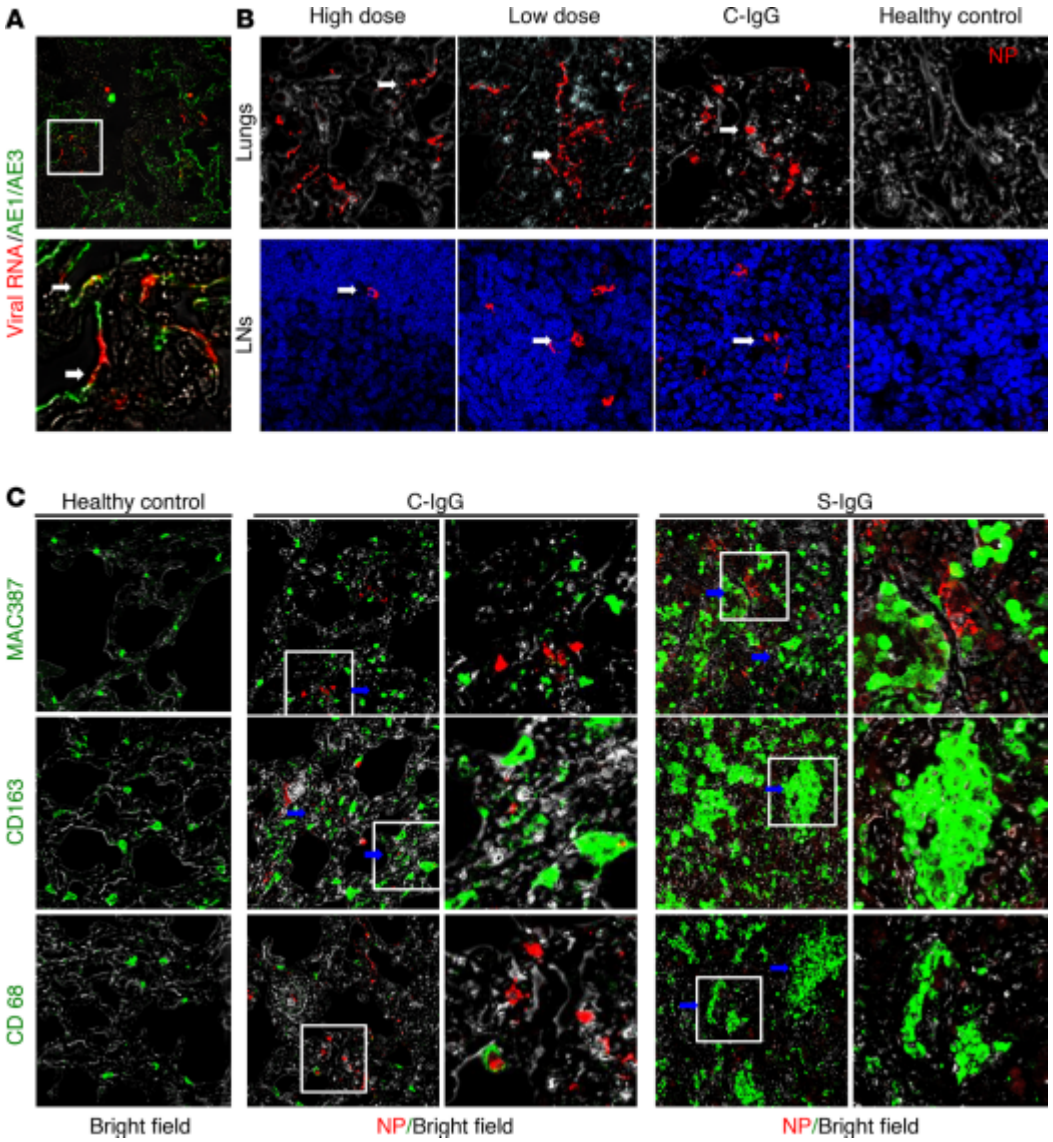

Figure 3. SARS-CoV infection and monocytes/macrophages infiltration in the lungs of C-IgG– and S-IgG–treated macaques at 2 dpi. (**A**) Represen images of SARS-CoV RNA (TRITC) and AE1/AE3 (FITC) cells in the lungs of infected macaques (white arrows). The upper photo shows a low magnification overview (200×); the bottom photo shows the boxed area in the upper photo. (**B**) Representative images of viral protein (NP) immunostaining of the lungs and hilar lymph nodes (LN) of 7 infected and 3 uninfected animals (TRITC, white arrows) (original magnification, 200×). (**C**) Representative images of viral NP and monocytes/macrophages. These sections showed significantly increased IMMs in the lungs of the S-IgG group compared with the C-IgG group (MAC387, CD163, or CD68, blue arrows). Tissue samples are double-immunostained for the SARS-CoV NP (TRITC) and markers for macrophages, including MAC387 (FITC), CD163 (FITC), and CD68 (FITC). Within the panel of representative images for the C-IgG and S-IgG groups, the left panel shows low magnification overview; the right panel shows the boxed area in the left panel (original magnification, 200×).

then measured the concentrations of 13 inflammatory cytokines in cell culture supernatants, including IL-1β, IFN-α, IFN-γ, TNF-α, MCP1, IL-6, IL-8, IL-10, IL-12p70, IL-17A, IL-18, IL-23, and IL-33. Sera from C-IgG recipients or healthy macaques were included as controls. In vitro–polarized classically activated MDM was also studied and compared with alternatively activated MDM in parallel. Consistent with previous report, unstimulated classically activated MDM produced high levels of IL-8 and IL-6; alternatively activated MDM only produced minimal levels of those cytokines (Figure 6A). Addition of SARS-CoV pseudovirus induced IL-8 production in alternatively activated MDM to levels comparable with those found in unstimulated, classically activated MDM, as well as in low-level MCP1 and IL-6 production (Figure 6B). By contrast, SARS-CoV pseudovirus caused less than a 1-fold increase in IL-8 secretion, but not other cytokine secretion, by classically activated MDM (Figure 6C). Strikingly, while none of the sera samples induced cytokine production when they were administered into MDMs alone,

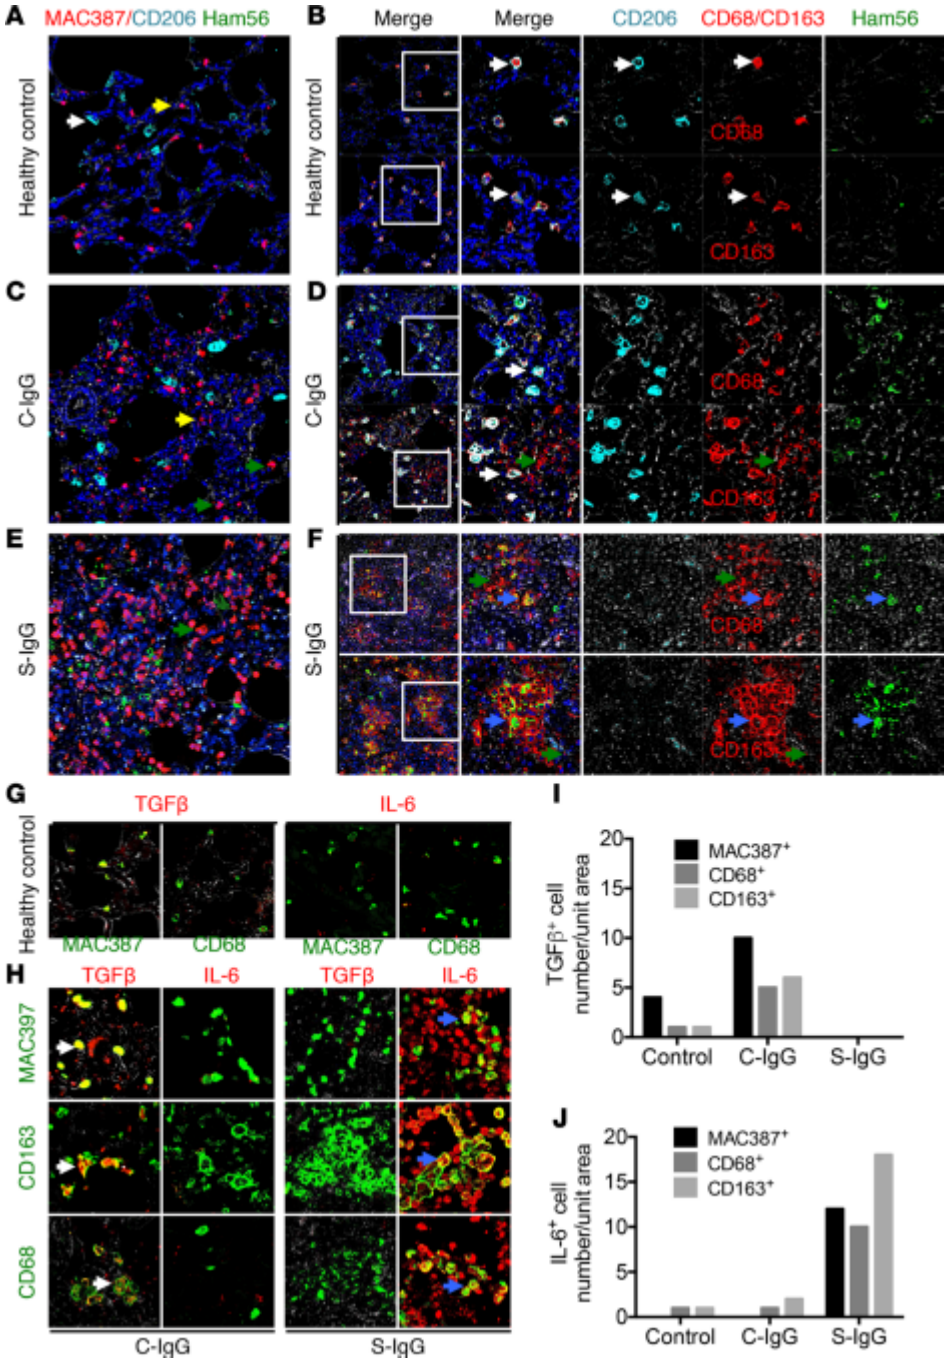

Figure 4. Comparison of monocyte/macrophage phenotype and function in the lungs of S-IgG– and C-IgG–treated macaques. (**A**–**F**) Phenotype of monocytes/macrophages subpopulations in the lungs of healthy, C-IgG–, and S-IgG–treated macaques (original magnification, 200×). These sections were triple-immunostained with antibodies for CD206 (cyan), HAM56 (FITC), and MAC387 (TRITC) (**A**, **C**, and **E**); CD206 (cyan), HAM56 (FITC), and CD68 (TRITC) (upper panel, **B**, **D**, and **F**); or CD163 (TRITC) (lower panel, **B**, **D**, and **F**). **A** and **B** show 2 subpopulations at steady states, including interstitial macrophages (IM) (MAC387$^+$HAM56$^-$CD206$^+$) (yellow arrow), and resident alveolar macrophages (AM) (CD163$^+$CD206$^+$HAM56$^-$) (white arrows). **C** and **D** show the presence of alternatively activated resident AM and accumulated IMMs in the C-IgG group. Alternatively activated AMs are CD206$^+$CD68$^+$CD163$^+$HAM56$^-$ (**D**, white arrows). IM are MAC387$^+$HAM56$^-$CD206$^+$ (**C**, yellow arrow). IMMs include newly infiltrating monocytes/macrophages (MAC387$^+$) (**C**, green arrow); and inflammatory macrophages (CD68$^+$CD206$^-$HAM56$^-$) (**D**, green arrow). **E** and **F** show significantly increased number of IMMs and decreased number of alternatively activated macrophages in the S-IgG group. IMMs include newly infiltrating monocytes/macrophages (MAC387$^+$) (**E**, green arrow) and inflammatory macrophages that are CD68$^+$HAM56$^-$ (green arrow, **F**, upper panel) and CD163$^+$CD206$^+$HAM56$^-$ (green arrow, **F**, lower panel). Resident AMs are no longer expressing CD206$^+$ (CD68$^+$CD163$^+$CD206$^-$) (blue arrow, **F**, upper panel). (**G**–**J**) TGF-β and IL-6 expression in macrophages in the lungs. These sections were double-immunostained with antibodies for TGF-β (TRITC) and MAC387, CD163, or CD68 (FITC). (**G**) shows low expression levels of TGF-β and IL-6 in IMs (MAC387$^+$) and AMs (CD68$^+$) in healthy macaques. **H** shows increased TGF-β expression in the C-IgG group (white arrows) but increased IL-6 in the S-IgG group (blue arrows). (**I** and **J**) show the numbers of TGF-β$^+$ and IL-6$^+$ monocytes/macrophages in 3 groups in a 200× field.

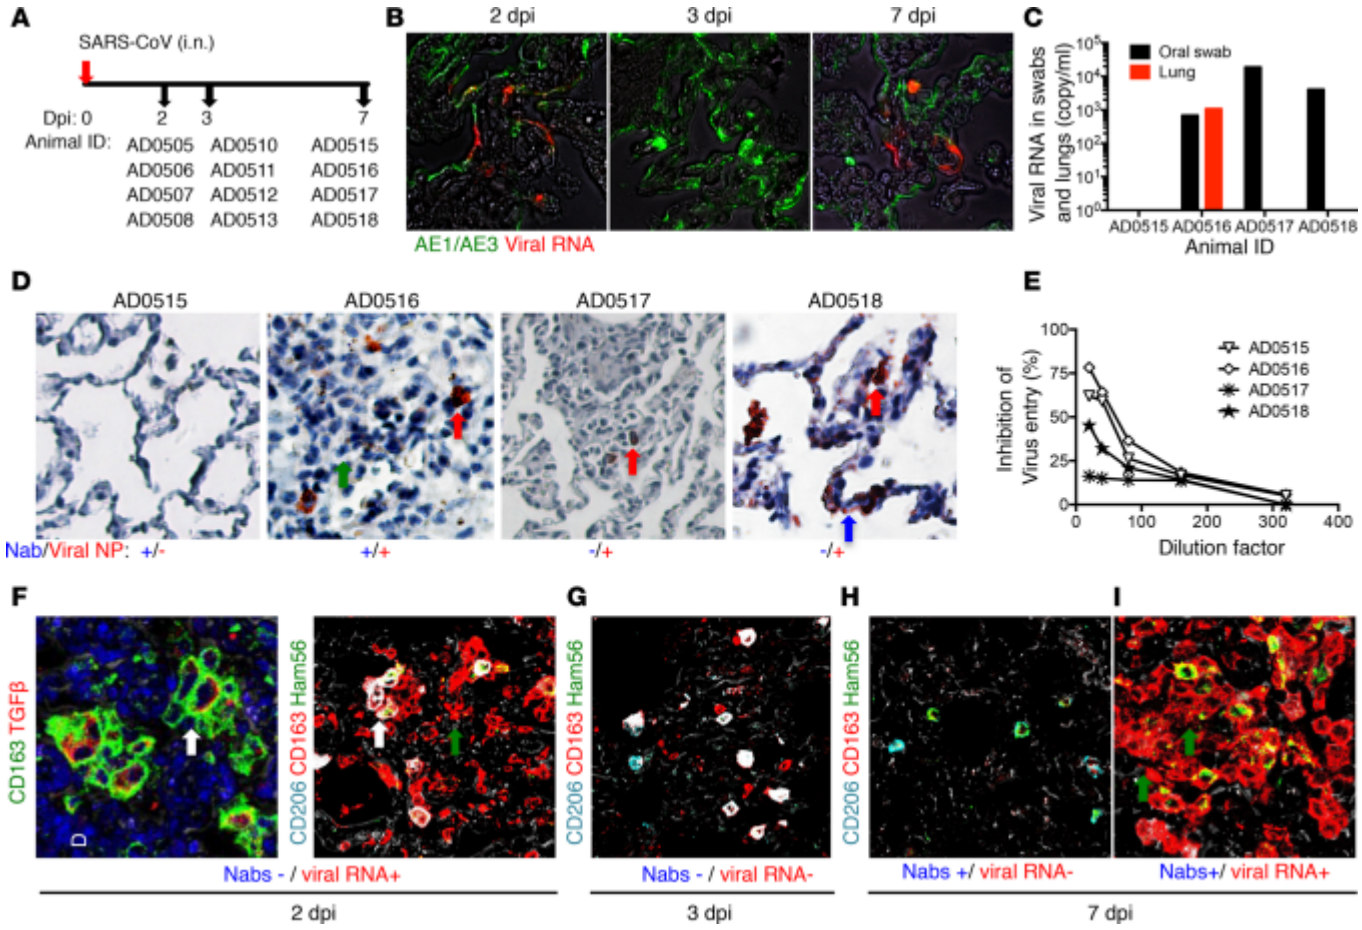

Figure 5. Dynamics of the viral replication, antibody response, and macrophage activation during acute SARS-CoV infection. (**A**) Experimental scheme. A total of 12 Chinese rhesus macaques were challenged i.n. with SARS-CoV ($\times 10^{5}$ $TCID_{50}$). Four animals each were sacrificed at 2, 3, and 7 dpi. (**B**) SARS-CoV RNA detection by ISH in the lungs at 2, 3, and 7 dpi (original magnification, 200 ×). Viral RNA in type I pneumocytes (FITC) was found at 2 dpi ($n = 2$) and 7 dpi ($n = 1$). (**C**) Viral RNA in the swabs and lung homogenates on 7 dpi. SARS-CoV RNA was detected using nested RT-PCR in swabs from 3 macaques (AD0516, AD0517, and AD0518) and lung homogenates from macaque AD0516 and AD0518. (**D**) Viral antigen and inflammatory infiltrates in the lungs at 7 dpi (200×). These sections were stained for SARS-CoV NP (red) and nucleus (blue) by IHC, showing NP signal in macrophage-like cells in AD0516 and AD0517 (red arrows), and type I pneumocytes in AD0518 (blue arrows), but substantial inflammatory infiltrates were only observed in AD0516 (green arrows). (**E**) Serum neutralizing activity. Serum neutralizing activity was detected in macaques AD0515 and AD0516 at 7 dpi. (**F**–**I**) Decreased wound-healing response in macaques with productive pulmonary viral infection and serum neutralizing activity (200×). These sections were double-immunostained for TGF-β (TRITC) and CD163 (FITC) or triple stained for CD206 (cyan), HAM56 (FITC), and CD163 (TRITC). The figure shows that wound-healing response took place within 2 dpi, with alternatively activated monocytes/macrophages (TGF-β+ CD206+ white arrows) and IMMs (CD163+ CD206+ green arrows) coexisting in the lungs (**F**). After viral clearance, IMMs diminish at 3 dpi (**G**), and the homeostasis was restored at 7 dpi (AD0515) (**H**). When pulmonary viral infection persists, IMM (CD163+ CD206+ green arrows) infiltration and accumulation is enhanced, and wound-healing macrophages (CD206+) are reduced in macaques that have faster NAb response (AD0516) (**I**).

administration of S-IgG sera caused a dose-dependent increase in the production of all 3 inflammatory cytokines in SARS-CoV–stimulated alternatively activated MDM, resulted in a greater than 10-fold increase in IL-6, an 8-fold increase in MCP1, and a 5-fold increase in IL-8 (Figure 6, D and E). This enhancement, however, was not observed when S-IgG sera were replaced with sera from C-IgG recipients or healthy macaques (Figure 6, F, G, and H), suggesting that S-IgG, but not other sera components, enhanced SARS-CoV–stimulated cytokine production by alternatively activated MDM. Administration of S-IgG sera had no effect on cytokine production by SARS-CoV–treated classically activated MDM (Figure 6, I, J, and K), indicating that S-IgG do not modulate virus-mediated classically activated macrophage functional response. MCP1 and IL-8 are key cytokines that regulate monocytes/macrophages migration and promote neutrophils infiltration, while IL-6 promotes persistent inflammation and injury. These results suggest that, in response to SARS-CoV infection, wound-healing macrophages produce IL-8 and low amounts of MCP1 to recruit neutrophils and blood monocytes, whereas the presence

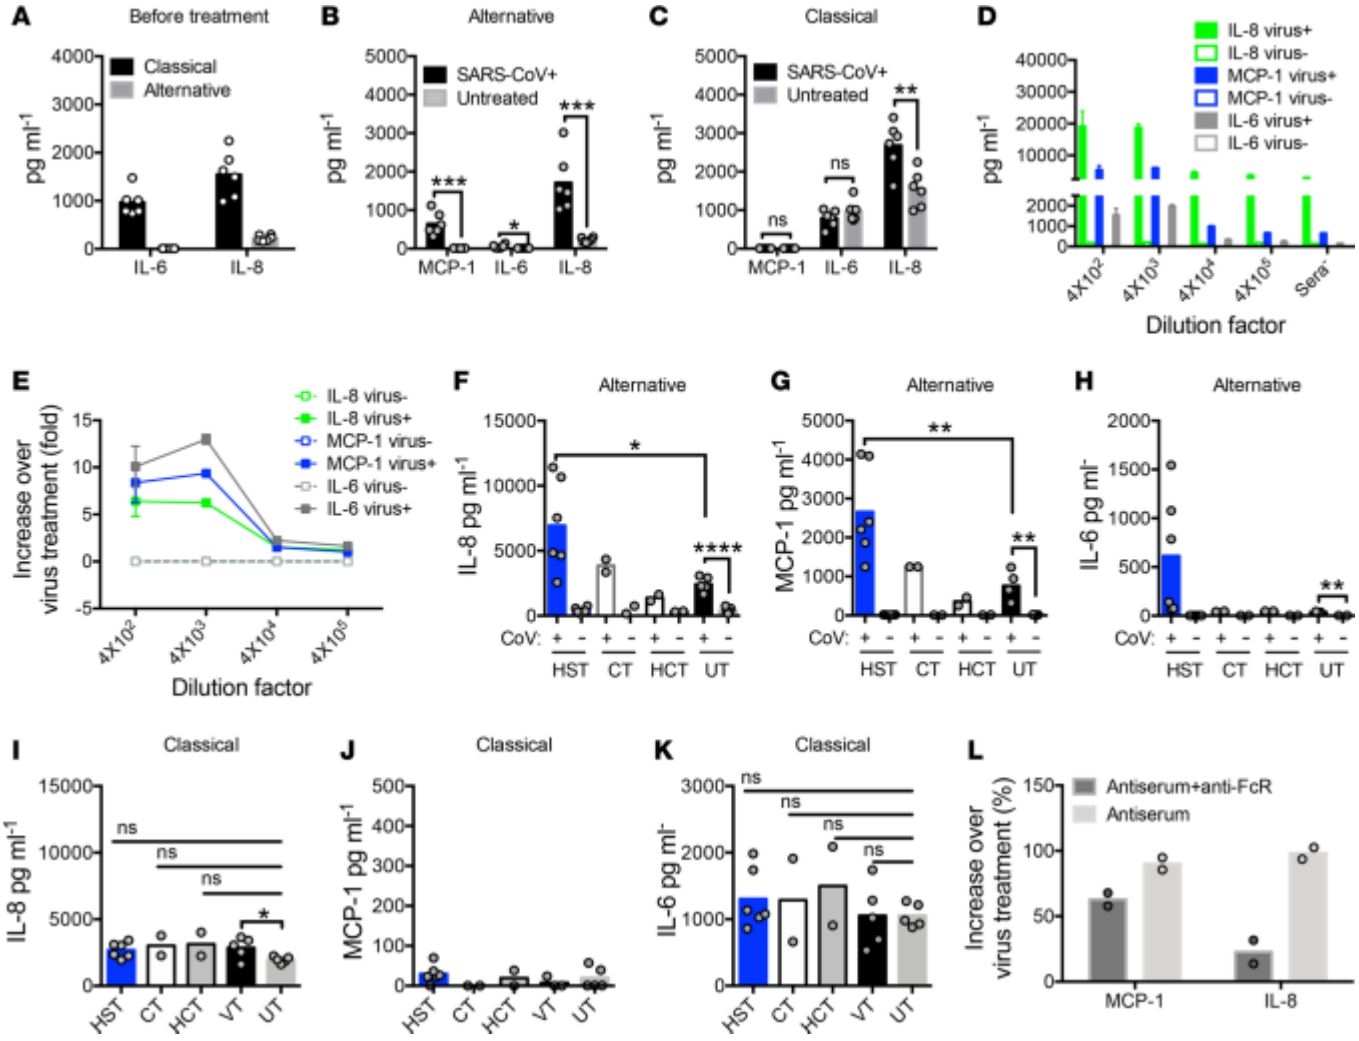

Figure 6. S-IgG significantly amplified proinflammatory cytokine production by SARS-CoV–treated alternatively activated macrophages. In vit polarized alternatively activated macrophages were either left unstimulated or were incubated with SARS-CoV pseudovirus alone or cocultured with SARS-CoV pseudovirus and diluted sera from the high-dose S-IgG group (n = 6) or C-IgG group (n = 2) collected at 2 dpi or from healthy macaques (n = 2) for 20 hours. Secreted cytokine and chemokine levels were measured in the culture supernatant and are shown in data represented as a column graph (**A–D** and **F–K**) and fold or percentage over supernatants from macrophages treated with virus alone and (**E**). **A** shows the levels of IL-8 and IL-6 in the supernatant of classically activated and alternatively activated MDM before treatment and **B** and **C** show that SARS-CoV treatment induced MCP1, IL-8, and very low levels of IL-6 production by alternatively activated MDM, as well as enhanced IL-8 production by classically activated MDM. **D** and **E** show that sera from S-IgG recipients caused dose-dependent increase in cytokine production from SARS-CoV–treated alternatively activat ed MDM. **F–H** show that virus treated alternatively activated MDM (VT), but not sera treated or untreated cells (UT), secreted proinflammatory cytokines IL-8 (**F**), MCP1 (**G**), and very low levels of IL-6 (**H**). Addition of sera (1:4,000 dilutions) from high-dose S-IgG (HST), but not C-IgG treated macaques (CT) or healthy controls (HCT), significantly amplified IL-8 (**F**), MCP1 (**G**), and IL-6 (**H**) production. **I–K** show that addition of sera (1:4,000 diluted) from high-dose S-IgG–treated (HST), C-IgG treated macaques (CT), or healthy controls (HCT) had no effect on MCP-1 (**J**), and IL-6 (**K**) production by SARS-CoV–treated classically activated MDM. **L** shows that blockade of FcγR significantly reduced antiserum-enhanced IL-8 secretion and partially reduced MCP1 secretion. Data represent mean values or mean values ± SEM of at least 3 independent experiments. Two-tailed unpaired Student's t test was used for statistical analysis. *P < 0.05; **P < 0.01; ***P < 0.001; ****P < 0.0001.

of S-IgG can result in 5- to 10-fold increases in IL-8, MCP1, and IL-6 production by wound-healing macrophages, leading to significantly enhanced and persistent monocytes infiltration and tissue injury. Critically, in the presence of Fcγ receptor (FcγR) blocking antibody, IL-8 was significantly reduced when cells were treated with SARS-CoV pseudovirus and sera from high-dose S-IgG–treated macaques (diluted 1:4,000), indicating that anti–SARS-CoV antibody modifies wound-healing response partially through FcγRs (Figure 6L). Therefore, we conclude that S-IgG directly modifies functional response of alternatively activated macrophages during acute infection, thus skewing wound-healing response, leading to hypercytokinemia, aggressive inflammation and severe lung injury.

Deceased SARS patients displayed higher levels of serum NAbs, accumulated proinflammatory macrophage infiltration, and absence of wound-healing macrophages in the lungs. To examine the role of S-IgG in promoting ALI in a clinical setting, we investigated antibody responses during the early stage of infection in 2 groups of deceased patients or individuals recovered from SARS and characterized the heterogeneity of monocytes/macrophages in the lungs of 3 deceased SARS patients. H&E staining of lung specimens derived from 3 deceased SARS patients revealed severe ALI (Figure 7A). Consistent with the macaque findings, IHC analysis revealed significant infiltration of $CD163^+$ monocytes/macrophages into the lungs of patients, with little TGF-β expression and loss of the wound-healing marker $CD206^+$, indicating predominantly proinflammatory macrophage activation and reduced inflammatory-resolving response (Figure 7B). Moreover, significantly higher levels of anti-S NAbs were detected in the sera of deceased patients (n = 6) during acute infection compared with recovered patients (n = 8) (Figure 7C). These results, therefore, are consistent with findings in experimental macaques.

Antisera from deceased SARS patients skewed wound-healing response during SARS-CoV infection partially through the FcγR. To examine whether human anti–SARS-CoV antibody modifies wound-healing response during SARS-CoV infection, we treated in vitro–polarized alternatively activated MDM with SARS-CoV pseudovirus for 20 hours in the presence of sera collected from SARS patients during acute infection. Macrophages treated with SARS-CoV pseudovirus or sera alone were included as controls. We then examined the protein levels of cytokines/chemokines in the cell culture supernatant. Consistent with findings in macaques, administration of sera from a deceased SARS patient (D1; Supplemental Table 5) into SARS-CoV–treated alternatively activated MDM caused a dose-dependent increase in the production of cytokines, leading to a 2- to 3-fold increase in MCP1 and IL-8 after 20 hours (Figure 8, A and B). This enhancement, however, was not observed in cells treated with sera alone (Figure 8, A–D). Administration of sera from recovered patients (n = 8; Supplemental Table 5) had no effect on cytokine production except 1 sample (Figure 8, C and D). These differences may be explained, at least in part, by their lower NAb titers, although it is also possible that sera from recovered patients contain different antibody populations. Consistently, the only serum sample — R2, which enhanced chemokine production — has a relatively higher NAb titer among the samples tested (Supplemental Table 5). Moreover, statistical analysis shows that IL-8 production strongly correlates with NAb titer of sera from deceased patients (Figure 8E). Furthermore, IL-8 production was significantly reduced when cells were treated with SARS-CoV pseudovirus and sera from deceased SARS patient (diluted 1:4,000) in the presence of FcγR blocking antibody, indicating that anti–SARS-CoV antibody modifies wound-healing response in humans partially through FcγRs (Figure 8F).

Discussion

Here, we present evidence of a detrimental role of anti–S-IgG in ALI during SARS-CoV infection. Respiratory CoVs infection poses a unique challenge to the immune system: not only must the virus be rapidly eliminated, but lung inflammation must also be controlled to prevent acute respiratory failure (33). In the present study, we show that, despite markedly reducing virus titers, anti–S-IgG caused lung injury during the early stages of infection by abrogating a wound-healing macrophage response and TGF-β production, while promoting proinflammatory cytokine IL-8 and MCP1 production and inflammatory macrophage accumulation. To our knowledge, our data demonstrate a previously unrecognized mechanism underlying virus-mediated ALI and suggest that modulation of the anti-S antibody response or blockage of Fcγ receptors during acute infection might be needed for effective treatment for respiratory CoV infection.

Many studies have demonstrated the role of NAbs induced by the S glycoproteins in protecting viral replication in susceptible hosts, including mice, ferrets, hamsters, and macaques (24, 34, 35). However, the effect of S-specific immunity in protecting against pulmonary immunopathology has been controversial. In some cases, vaccination-induced immunity assists the viral clearance and protects mice or ferrets against lethal challenge (36–39), whereas in many other situations, multiple vaccine platforms appear to induce increased eosinophilic proinflammatory pulmonary response upon challenge (18, 23, 40). These differences may be explained, in part, by the characteristics of the vaccine being studied, the infectious dose, and the viral strain employed, as well as by the type or quality of immune response elicited. Recent studies suggest that $CD8^+$ T cell response plays a crucial role in viral clearance and protection of mice against eosinophilic immunopathology and lethal SARS-CoV infection, whereas immunopathology predominantly reflects an inadequate vaccine-induced Th1 response (20–23).

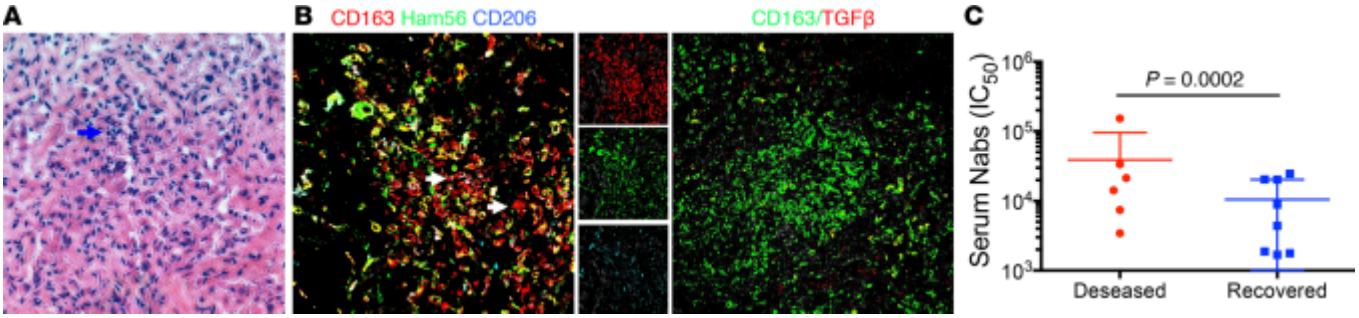

Figure 7. NAb response and phenotype analysis of accumulating monocytes/macrophages in the lungs in deceased SARS patients. (**A**) Pathological changes of the lung tissue. Sections from deceased SARS patients were stained with H&E and are representative of 3 patients (original magnification, 100×), showing symptom of acute DAD with massive cell infiltration in alveolar cavities (blue arrow). (**B**) Massive accumulation of IMMs and absence of wound-healing macrophage response in the lungs of deceased patients. These sections were triple-immunostained with antibodies for CD206 (cyan), HAM56 (FITC), and CD163 (TRITC) or double-immunostained with TGF-β (FITC) and CD163 (FITC) (original magnification, 200×). The right panel in the left image shows single colors from the left image (200×). These representative images show accumulation of IMMs (CD163+HAM56+, white arrows) and the absence of wound-healing response, indicated by loss of the signal for CD206 (cyan, B1) and TGF-β (TRITC, B2) in the lungs. (**C**) Serum-neutralizing activity against SARS-CoV. Sera collected from deceased ($n = 6$), or recovered (blue, $n = 8$) SARS patients at the early stage of infection were tested for the capacity to neutralize SARS-CoV pseudotype virus. Two-tailed unpaired Student's *t* test was used for statistical analysis.

In fact, a protective effect against pulmonary immunopathology mediated by full length S protein–based vaccine in SARS-CoV–infected nonhuman primate models has not been described, to our knowledge. Although several vaccine candidates protected macaques against viral replication in the lungs, pulmonary immunopathology was not evaluated in these studies (24, 41, 42). By contrast, it was shown that SARS-CoV–specific immune memory induced by prior infection enhanced lung inflammation following homologous challenge in African green monkeys (17). Similarly, augmentation of disease by vaccination has also been described in studies of atypical measles and dengue hemorrhagic fever, as well as several respiratory diseases, including respiratory syncytial virus (RSV) and pandemic influenza (16, 43). In the study of RSV vaccine conducted in 1966 and 1967, 80% of RSV vaccinees needed hospitalization, whereas only 5% of RSV-infected children in the control vaccine group required admission, although the underlying mechanisms remain incompletely understood. Using Chinese rhesus macaques, we show that an ADS-MVA–based vaccine protected macaques against viral replication but significantly enhanced acute DAD at both 7 and 35 dpi compared with the control ADC-MVA group, suggesting that S-specific but not MVA-specific immunity promotes ALI (Figure 1). Until now, it remains unknown if SARS vaccine candidates with a focus on the receptor-binding domain (RBD) of S protein can avoid the induction of ALI in nonhuman primates. These vaccines have been shown to induce highly potent NAb responses and elicit long-term protective immunity in immunized small animals (38).

SARS-CoV infection of Chinese macaques is often characterized by the rapid control of viral replication with mild lung lesions in most macaques (25). The mechanisms underlying why Chinese macaques do not often develop ALI, as observed in most SARS patients, are largely unknown. Our data suggest that these effects, in part, reflect the rapid control of viral replication in the lungs, which peaked between 24 and 48 hours after inoculation (hpi) and diminished within 7 days, thus creating an interval between lung inflammation and high titer antibody production in most macaques. Indeed, although SARS-CoV infection resulted in significant infiltration of macrophages in the lungs, the number of macrophages was rapidly reduced following virus clearance at 3 dpi (Figure 5). At 7 dpi, inflammation appeared to be mostly resolved (Figure 5). By contrast, control of virus replication is less efficient in SARS patients, and the peak in viral load coincides with the first appearance of an antibody response, approximately 10 days after the onset of symptoms (6).

The low rate of ALI and interval between lung inflammation resolution and antibody production, however, makes Chinese macaques an ideal animal model for the present study. Using vaccination and passive immunization, we conditioned anti-S antibody titers in macaques during the early stage of infection when ALI was not typically observed. We found that prior administration of anti–S-IgG led to massive accumulation of monocytes/macrophages in the lungs within 2 dpi. This result is consistent with previous reports, in which mice given the SARS vaccine exhibited an immunopathologic lung reaction after the subsequent challenge with SARS-CoV (18, 19). Moreover, in SARS patients, clinical course and outcome are more favorable in children younger than 12 years of age compared with adolescents and adults (44), indicating that prior alternative CoV infection might

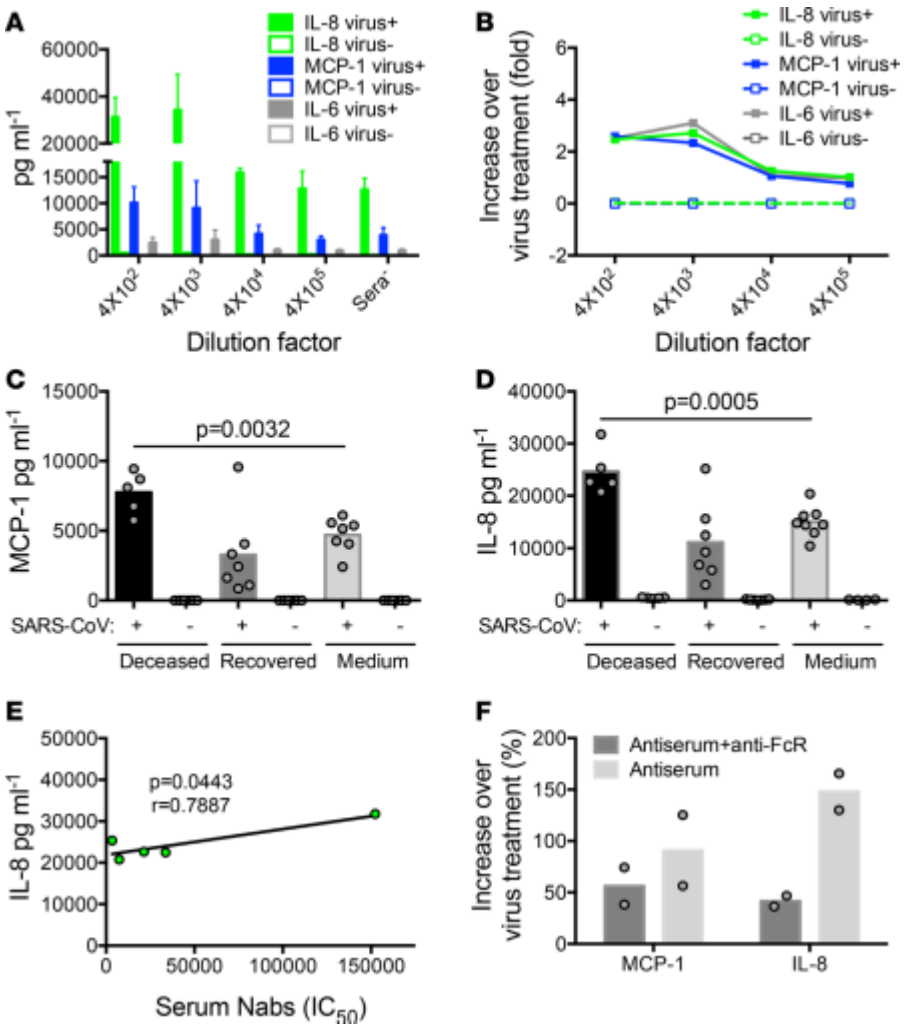

Figure 8. Sera from deceased SARS patients skewed wound-healing macrophage response partially through FcγR. In vitro–polarized alternatively activated MDM were either left unstimulated or were incubated with SARS-CoV pseudovirus alone or cocultured with SARS-CoV pseudovirus and 1–400,000 serials diluted or 1/4,000 diluted sera from deceased (n = 5) or recovered SARS patients (n = 7) for 20 hours. Cells treated with sera from patients alone served as controls. Secreted cytokine and chemokine levels were measured in the culture supernatant and are shown in data represented as a column graph (**A**, **C**, and **D**) and fold or percentage over supernatants from macrophages treated with virus alone (**B** and **F**). **A** and **B** show that addition of sera from deceased patient (D1) dose-dependently enhanced production of IL-8, IL-6, and MCP-1 by SARS-CoV–treated alternatively activated MDM. **C** and **D** show significantly enhanced IL-8 and MCP-1 production by alternatively activated macrophages treated with sera from deceased SARS patients and virus compared with cells treated with virus alone. Sera treatment alone did not induce IL-8 or MCP-1 production. (**E**) Correlation of IL-8 production with NAb titers of sera of deceased patients. Solid lines denote the relationship between histopathology scores and serum neutralizing activity. (**F**) Blockade of human FcγR significantly reduced antiserum-enhanced IL-8 secretion and partially reduced MCP-1 secretion. In vitro–polarized alternatively activated human monocyte–derived macrophages were cocultured with SARS-CoV pseudovirus and 1–4,000 diluted sera from deceased patient (D1) with or without FcγR blocking antibody for 20 hours. Secreted cytokine and chemokine levels were measured in the culture supernatant and are shown in data represented as increase over supernatants from macrophages treated with virus alone. Data represent mean values or mean values ± SEM of at least 3 independent experiments. Two-tailed unpaired Student's t test and Spearman's rank correlation test were used for statistical analysis.

play a role in driving enhanced pulmonary inflammation. A recent study reported that pathogenic immune complexes promoted lung injury during the 2009 H1N1 pandemic (16). It remains unknown whether immune complexes may also play a role in driving ALI during SARS-CoV infection.

Detailed analyses of macrophage heterogeneity at different stages of infection and in lungs with severe injury or mild lesion revealed distinct roles for proinflammatory and wound-healing macrophages in SARS disease progression. We observed that the early transition of macrophage responses from proinflammatory

to wound healing with increased TGF-β expression is associated with inflammation resolution and mild lung injury. By contrast, abrogated wound healing by S-IgG resulted in decreased TGF-β production and prolonged classical macrophage activation, and it promoted severe lung injury. Our findings are primarily based on imaging of formalin-fixed tissues of infected macaques, which may have technical limitations. A detailed flow cytometric analysis would be helpful to further characterize macrophage subpopulations in infected lungs. Unfortunately, we were not allowed to obtain any live cells, including macrophages, for analysis by flow cytometry outside the BSL-3 laboratory in China, which is in line with "WHO biosafety guidelines for handling of SARS specimens" (https://www.who.int/csr/sars/biosafety2003_04_25/en/). Having said this, TGF-β is mainly derived from wound-healing macrophages but not from classically activated macrophages. Therefore, by staining both TGF-β and CD206 (another biomarker of wound-healing macrophages), we believe that the finding of reduction of this type of macrophages in the S-IgG–treated lungs is convincing.

Patients who received convalescent plasma from recovered SARS patients had shorter hospital stays and lower mortality rates without evident adverse effects (45–47). These results might reflect a different quality of antibodies in recovered patients from deceased patients during early infection. Indeed, we previously observed that deceased patients had significantly higher NAbs with a very low level of anti-N antibodies in serum during the early stage of infection (14). In contrast, recovered patients had more rapid anti-N antibody and slower NAb development (14). Consistently, serum from deceased patients — but not SARS survivors during early stages of infection — enhanced IL-6, IL-8, and MCP1 production by wound-healing macrophages (Figure 8). We previously identified epitopes in S protein that elicited NAbs and antibodies that enhanced SARS-CoV infection (48, 49). Further studies that will attempt to identify antibodies and epitopes that mediate prevention or enhancement of ALI might be needed for future vaccine design and immunotherapy.

Lastly, blockade of FcγRs reduced proinflammatory cytokine production, suggesting a potential role of FcγRs for the postulated reprogramming of alternatively activated macrophage FcγRs are functionally divided into activating and inhibitory receptors. Activating FcγRs, such as FcγRI, FcγRIIA, and FcγRIII, triggers production of proinflammatory chemokines and cytokines through an immunoreceptor tyrosine–based activation motif (ITAM) in their intracytoplasmic domain and SRC family kinases and spleen tyrosine kinase (SYK), whereas the inhibitory FcγR, FcγRIIB, has an immunoreceptor tyrosine–based inhibition motif (ITIM) in its intracytoplasmic domain and counteracts the signals that are mediated by activating FcγRs. Based on literature and our experiments, human monocyte–derived wound-healing macrophages express higher levels of CD16 (FcγRIII) and CD32A (FcγRIIA) (50). Therefore, it is likely that S-IgG promoted proinflammatory cytokine production through FcγRI and/or FcγRIIA. S-IgG did not affect classically activated macrophage function in vitro. This difference can be possibly explained by the high baseline level of proinflammatory cytokines before infection and the downregulated expression of FcγRs on classically activated MDM by SARS-CoV treatment.

Methods

Immunization of animals. We vaccinated Chinese rhesus macaques as previously described (51). Briefly, 16 Chinese rhesus monkeys were immunized twice on days 0 and 28. Eight of these animals received ADS-MVA, whereas the other 8 animals received ADC-MVA. ADS-MVA and ADC-MVA vectors encoding SARS-CoV S protein or HCV E1E2 were constructed and produced as previously described (51). The dose for both immunizations was 5×10^8 $TCID_{50}$. The vaccine strain SARS-CoV HKU39849 (AY278491) shares 100% sequence homology of the S gene with the challenge strain $SARS\text{-}CoV_{PUMC}$ (AY350750).

Animals, tissues, and SARS-CoV infection. SARS-CoV–infected animals and control animals were all adult female Chinese rhesus macaques. A total of 42 Chinese rhesus macaques were challenged i.n. with a live pathogenic SARS-CoV (PUM, $TCID_{50}$ = 50) as previously described (25). An additional 3 uninfected macaques were inoculated with PBS as negative controls. Animals were subjected to daily measurement of anal temperature, routine blood assays, and chest radiography. Animals were euthanized at 2, 3, 7, 21, and 35 days after inoculation (Figure 1, Figure 2, and Figure 6). All animals were humanely euthanized with an i.v. overdose of pentobarbital and were immediately necropsied. Lung tissues (left and right cranial, middle and caudal lobes, and right accessory lobe) were collected and fixed in 10% neutral-buffered formalin, embedded in paraffin, and sectioned at 5 μm.

Passive transfer of IgG. SARS-CoV S protein–immune serum was generated by vaccination with ADS-MVA vectors. IgG was purified from pooled sera by protein G affinity chromatography to >95% purity. IgG was depyrogenated, concentrated to 20–30 mg protein ml^{-1}, and administered i.v. Recipients received 200 mg or 5 mg of purified IgG per kg body weight at 48 hours before the viral challenge.

Neutralization. A neutralization assay was established to determine the humoral immune responses generated by the vaccine as previously described (51). The neutralizing activity of heat-inactivated animal sera was determined using a pseudotype viral entry assay. The pseudotype virus was generated through cotransfection of 293T cells with 2 plasmids, pcDNA-Sopt9 and pNL4-3Luc_Env_Vpr_, carrying the optimized S gene and a human immunodeficiency virus type 1 backbone, respectively. The serial diluted serum samples were incubated with equal amounts of pseudotype virus at 37°C for 1 hour. The serum-virus mixtures were subsequently added into preseeded HEK 293T-ACE2 cells. After 56 hours, infected cells were lysed to measure luciferase activity.

Nested RT-PCR and isolation of SARS-CoV. Pharyngeal swab samples were collected from infected monkeys on the first day after inoculation and subsequently tested for SARS-CoV using nested RT-PCR as previously described (25). Briefly, RNA was isolated using TRIZOL (Invitrogen). RT-PCR was performed in a 50 μl reaction volume with outer primer pair (5′-GCTGCATTGGTTTGTTATATCGTTA-TGC-3′) and (5′-ATACAGAATACAT-AGATTGCTGTTATCC-3′), inner primer pair (5′-TCACTTGCTTC-CGTTGAGGTAGC-CAGCGTGGT-GGTTCATACAA-3′) and (5′-GGTTTCGGATGTTACAGC-GTCTCCCGG-CAGAAAGCTGTAAGCT-3′). All PCR products were verified by nucleotide sequencing. SARS-CoV was isolated as previously described. Briefly, pharyngeal swab samples from the infected macaques were inoculated onto Vero-E6 cells and cultured in DMEM (Thermo Fisher Scientific). Both cytopathic effect (CPE) and immunofluorescence assay (IFA) (incubation with 1:10 dilution of SARS patient serum) were used to determine the infection status of the animals.

Double and triple immunofluorescence staining on paraffin sections. The samples were deparaffinized and rehydrated. After blocking with normal goat serum for 30 minutes at room temperature, a rabbit anti–SARS-CoV nucleocapsid antibody (ss-006-0100, ENZYME) was applied at 4°C overnight, followed by an Alexa Fluor 448 conjugated goat anti–rabbit IgG antibody for 1 hour at room temperature. Additional immunofluorescence staining was subsequently performed by overnight incubation with primary antibodies, followed by the detection of signals using appropriate fluorescent secondary antibodies (MilliporeSigma) for 1 hour at room temperature.

Primary antibodies for immunofluresence staining. The following primary antibodies were used in this study: SARS-CoV NP (ss-006-0100, ENZYME); MAC387 (clone MAC387, AbD, Serotec); CD68 (clone KPI, DAKO; ab125047, Abcam); CD163 (clone EDHu1, AbD and ab183476, Abcam); HAM56 (clone HAM56, DAKO); CD206 (HPA004114, MilliporeSigma); TGF-β (sc-146, Santa Cruz Biotechnology Inc.); IL-6 (sc-1265, Santa Cruz Biotechnology Inc.); AE1/AE3 (clone AE1/AE3, DAKO).

ISH studies. ISH was developed for the detection of SARS-CoV. DNA fragments of N and S proteins from the SARS-CoV strain from Hong Kong (AY278491) were used as templates to generate RNA probes. The probes were labeled with digoxigenin (GENEWIZ Inc.). After deparaffinization and rehydration, the sections were treated with microwave heating in an 800 W domestic microwave oven (NN-ST556M, Panasonic) at medium power for 10 minutes in 0.01 M sodium citrate buffer. Hybridization was performed at high stringency with 150 ng/ml of denatured probe at 45°C for 16 hours in 50 μl of hybridization mix (50% formamide, 10% dextran sulfate in 2× saline sodium citrate [SSC]) in a moist chamber. Excess probe was removed by washing twice in 2× SSC for 20 minutes at 45°C, followed by 2 washes in 1× SSC and 0.1× SSC for 20 minutes at 45°C. Immunological detection was conducted using the DIG Nuclear Acid Detection Kit (Roche Diagnostics) according to the manufacturer's instructions. Briefly, after incubation with 1% blocking reagent for 30 minutes, the sections were incubated with sheep anti-digoxigenin alkaline phosphatase conjugate (11093274910, Roche Diagnostics) diluted at 1: 500 for 2 hours at room temperature. After 3 separate washes with washing buffer (0.1 M maleic acid, 0.15 M NaCl [pH 7.5], 0.3% Tween 20), the signal was developed using 200 μl of a HNPP/Fast Red TR mix (1758888, Roche Diagnostics) in the dark for 45 minutes. The sections were counterstained with DAPI. Tissue sections incubated with sense RNA probe were used as a negative control.

Confocal microscopy. Confocal microscopy was performed using a Carl Zeiss LSM 700 confocal microscope equipped with 4 lasers (Zeiss). ZEN (Zeiss) was used to assign colors to the 4 channels collected: Alexa Fluor 568 and HNPP/Fast Red, which fluoresces when exposed to a 568-nm wavelength laser and appears red; Alexa Fluor 488 (Molecular Probes), which appears green; Alexa Fluor 647 (Molecular Probes), which appears cyan; and the differential interference contrast (DIC) image, which is in gray scale. The 4 channels were simultaneously collected. To differentiate between individual cells, Hoechst 33258 (nuclear marker; Molecular Probes) was used at 1 μg/ml and incubated for 5 minutes, followed by rinsing with water. The colocalization of antigens was demonstrated by the addition of colors as indicated in the figure legend.

Monocyte isolation, differentiation, and polarization of macrophages. Monocytes were purified from peripheral blood mononuclear cells obtained from blood buffy coats (provided by Red Cross, Hong Kong, China) or monkey peripheral blood, as we previously described (52). Monkey peripheral blood was obtained in heparinized vacutainer collection tubes from healthy female rhesus monkeys. To generate M1 macrophages, monocytes were differentiated in RPMI 1640 medium (Thermo Fisher Scientific) supplemented with GM-CSF (400 IU/ml), 2 mM glutamine, 10% decomplemented FCS, 100 IU/ml penicillin, and 100 μg/ml streptomycin (Thermo Fisher Scientific) for 4 days, followed by exposure to fresh medium supplemented with 5% FCS and containing GM-CSF and LPS (100 ng/ml) + IFN-γ (20 ng/ml) for an additional 72 hours. To generate M2 macrophages, monocytes were differentiated in RPMI 1640 medium (Thermo Fisher Scientific) supplemented with M-CSF (50 ng/ml), 2 mM glutamine, 10% decomplemented FCS, 100 IU/ml penicillin, and 100 μg/ml streptomycin for 4 days, followed by exposure to fresh medium supplemented with 5% FCS and containing M-CSF (50 ng/ml) + IL-4 (20 ng/ml) for an additional 72 hours.

Quantification of cytokine levels. A panel of 13 cytokines, including IL-1β, IFN-α, IFN-γ, TNF-α, MCP1, IL-6, IL-8, IL-10, IL-12p70, IL-17A, IL-18, IL-23, and IL-33 in monkey sera and in culture medium were quantified using multiplexing laser bead technology (BioLegend). To assess the cytokine production of macrophages, in vitro–polarized cells were washed 3 times with PBS and were subsequently activated with SARS-CoV pseudotype virus in RPMI 1640 medium (Thermo Fisher Scientific) with or without administration of highly diluted and heat-inactivated (56°C) sera from macaques or SARS patients. FcγR-specific mouse monoclonal antibody (5 μg, clone 3G8, anti-hCD16, 16016682; clone FLI8.26, anti-hCD32, 16032981; and clone 10.1, anti-hCD64, 16064981 [BD Pharmingen]) was used for blockade of human FcγR. The supernatant of these cultures was recovered after 20 hours of stimulation, and the cytokine levels were measured and analyzed.

Statistics. All statistical analyses were performed using the 2-tailed Student's *t* test. *P* values less than 0.05 were considered statistically significant. Data are presented as the mean values ± SEM of at least 3 independent experiments unless otherwise indicated.

Study approval. The experiment was conducted in a Biosafety Level 3 animal facility. Handling and experimental procedures, including injections, blood collection, virus challenge, and sacrificing were approved and performed according to the animal welfare committee on the Use of Live Animals in Teaching and Research of Institute of Laboratory Animal Science, Beijing, China. All study subjects gave informed consent, and procedures were reviewed and approved by the University of Hong Kong Research Ethics Committee.

Author contributions

ZC, LL, and QW designed the study. LL and QW analyzed the data. LL, ZC, KYY, SP, and AL contributed to drafting the manuscript. ZC is the principal investigator, with overall responsibility for the design of the study. QW and CQ coordinated the autopsy organization and collection of autopsy materials of Chinese macaques. QW was involved in the development and performance of the RT-PCR assay. LL, HT, TW, and KWC performed the neutralization assay. LL, XA, and AL were involved in the development of the H&E, SARS-CoV IHC, and ISH assays. HW performed the ISH assay and the IHC staining of NP and calculation of the mean florescence intensity in the lungs. LL, HK, and KN performed the H&E and double- or triple-IHC staining. JF and HT performed culture of monocyte-derived macrophages. QL, HT, JP, and ZT performed analysis of cytokine production in cell culture supernatant and monkey sera. KHC and KYY coordinated the collection of sera and tissue sample from SARS patients. All authors were involved in the correlative interpretation of the pathological and molecular data.

Acknowledgments

COVID-19: an Immunopathological View

Kamran Kadkhoda[a]

[a]Immunopathology Laboratory, Robert J. Tomsich Pathology & Laboratory Medicine Institute, Cleveland Clinic, Cleveland, Ohio, USA

ABSTRACT Since its emergence in December 2019, it took only a couple of months for an outbreak of the novel coronavirus disease 2019 (COVID-19) to be declared a pandemic by the World Health Organization (WHO). This along with the highly infectious nature of the disease and the associated mortality call for particular attention to the underlying (immuno)pathomechanism(s). The latter will inform case management and vaccine design. Unravelling these mechanisms can assist basic scientists, laboratory medicine practitioners, clinicians, public health practitioners, funding agencies, and health care policymakers in responding to the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic.

KEYWORDS COVID-19, SARS-CoV-2, immunopathology

Xu et al. (1) reported on a 50-year-old man with no known underlying conditions who presented with pneumonia. Despite the presence of lymphopenia and absence of neutropenia, all inflammatory cells observed on the lung biopsy specimen were mononuclear cells. Peripheral blood lymphocytes showed high levels of activation markers (HLA-DR and CD38) by flow cytometry. These cells were strongly perforin- and/or granulysin-positive $CD8^{ffi}$ T cells or were inflammatory Th17 cells. This had led to significant damage to the lung tissues as demonstrated by diffuse alveolar damage, indicating acute respiratory distress syndrome (ARDS). This is consistent with high-level surface expression of angiotensin-converting enzyme 2 (ACE2), the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) receptor, on pneumocytes (2). Unfortunately, the patient passed away, but it is important to note that methylprednisolone was started on day 8 after the onset of symptoms, while the catastrophic ARDS cascade was already under way. Interestingly, inhalational alpha interferon (IFN-ffi) was also instituted along with methylprednisolone. Since IFN-ffi can boost antiviral immune responses, it might have further played a role in the tissue damage in this case. On a related note, previous studies with macaques using SARS-CoV had shown that older macaques had stronger innate immune responses (including those related to IFN-ffi) compared with younger macaques. In contrast, expression of IFN-ffi, as an anti-inflammatory cytokine, was reduced in older macaques (3). It has recently been shown that interleukin-6 (IL-6) was also expressed significantly higher in patients who succumbed to coronavirus disease 2019 (COVID-19) than in survivors (4). Observations like this case made by a number of front-line clinicians since the inception of the COVID-19 pandemic have led to pointing fingers at immunopathology as the potential main culprit.

There have been several studies including the large epidemiological joint report by WHO and China (5) stating that the case fatality rate (CFR) is exceedingly low in pediatric patients especially in the very young (CFR of 21.9% for individuals over 80 years of age versus 0% for individuals under 8 years of age). This is a striking finding that further suggests an immunopathological component to this observation. Another observation is the seroprevalence of community-acquired coronaviruses among adults is very high (90 to 100%) (6), but this is not necessarily the case in pediatric patients (7). Additionally, there are antigenic commonalities among coronaviruses (CoVs); for in-

stance, similar to SARS-CoV-2, CoV-NL63 also uses ACE2 as the receptor (8). As individuals age, the chance of exposure to common community-acquired CoVs (229E, OC43, NL63, and HKU1) increases. As a consequence, with such background anamnesis, once individuals are exposed to novel (zoonotic) CoVs such as SARS-CoV-2, the fast and furious immune response does the damage (the original antigenic sin [OAS]). According to OAS, the initial antigen imprints an immune response so that subsequent exposure to related antigen(s) preferentially chooses the already-existing memory cells. The resultant response, although brisk and apparently strong (a high-titer IgG response would be faster than that of IgM), may be unduly insufficient and inappropriate to the point that it might be initially nonprotective. In the context of COVID-19, since ACE2 is highly expressed in the gastrointestinal (GI) tract (9), shedding the virus in the stool is prolonged (10); however, diarrhea is uncommon likely because virus-specific effector memory T cells typically home to the mucosal surfaces they had previously encountered with an infection with a common CoV, i.e., upper and lower respiratory tract. As a result, despite ARDS in the lungs, almost no significant intestinal damage occurs, if at all. To further confound matters, lungs also express high levels of CD32a (Fc! RIIa, typically on alveolar macrophages), whereas GI tissues express almost no CD32a protein (The Human Protein Atlas [https://www.proteinatlas.org/] [accessed March 2020]). It has recently been shown that SARS-CoV and the Middle East respiratory syndrome (MERS)-CoV take advantage of non- or subneutralizing antibodies and enter cells via surface CD32a receptors (Trojan horse mechanism) (11, 12). Therefore, another even more biologically plausible pathomechanism is the so-called antibody-dependent enhancement (ADE). ADE has also been shown in infection with dengue viruses, Zika virus, Ebola virus, and human immunodeficiency virus. ADE is not only triggered by neutralizing antibodies but also by nonneutralizing antibodies. Additionally, antibody affinity plays an important role in ADE (11, 13). The most important pathomechanism in COVID-19, therefore, could be ADE in which CD32a plays the central role. CD32a is expressed on the surfaces of monocytes and macrophages among other cells such as alveolar macrophages, and once aggregated by several IgG molecules, it transduces its signal through the associated immunoreceptor tyrosine-based activation motif (ITAM). This results in the release of proinflammatory cytokines including IFN-! , tumor necrosis factor alpha, interleukin-1 (IL-1), and IL-6 (14). This IL-6 overproduction is the justification for using IL-6 receptor antagonists such as tocilizumab in COVID-19 clinical trials. It should be noted, however, that activation of ITAM occurs through phosphorylation by certain members of Src family of tyrosine kinases such as Fyn and Syk. Interestingly, agents such as cerdulatinib have dual inhibitory function against Syk as well as against Janus kinase family members (such as JAK1/2) (15), the latter also play key roles in IL-6 receptor signaling (16).

To complete the picture, SARS-CoV nucleoprotein and RNA had previously been found within alveolar macrophages of nonsurvivors (17). These cells also express dendritic cell-specific intercellular adhesion molecule-grabbing nonintegrin (DC-SIGN; CD209 and also CD209L). These surface molecules have been reported to be coreceptors for SARS-CoV entry (18). In this way, alveolar macrophages can function as a local niche for the virus and thereby pass it on to other cells.

Findings similar to the aforementioned epidemiological finding have been made for MERS-CoV in which disease severity increases with age and severe disease has been uncommon among pediatric patients (19). Furthermore, along the lines of ADE, it has been known for decades that immunization of cats with spike protein of feline CoV leads to more severe future infections with feline CoV in cats (11). Therefore, ADE is perhaps more effective when the time intervals between CoV infections are just long enough so antibody titers drop to at least subneutralizing levels. This may explain why association of older age with severe COVID-19 is not always the rule. Infection of alveolar macrophages through ADE may explain their excessive activation and generation of local hyperinflammatory environment and the resultant systemic cytokine storm that may even fulfill criteria for secondary hemophagocytic lymphohistiocytosis and macrophage activation syndrome. The pivotal involvement of macrophages is further highlighted by the fact that very high levels of ferritin are seen in severe

Downloaded from http://msphere.asm.org/ on April 22, 2020 by guest

COVID-19 cases (20). Additionally, the fact that severe COVID-19 is associated with much higher viral load compared with mild cases further suggests that ADE could play an important role in severe cases (21). Another explanation for age-associated severity of COVID-19 may be attributed to C-reactive protein (CRP). It is known that CRP levels increase with age and that serum CRP levels in adults are higher than in children, with the highest median level observed in the elderly (22). Furthermore, it has been demonstrated that CD32a is the major biological receptor for CRP (23).

Furthermore, the course of COVID-19 is in general more severe in those with underlying conditions such as hypertension, poorly controlled diabetes mellitus, and cardiovascular disease among others (4). This may be attributed to the known increased expression of CD32a on monocytes and macrophages in these patients (24). However, it is a common assumption that immunocompromised patients are at increased risk of developing severe COVID-19. To challenge this assumption, a report from Italy (25) showed that 3 out of 111 liver transplant recipients who passed away due to COVID-19 had received their transplants 10 years prior to death. Interestingly, these patients were stable with very low trough concentrations of calcineurin inhibitors in plasma. They, however, were all male, older than 65 years, overweight, diabetic, and on treatment for hypertension. In contrast, in the same study, 3 out of 40 individuals who had recently received liver transplants and were on intense immunosuppression drugs (without the other risk factors mentioned for the former group) and who tested positive for SARS-CoV-2 experienced an uneventful course of COVID-19. The CFR in the former group was 3% in contrast to the overall CFR of ca. 10% in Italy. Abatement of IFN-ffi signaling by calcineurin inhibitors may explain these observations. IFN-ffi can also be largely produced as a result of CD32a activation (26). Similar observations in other immunocompromised patient populations with larger sample sizes will be paramount to further understand the role of immunopathology in COVID-19.

All in all, further corroborative research is urgently needed to find out why advanced age is a major risk factor for COVID-19 and whether immunopathomechanisms can potentially be harnessed early enough to prevent irreversible consequences. This may be ground-breaking and would not only change the current individual patient management but also potentially inform prudent vaccine design and recommendations as was the case with dengue virus vaccination. The implications of ADE will be immense if IgG serology is used to determine immune status for health care workers, as a positive result does not necessarily mean one is immune to COVID-19 (even with a test specificity of 100%). More importantly, ADE may cause harm if plasma from clinically resolved patients is used for treatment. A very careful balance between risks and benefits established through large multicenter randomized controlled trials will provide answers to all these questions.

ACKNOWLEDGMENT

I sincerely thank Stanley Plotkin for reviewing the article.

According to OAS, the initial antigen imprints an immune response so that subsequent exposure to related antigen(s) preferentially chooses the already-existing memory cells. The resultant response, although brisk and apparently strong (a high-titer IgG response would be faster than that of IgM), may be unduly insufficient and inappropriate to the point that it might be initially nonprotective. In the context of COVID-19, since ACE2 is highly expressed in the gastrointestinal (GI) tract (9), shedding the virus in the stool is prolonged (10); however, diarrhea is uncommon likely because virus-specific effector memory T cells typically home to the mucosal surfaces they had previously encountered with an infection with a common CoV, i.e., upper and lower respiratory tract. As a result, despite ARDS in the lungs, almost no significant intestinal damage occurs, if at all. To further confound matters, lungs also express high levels of CD32a (Fc! RIIa, typically on alveolar macrophages), whereas GI tissues express almost no CD32a protein (The Human Protein Atlas [https://www.proteinatlas.org/] [accessed March 2020]). It has recently been shown that SARS-CoV and the Middle East respiratory syndrome (MERS)-CoV take advantage of non- or subneutralizing antibodies and enter cells via surface CD32a receptors (Trojan horse mechanism) (11, 12). Therefore, another even more biologically plausible pathomechanism is the so-called antibody-dependent enhancement (ADE). ADE has also been shown in infection with dengue viruses, Zika virus, Ebola virus, and human immunodeficiency virus. ADE is not only triggered by neutralizing antibodies but also by nonneutralizing antibodies. Additionally, antibody affinity plays an important role in ADE (11, 13). The most important pathomechanism in COVID-19, therefore, could be ADE in which CD32a plays the central role. CD32a is expressed on the surfaces of monocytes and macrophages among other cells such as alveolar macrophages, and once aggregated by several IgG molecules, it transduces its signal through the associated immunoreceptor tyrosine-based activation motif (ITAM). This results in the release of proinflammatory cytokines including IFN-! , tumor necrosis factor alpha, interleukin-1 (IL-1), and IL-6 (14). This IL-6 overproduction is the justification for using IL-6 receptor antagonists such as tocilizumab in COVID-19 clinical trials. It should be noted, however, that activation of ITAM occurs through phosphorylation by certain members of Src family of tyrosine kinases such as Fyn and Syk. Interestingly, agents such as cerdulatinib have dual inhibitory function against Syk as well as against Janus kinase family members (such as JAK1/2) (15), the latter also play key roles in IL-6 receptor signaling (16).

To complete the picture, SARS-CoV nucleoprotein and RNA had previously been found within alveolar macrophages of nonsurvivors (17). These cells also express dendritic cell-specific intercellular adhesion molecule-grabbing nonintegrin (DC-SIGN; CD209 and also CD209L). These surface molecules have been reported to be coreceptors for SARS-CoV entry (18). In this way, alveolar macrophages can function as a local niche for the virus and thereby pass it on to other cells.

Findings similar to the aforementioned epidemiological finding have been made for MERS-CoV in which disease severity increases with age and severe disease has been uncommon among pediatric patients (19). Furthermore, along the lines of ADE, it has been known for decades that immunization of cats with spike protein of feline CoV leads to more severe future infections with feline CoV in cats (11). Therefore, ADE is perhaps more effective when the time intervals between CoV infections are just long enough so antibody titers drop to at least subneutralizing levels. This may explain why association of older age with severe COVID-19 is not always the rule. Infection of alveolar macrophages through ADE may explain their excessive activation and generation of local hyperinflammatory environment and the resultant systemic cytokine storm that may even fulfill criteria for secondary hemophagocytic lymphohistiocytosis and macrophage activation syndrome. The pivotal involvement of macrophages is further highlighted by the fact that very high levels of ferritin are seen in severe

Downloaded from http://msphere.asm.org/ on April 22, 2020 by guest

COVID-19 cases (20). Additionally, the fact that severe COVID-19 is associated with much higher viral load compared with mild cases further suggests that ADE could play an important role in severe cases (21). Another explanation for age-associated severity of COVID-19 may be attributed to C-reactive protein (CRP). It is known that CRP levels increase with age and that serum CRP levels in adults are higher than in children, with the highest median level observed in the elderly (22). Furthermore, it has been demonstrated that CD32a is the major biological receptor for CRP (23).

Furthermore, the course of COVID-19 is in general more severe in those with underlying conditions such as hypertension, poorly controlled diabetes mellitus, and cardiovascular disease among others (4). This may be attributed to the known increased expression of CD32a on monocytes and macrophages in these patients (24). However, it is a common assumption that immunocompromised patients are at increased risk of developing severe COVID-19. To challenge this assumption, a report from Italy (25) showed that 3 out of 111 liver transplant recipients who passed away due to COVID-19 had received their transplants 10 years prior to death. Interestingly, these patients were stable with very low trough concentrations of calcineurin inhibitors in plasma. They, however, were all male, older than 65 years, overweight, diabetic, and on treatment for hypertension. In contrast, in the same study, 3 out of 40 individuals who had recently received liver transplants and were on intense immunosuppression drugs (without the other risk factors mentioned for the former group) and who tested positive for SARS-CoV-2 experienced an uneventful course of COVID-19. The CFR in the former group was 3% in contrast to the overall CFR of ca. 10% in Italy. Abatement of IFN-ffi signaling by calcineurin inhibitors may explain these observations. IFN-ffi can also be largely produced as a result of CD32a activation (26). Similar observations in other immunocompromised patient populations with larger sample sizes will be paramount to further understand the role of immunopathology in COVID-19.

All in all, further corroborative research is urgently needed to find out why advanced age is a major risk factor for COVID-19 and whether immunopathomechanisms can potentially be harnessed early enough to prevent irreversible consequences. This may be ground-breaking and would not only change the current individual patient management but also potentially inform prudent vaccine design and recommendations as was the case with dengue virus vaccination. The implications of ADE will be immense if IgG serology is used to determine immune status for health care workers, as a positive result does not necessarily mean one is immune to COVID-19 (even with a test specificity of 100%). More importantly, ADE may cause harm if plasma from clinically resolved patients is used for treatment. A very careful balance between risks and benefits established through large multicenter randomized controlled trials will provide answers to all these questions.

Research Article | Infectious disease | Pulmonology

Newly emerging viruses, such as severe acute respiratory syndrome coronavirus (SARS-CoV), Middle Eastern respiratory syndrome CoVs (MERS-CoV), and H7N9, cause fatal acute lung injury (ALI) by driving hypercytokinemia and aggressive inflammation through mechanisms that remain elusive. In SARS-CoV/macaque models, we determined that anti–spike IgG (S-IgG), in productively infected lungs, causes severe ALI by skewing inflammation-resolving response. Alveolar macrophages underwent functional polarization in acutely infected macaques, demonstrating simultaneously both proinflammatory and wound-healing characteristics. The presence of S-IgG prior to viral clearance, however, abrogated wound-healing responses and promoted MCP1 and IL-8 production and proinflammatory monocyte/macrophage recruitment and accumulation. Critically, patients who eventually died of SARS (hereafter referred to as deceased patients) displayed similarly accumulated pulmonary proinflammatory, absence of wound-healing macrophages, and faster neutralizing antibody responses. Their sera enhanced SARS-CoV–induced MCP1 and IL-8 production by human monocyte–derived wound-healing macrophages, whereas blockade of FcγR reduced such effects. Our findings reveal a mechanism responsible for virus-mediated ALI, define a pathological consequence of viral specific antibody response, and provide a potential target for treatment of SARS-CoV or other virus-mediated lung injury.

Introduction

Severe acute respiratory syndrome coronavirus (SARS-CoV) causes fatal human respiratory disease (1–3). Patients with SARS (hereafter referred to as SARS patients) displayed the characteristics of acute lung injury (ALI), including diffuse alveolar damage (DAD), epithelial necrosis, and fibrin and hyaline deposition (4, 5). Most patients who die of SARS develop acute respiratory distress syndrome (ARDS), the most severe form of ALI (6, 7). Recent outbreaks of severe acute respiratory infections of emerging viruses, including Middle Eastern respiratory syndrome CoVs (MERS-CoV), highly pathogenic avian influenza viruses (e.g., H5N1 and H7N9), highlight the need to characterize the mechanisms responsible for virus-mediated ALI or ARDS.

Fundamental to ARDS is the acute onset of lung inflammation, which is intimately tied to monocyte/macrophage polarization and function (7, 8). Lung macrophages are highly plastic and heterogeneous cells that are resident in the lung interstitium and alveoli or recruited upon inflammatory stimuli. Inflammatory monocytes and resident tissue macrophages play critical roles in initiating and maintaining inflammation

during the acute stage of ARDS, as well as in the resolution phages of inflammation and recovery from ARDS. At steady state, resident macrophages are normally quiescent to prevent damaging the alveoli and are critically involved in normal tissue homeostasis. After tissue injury or during infection, resident macrophages become activated. Circulating monocytes can be efficiently recruited to the site of injury. Inflammatory monocytes/macrophages (IMMs) and resident macrophages undergo marked phenotypic and functional changes, and they can be classified into proinflammatory (M1 or classically activated) and inflammatory-resolving (M2, alternatively activated, wound-healing, or antiinflammatory) macrophages, with a continuum of macrophage polarization existing beyond these discrete categories (9). During acute infection, monocytes/macrophages often display a phenotype of classically activated macrophages. These cells mediate host defenses against viruses and also promote lung injury by producing nitric oxide (NO); ROS; IL-1, IL-6, and IL-8; and TNF. Simultaneously, some macrophages may become alternatively activated, exerting antiinflammatory function and regulating wound healing by producing matrix metalloproteinases (MMPs), growth factors, and antiinflammatory cytokines, particularly TGF-β. When the pathogen or inflammatory stimulus is eliminated, proinflammatory macrophages diminish. The predominant macrophage population assumes a wound-healing phenotype. At the final recovery stage, macrophages show a regulatory/suppressive phenotype, secreting increased levels of IL-10, which facilitates the resolution of wound healing and restores homeostasis. When the wound-healing response is well organized and controlled, the inflammatory response resolves quickly, and normal tissue architecture is restored. Disturbances in wound-healing response can lead to uncontrolled production of inflammatory mediators, contributing to a state of persistent injury (9–11). In patients who eventually died of SARS (hereafter referred to as deceased patients) and animal models, extensive lung damage is associated with high initial viral loads, increased IMM accumulation in the lungs, and elevated serum proinflammatory cytokine (IL-1, IL-6, IL-8, CXCL-10, and MCP1) levels (4, 5, 12, 13). While much is known about the terminal phase of SARS, little is known about the early immune events during the acute phase of infection. Studies defining macrophage heterogeneity and function during acute infection and ALI using nonhuman primate and patient specimens are limited, and the factors driving the hypercytokinemia and aggressive inflammation remain elusive.

During the SARS outbreak in Hong Kong, most patients (70%–80%) presented with abnormal chest radiographs, with approximately one-quarter of these individuals progressing to ALI. After 12 days, 80% of these SARS patients developed ARDS, coincident with IgG seroconversion (6). In a detailed analysis of antibody responses against SARS-CoV spike (S) glycoprotein, we reported that the anti-S neutralizing antibody (NAb) response developed significantly faster in deceased patients compared with recovered patients after the onset of clinical symptoms (14). It took an average of 20 days for the recovered patients to reach their peak of NAb activities, as opposed to only 14.7 days for the deceased patients. Moreover, the actual NAb titer is significantly higher in deceased patients compared with that in the recovered patients during the same time period (14). These findings suggest a role of anti-S antibodies in SARS-CoV–mediated ALI during acute infection. Consistently, preexisting serum antibodies against influenza antigens were found to associate with worse clinical severity and poor outcomes in patients during the 2009 influenza pandemic (15, 16). Moreover, multiple vaccine platforms and viral infection appeared to induce SARS-CoV–specific immune memory that enhanced lung inflammation following homologous challenge in mice and African green monkeys (17–19). The mechanism responsible for the immunopathologic reaction remains elusive. Recent studies suggested that T cells play a crucial role in protection of mice against lethal SARS-CoV infection (20–22). Enhanced pulmonary immunopathology in vaccinated and challenged animals reflects an inadequate Th1 response (22, 23). The role of virus-specific antibody responses in SARS-CoV–induced lung injury has yet to be clearly defined. Therefore, we used vaccination and anti–S-IgG passive immunization strategies to evaluate the effects of anti-S antibodies on SARS-CoV–induced ALI in Chinese rhesus monkeys (*Macaca mulatta*). Our results now show that, in productively infected lungs, anti–S–IgG causes severe ALI by skewing inflammatory resolving responses during acute infection.

Results

Vaccine-induced S-specific immunity resulted in severe ALI in SARS-CoV–infected Chinese macaques. We initially compared the pathological changes in the lungs of rhesus macaques vaccinated with a modified vaccinia Ankara (MVA) virus encoding full-length SARS-CoV S glycoprotein (ADS-MVA) or control at 7 and 35 days after pathogenic SARS-CoV$_{PUMC}$ (1×10^5 tissue culture infectious dose of 50% [$TCID_{50}$]) challenge (24). Three healthy macaques were included as controls. Sixteen macaques were i.m. immunized twice: 8 animals with

ADS-MVA and another 8 animals with a control MVA (ADC-MVA) (Figure 1A) (24). Vaccination with ADS-MVA induced high levels of anti–SARS-CoV NAbs in all 8 macaques, with sera IC_{50} values ranging from 10,232- to 28,703-fold dilutions (Figure 1B). None of the macaques developed fever during or after vaccination (normal body temperature 37.8°C–38.1°C). The IC_{50} values of these sera were maintained, with an over-2,000–fold reciprocal serum dilution at 4 weeks after the secondary immunization, a time when all of the animals were i.n. challenged (Figure 1B). After viral challenge, all macaques developed fever between 1 and 5 days after inoculation (dpi) ranging from 38.6°C–39.2°C, and sera from control vaccinated macaques showed increased neutralizing activity after 14 dpi, indicating establishment of infection (Figure 1B). SARS-CoV RNA was readily detected on oral swabs from all control macaques examined at multiple time points using real-time reverse transcription PCR (real-time RT-PCR) but only in 3 of the 8 ADS-MVA–vaccinated macaques with lower NAb titers at 2 dpi (SL11, SE13, and SL14) (Figure 1C), suggesting reduced productive viral infection in the immunized macaques through S-specific immunity.

However, histological examination revealed acute DAD with various degrees of severity in 6 ADS-MVA–vaccinated macaques at 7 and 35 dpi, whereas most control macaques in the ADC-MVA group showed minor to moderate inflammation (Figure 1D). To better characterize the pathological changes, we adopted a 6-grade scoring system to describe the severity of the lung damage from least severe to most severe: 0, –; 1, +; 2, ++; 3, +++; 4, ++++; and 5, +++++ (Supplemental Figure 1; supplemental material available online with this article; https://doi.org/10.1172/jci.insight.123158DS1). In the control vaccinated group, 5 macaques showed minor inflammation with slight septa broadening and inflammatory cells infiltration that we scored as + (CL23, CE25, CE20, CE21, and CL19; Figure 1D, Supplemental Figure 1B, and Supplemental Figure 2). Two macaques showed moderate inflammation with more interstitial mononuclear inflammatory infiltration and were scored as ++ (CL26, CE24; Supplemental Figure 1C and Supplemental Figure 2). Only 1 macaque showed typical symptoms of acute DAD with extensive exudation and cell infiltration at 35 dpi (CL22, scored as ++++; Supplemental Figure 2). In the ADS-MVA–vaccinated group, 4 macaques showed typical symptom of acute DAD with extensive exudation and many-cell infiltration in alveolar cavities (SL11, SE12, SL16, and SL18, scored as ++++; Supplemental Figure 1E and Supplemental Figure 2). One macaque showed severe acute DAD with exudation, hyaline membrane formation along the alveoli, pneumocyte desquamation, and damaged alveolus filled with hemorrhage and inflammatory cells (SL15, scored as +++++; Figure 1D). One macaque showed early symptom of acute DAD (SL14, scored as +++; Supplemental Figure 1D), and the remaining 2 macaques showed moderate inflammation (SE13 and SE17, scored as ++; Supplemental Figure 2). The comparison of lung histopathological scores of 2 groups showed significantly enhanced lung injury in the ADS-MVA–vaccinated group at both 7 and 35 dpi compared with the control ADC-MVA group, suggesting that S-specific— but not MVA-specific — immunity promotes ALI during SARS-CoV infection (Figure 1E). Moreover, there is a moderate correlation between lung pathological scores and sera NAb titers at 0 dpi (Figure 1F), suggesting a role of S-specific antibody in enhancing SARS-CoV–mediated lung injury.

Anti–S-IgG induced severe lung injury during acute SARS-CoV infection. In our previous study, i.n. inoculation of Chinese macaques with $SARS\text{-}CoV_{PUMC}$ (1×10^5 $TCID_{50}$) led to lower respiratory tract infection in all animals within 2 days (25). However, most of them rapidly cleared infection in the lungs, and all of the animals ($n = 8$) exhibited mild lung lesions before 3 dpi (25). Severe lung injury in SARS-CoV–infected Chinese macaques has not been detected until 7 dpi (26, 27). To determine the effect of anti-S antibody on the extent of SARS-CoV–mediated lung injury, we adoptively transferred 5 mg (low dose) and 200 mg (high dose) purified anti–S-IgG from ADS-MVA–vaccinated but unchallenged macaques into 2 groups of unvaccinated macaques ($n = 6$/group) via i.v. injection, and then i.n. challenged recipients with $SARS\text{-}CoV_{PUMC}$ (1×10^5 $TCID_{50}$) (Figure 2A). As controls, another 2 macaques were administered 200 mg of control IgG (C-IgG) derived from ADC-MVA–vaccinated macaques. We sacrificed half of the macaques in each group at 2 dpi to avoid potential disruption by virus infection–induced antibodies against nucleocapsid protein (N) and other viral proteins — and prior to when induction of ALI was typically observed. The remaining half of the macaques in each group was sacrificed at 21 dpi to evaluate long-term impact (Figure 2A). At day 2, sera from macaques that received low- or high-dose S-IgG showed neutralizing activity, with IC_{50} values ranging from 10–260 and 1,000–10,000, corresponding to the dose of sera transfer; macaques that received C-IgG failed to show neutralizing activity (Figure 2B and Supplemental Table 1). While NAb titers in the sera of macaques in the high-dose group declined steadily between 2 and 21 dpi, macaques in the low-dose and control groups displayed increased NAb titers over time (Figure 2B), suggesting active viral replication.

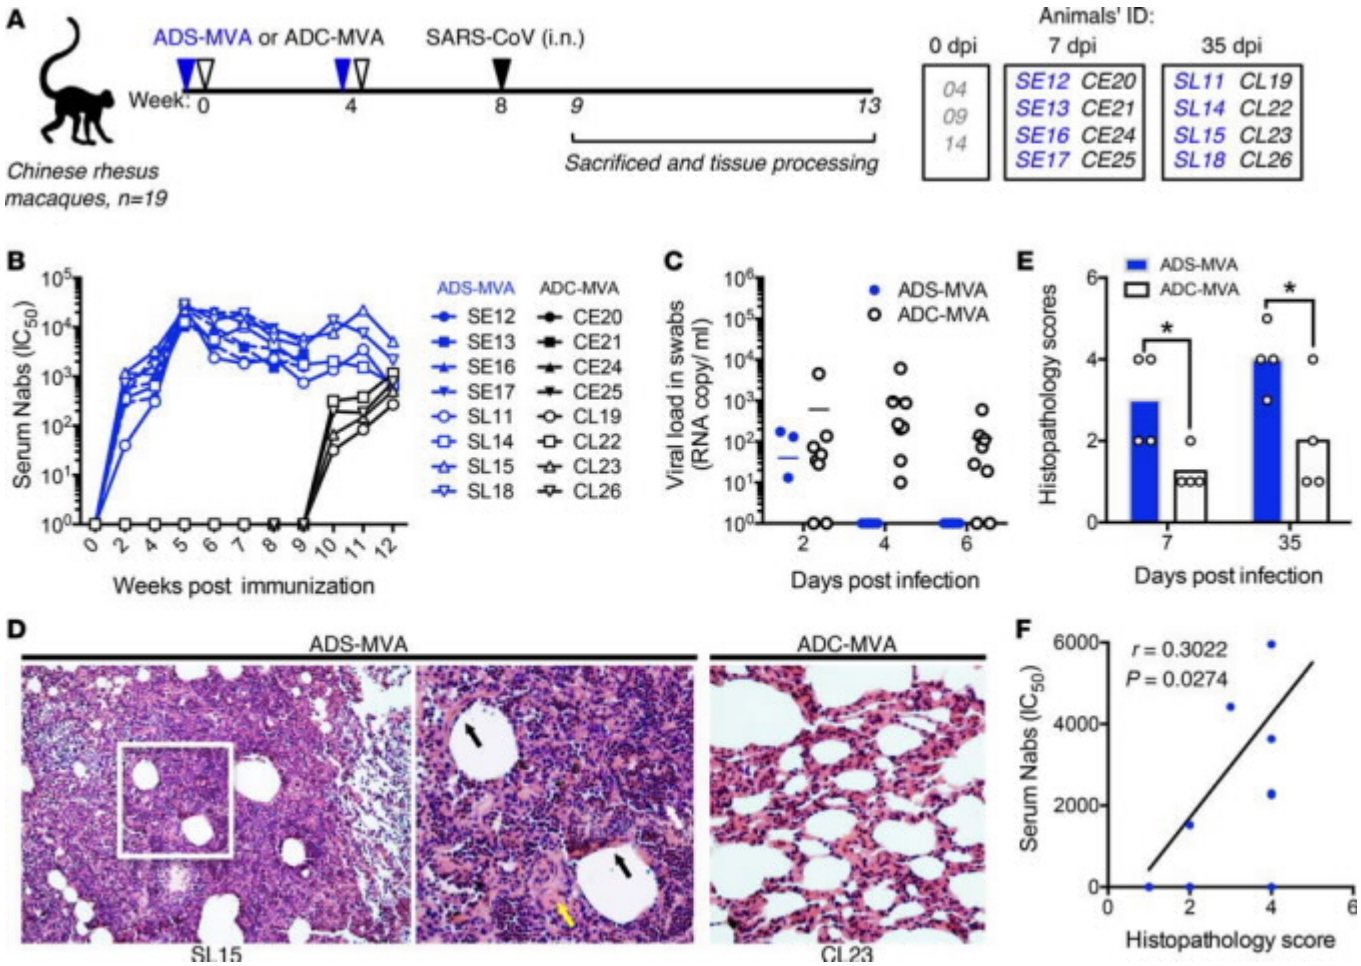

Figure 1. ADS-MVA–induced S-specific immune response enhanced pulmonary pathology in SARS-CoV–infected Chinese rhesus macaques. (**A**) imental design used to investigate the influence of S-specific immunity on SARS-CoV–induced lung injury. Two groups of Chinese rhesus macaques (*n* = 8/group) were subjected to i.m. injections of ADS-MVA or control vaccine ADC-MVA at weeks 0 and 4, followed by i.n. challenge with live pathogenic SARS-CoV_{PUMC} (1×10^5 $TCID_{50}$) at 4 weeks after the second vaccination. Four animals each were sacrificed at 1 and 5 weeks after inoculation. Three healthy macaques were included as controls. (**B**) Serum neutralizing activity. Sera collected from macaques were tested for a capacity to neutralize SARS-CoV pseudotype virus. (**C**) Detection of viral RNA in oral swabs. SARS-CoV RNA was detected by nested RT-PCR in the swabs at the indicated time points relative to infection. (**D**) Pathology changes of the lung tissue. Sections were stained with H&E. **D** shows symptom of acute DAD exhibited in 6 of 8 ADS-MVA–vaccinated macaques with extensive exudation (yellow arrow), hyaline membranes lining the alveolar walls (black arrows), and massive cell infiltration in alveolar cavities (white arrow). Left image shows a low magnification overview (100×). Middle image shows higher magnification of the boxed area in left image (200×). Right image shows minor inflammation observed in 7 macaques received ADC-MVA (*n* = 8) with slight alveolar septa broadening and sparse monocyte infiltration (original magnification, 100×). (**E**) Histopathological scores of the ADS-MVA group, including lung samples collected at both 7 and 35 dpi, were compared against the ADC-MVA control group. See Supplemental Figure 1 for the scoring index based on severity of lung histopathology. Data represent mean ± SEM values. Statistical analysis was undertaken using 2-tailed unpaired Student's *t* test. $^*P < 0.05$, *n* = 4. (**F**) Correlation of lung histopathological scores of all macaques with sera NAb titers at 0 dpi. Solid lines denote the relationship between histopathology scores and serum neutralizing activity. Statistical analysis was performed using Spearman's rank correlation test.

Indeed, SARS-CoV RNA was detected using real-time RT-PCR on oral swabs, and/or virus was recovered from lung tissue in both control animals and 5 of 6 animals (83%) in the low-dose group. Only 2 of 6 animals (33%) in the high-dose group were viral RNA^+ (Figure 2C and Supplemental Table 1), suggesting reduced viral production by high-dose S-IgG.

Consistent with the findings in the control ADC-MVA–vaccinated group, histopathological examination of the lungs indicated minor and moderate inflammation at day 2 and 21 in C-IgG recipients, respectively. In contrast, all S-IgG recipients exhibited symptoms of acute DAD with various degrees of exudation, hyaline membrane formation, and hemorrhage and inflammatory cells within alveolus at both day 2 and 21 (Figure 2, D and E, and Supplemental Table 2). Of note, despite the presence of high titer sera NAbs during the chronic stage of infection (Figure 1B and Figure 2B), only 1 of 5 C-IgG and control

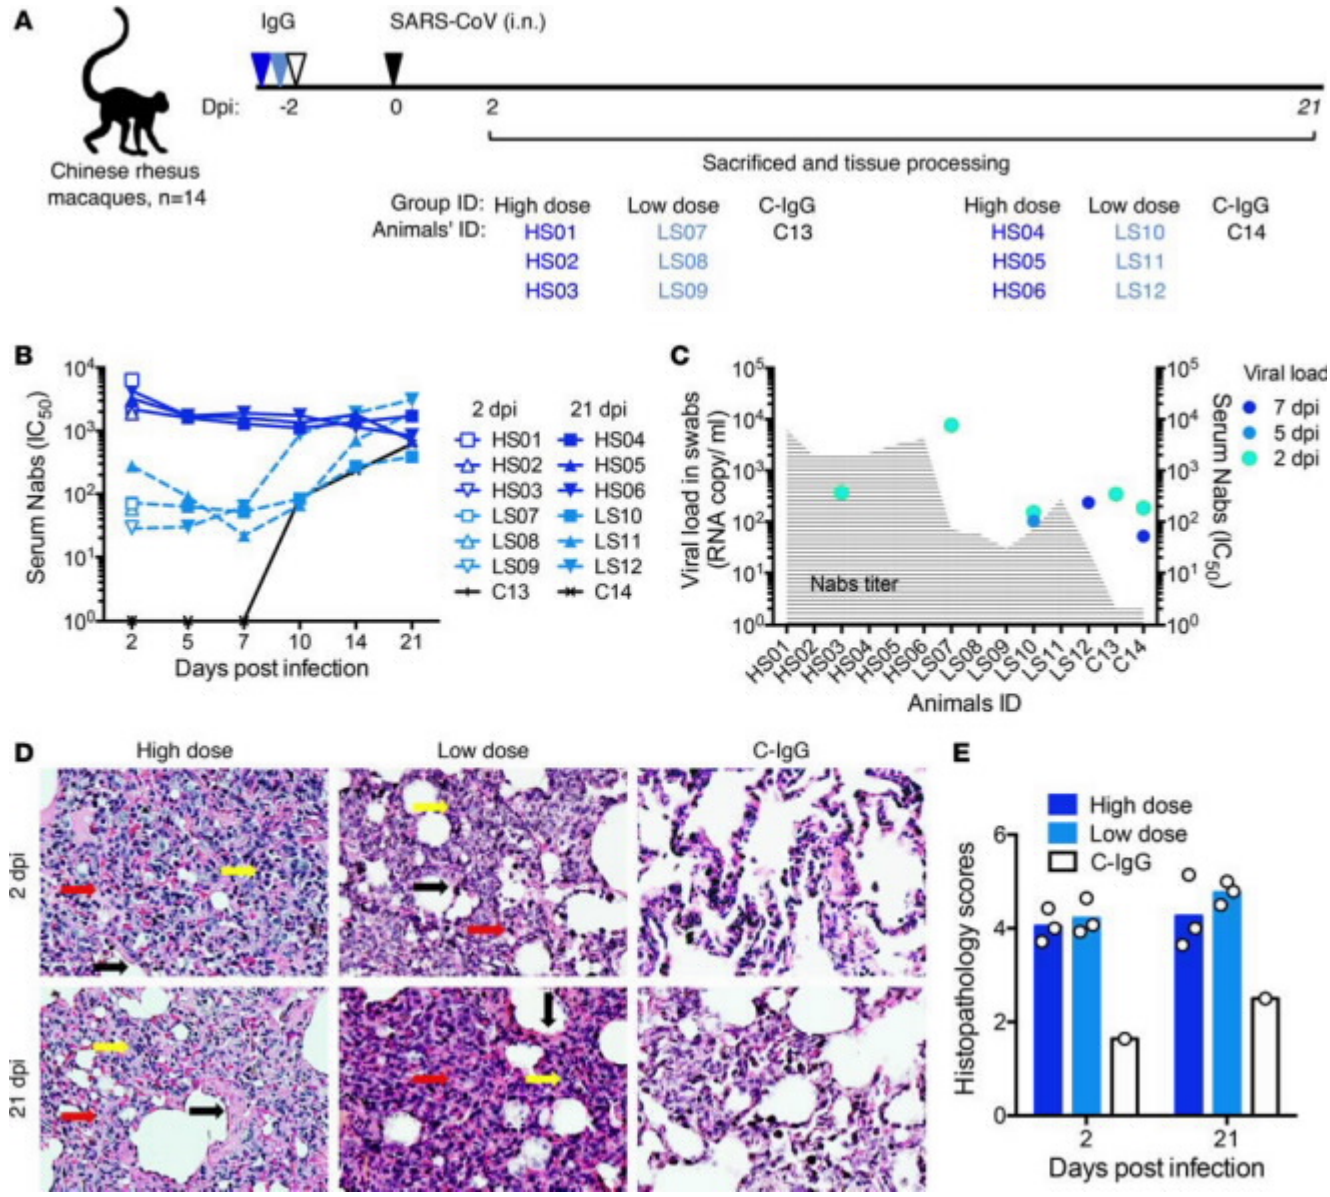

Figure 2. Anti-spike antibodies induced ALI in SARS-CoV–infected Chinese rhesus macaques. (**A**) Experimental design used to investigate the influence of S-IgG on SARS-CoV–induced lung injury. Two groups of Chinese rhesus macaques (*n* = 6/group) were subjected to i.v. injection of high-dose (200 mg) or low-dose (5 mg) purified S-IgG from ADS-MVA–vaccinated but unchallenged macaques. As controls, another 2 macaques were administered 200 mg of C-IgG derived from ADC-MVA–vaccinated macaques. After 2 days, 3 groups of macaques were challenged i.n. with SARS-CoV (10^6 $TCID_{50}$). Half of the animals from each group were sacrificed at 2 and 21 dpi. Sera (**B**) from macaques at the indicated time points were tested for the capacity to neutralize SARS-CoV pseudotype virus. (**C**) Detection of viral RNA in oral swabs. SARS-CoV RNA was detected by nested RT-PCR in the swabs from one of the high-dose S-IgG–treated macaques (*n* = 6), 3 low-dose S-IgG–treated macaques (*n* = 6), and 2 C-IgG–treated macaques (*n* = 2) at the indicated time points. Left *y* axis shows the viral RNA copy number per milliliter swab. Right *y* axis shows the serum NAb titers of each macaque at 2 dpi, which are highlighted by shaded area. (**D**) Pathology changes of the lung tissue (200×). Sections from macaques were stained with H&E. Images show symptom of acute DAD exhibited in macaques received high-dose and low-dose S-IgG (*n* = 2) with extensive exudation (red arrows), hyaline membranes (black arrows), and massive cell infiltration (yellow arrows) at 2 and 21 dpi. Right panel shows minor and moderate inflammation in the macaques received C-IgG with slight alveolar septa broadening and sparse monocyte infiltration at 2 and 21 dpi. (**E**) Histological scores of the high-dose and low-dose S-IgG groups, including lung samples collected at both 2 and 21 dpi, were compared against the C-IgG group. See Supplemental Figure 1 for the scoring index based on severity of lung histopathology.

ADC-MVA vaccine recipients showed acute DAD (Figure 1E and Figure 2E), indicating a time-restricted role for S-IgG, which mostly causes severe ALI in acutely infected macaques. Therefore, we conclude that, despite viral suppression, the presence of S-IgG at the acute stage of SARS-CoV infection caused severe ALI that persists until late stages.

S-IgG failed to prevent SARS-CoV lower respiratory tract infection and amplified IMM infiltration and accumulation in the lungs. To determine the potential cause of S-IgG–enhanced ALI, we measured viral infection and monocytes/macrophages infiltration in the lungs and serum cytokine profile at 2 dpi. We previously found that pulmonary infection of Chinese macaques could be rapidly controlled. Viral RNA$^+$ cells were detectable in the lungs of only 2 of 4 animals at 2 dpi, although all of them were viral nucleoprotein-positive (NP$^+$) in the lungs and the hilar lymph nodes (LNs), where the lymphatics of the lungs drain (25). Therefore, we measured viral RNA$^+$ cells by in situ hybridization (ISH), as well as NP signals in the lungs and the hilar LNs by IHC staining to evaluate the actual pulmonary infection of each macaque. Consistent with the results by viral isolation (Supplemental Table 1), viral RNA was detected in pneumocytes of 1 macaque in the high-dose (HS02, 33%), 2 macaques in the low-dose (LS01, LS02; 66%), and the C-IgG–treated macaque (Figure 3A and Supplemental Table 3), suggesting reduced productive infection by S-IgG. However, an NP antibody identified positive signals in the lungs and hilar LNs of all S-IgG and C-IgG recipients (7 of 7 macaques) but not healthy controls (Figure 3B and Supplemental Table 3), suggesting that S-IgG failed to prevent SARS-CoV entry, and SARS-CoV established lower respiratory tract infection in all of the challenged animals.

Consistent with previous findings in SARS-CoV–inoculated naive Chinese macaques (n = 4) (25), double-immunostaining with the NP antibody and antibodies specific to the stages of macrophage differentiation and inflammation (MAC387, CD68, CD163) revealed significant infiltration of IMMs in the lungs of C-IgG recipients, consisting of newly infiltrated (MAC387$^+$) and inflammatory (CD163$^+$) monocytes/macrophages (Figure 3C and Supplemental Figure 3). The CD163$^+$ cells greatly exceeded the CD68$^+$ population and typically gathered around NP$^+$ cells to form cell clusters (Figure 3C), showing an association between viral infection and IMM infiltration in these macaques.

Compared with C-IgG recipients, more robust signals for MAC387 and CD163 were identified in the lungs of S-IgG recipients (Figure 3C and Supplemental Figure 3), suggesting enhanced IMM infiltration by S-IgG. MAC387$^+$ and CD163$^+$ monocytes/macrophages not only gathered around NP$^+$ cells, but also formed clusters in tissues with little NP signal (Figure 3C), suggesting that infection-induced recruitment from circulation continued after viral clearance and accumulated at the inflamed site. Moreover, more-concentrated CD68$^+$ signals were found, indicating altered macrophages functional response by S-IgG treatment (Figure 3C). Consistently, elevated serum levels of IL-8 were observed in macaques treated with high-dose S-IgG at 2 dpi (Supplemental Figure 3), and the IL-8 levels are strongly correlated with anti–SARS-CoV NAb titers (Supplemental Figure 3). IL-8 is a macrophage-derived inflammatory cytokine important in initiating ALI. These results, therefore, suggest that S-IgG likely altered macrophage functional response in the lungs during acute infection, resulted in increase in IL-8 production, and enhanced ALI and IMM infiltration and accumulation.

Alveolar monocytes/macrophages assumed wound-healing function as early as 2 dpi in macaques not treated with S-IgG. Macrophage activation is dynamic and plastic. Different monocyte/macrophage activation statues have different specialized and critically timed roles, taking part in either the initiation and maintenance or resolution of inflammation (9). A well-organized wound-healing response leads to timely resolution of inflammation, whereas disturbance in wound-healing response results in persistent inflammation and injury. To understand the S-IgG–caused excessive inflammation, we further defined macrophage heterogeneity and activation statues in the lung lesions of C-IgG (n = 1) and S-IgG recipients (n = 3) at 2 dpi. Three healthy macaques and 4 naive Chinese macaques challenged with the same dose of SARS-CoV$_{PUMC}$ and scarified at 2 dpi from a previous study were included as controls (25).

By combining 5 macrophages markers (MAC387, CD68, CD163, HAM56, and CD206) (28–30), 2 subpopulations of resident macrophages were shown in the lungs of Chinese rhesus macaques at steady state as previously described (29). They are interstitial macrophages (IMs; MAC387$^+$HAM56$^-$CD206$^-$) (Figure 4A) and resident alveolar macrophages (AMs; CD68$^+$ HAM56$^-$) expressing low levels of CD163 and CD206, a marker specific to the macrophage wound-healing response, corresponding to their intrinsic antiinflammatory function (Figure 4B) (29). In lung lesions of both C-IgG–treated and naive macaque groups challenged with SARS-CoV$_{PUMC}$, IMMs were further characterized and divided into 2 subpopulations. One subpopulation was the recently recruited MAC387$^+$HAM56$^-$CD68$^-$ monocytes (Figure 4C) (29), which is like IM but is larger in size and primarily coexpressed CD163 (Supplemental Figure 4). The other subpopulation was single CD163$^+$ inflammatory macrophages that had differentiated from newly recruited MAC387$^+$ monocytes/macrophages (Figure 4D and Supplemental Figure 4) (29). Importantly, resident

AMs (CD68$^+$) differentiated into HAM56$^+$ cells, with a slight increase in numbers and increased size, with stronger CD163 and — more importantly — CD206 staining, suggesting that they are alternatively activated (Figure 4D). Strikingly, elevated levels of TGF-β expression were detected in all MAC387$^+$ — and most enlarged CD163$^+$ — as well as CD68$^+$ macrophages in the lungs of both C-IgG–treated and unvaccinated macaques compared with healthy controls (Figure 4, G–I), indicating that many IMMs and activated resident AMs have assumed a wound-healing function in infected lungs within 2 days of infection.

S-IgG treatment skewed wound-healing macrophage response in the lungs during acute SARS-CoV infection. Compared with the macaques not treated with S-IgG, the number of IMMs (MAC387$^+$ and CD163$^+$HAM56$^-$) significantly increased in S-IgG recipients (Figure 4, E and F). Moreover, many recently recruited MAC387$^+$HAM56$^-$ monocytes/macrophages did not coexpress CD163 (Supplemental Figure 4), representing the newest recruited blood monocytes, as a result of enhanced monocytes infiltration by S-IgG. Importantly, the majority of CD163$^+$HAM56$^-$ IMMs coexpressed CD68 (Supplemental Figure 4), suggesting a change of function of this subpopulation by S-IgG. Moreover, resident macrophages (CD68$^+$HAM56$^+$) in the lungs of S-IgG recipients no longer express CD206, which — being surrounded by many CD163$^+$ IMMs (Figure 4F) — suggests a loss of wound-healing function and a role in recruiting blood monocytes. Consistently, S-IgG–treated macaques displayed a loss of TGF-β and high expression of IL-6 in all macrophage subpopulations (Figure 4, G, H, and J). IL-6 favors macrophage accumulation at the site of injury and is important for the development of persistent inflammation and ALI (31, 32). Therefore, we conclude that, while AMs underwent phenotypic and functional changes in acutely infected lungs, many monocytes/macrophages assumed a wound-healing function for inflammation resolution, but the presence of S-IgG skewed the wound-healing response, leading to uncontrolled inflammation and tissue injury.

Onset of an antibody response prior to viral clearance is associated with abrogated wound-healing responses and increased IMM lung infiltration in unvaccinated Chinese rhesus macaques. To understand the mechanism underlying the time-restricted role of S-IgG in promoting ALI, we conducted a temporal analysis of the productive viral infection, antibody response, and macrophage functional changes in unvaccinated Chinese macaques during the first week of infection. Naive macaques were challenged i.n. with 1×10^6 $TCID_{50}$ $SARS\text{-}CoV_{PUMC}$ and sacrificed at 2, 3, and 7 dpi (4 macaques/group) (Figure 5A) (25). Successful lower respiratory tract infection was confirmed by detection of viral NP using IHC staining in the lungs of all macaques (25). Viral RNA$^+$ alveolar pneumocytes were primarily found at 2 dpi (2 of 4 macaques), and infrequently at 3 dpi (0 of 4 macaques; Figure 5B and Supplemental Table 4) (25). At 7 dpi, viral RNA was detectable in the lungs of 2 macaques, AD0516 and AD0518, suggesting productive infection there (Figure 5, B and C). Only few scattered NP$^+$ cells were found in AD0517 (Figure 5D). Neither NP nor viral RNA was found in the lungs or swabs of AD0515, suggesting clearance of productive viral pulmonary infection in this macaque (Figure 5D and Supplemental Table 4). Serum NAb was not observed at 2 and 3 dpi until 7 dpi in 2 of 4 macaques, AD0515 and AD0516 (Supplemental Table 4 and Figure 5E).

In agreement with the findings in the C-IgG group, temporal analysis of macrophage heterogeneity revealed significantly increased number of IMMs (CD163$^+$CD206$^-$) in viral RNA$^+$ lungs at 2 dpi (Figure 5F, right image). The IMMs diminished at 3 dpi (4 of 4 macaques) (Figure 5G) and became nearly completely absent at 7 dpi in macaques without productive pulmonary viral infection (2 of 4 macaques, AD0515 and AD0517) (Figure 5H), indicating that inflammatory response resolved with 7 days following the control of productive infection. Critically, wound-healing macrophages (CD163$^+$CD206$^+$ and CD163$^+$TGF-β$^+$) were observed in the lungs of all macaques at 2 dpi, despite productive pulmonary viral infection in macaques AD0506 and AD0508 (Figure 5F). In contrast, macaque AD0516, with serum NAbs and productive virus infection in the lungs, displayed a significantly enhanced proinflammatory macrophage response and reduced inflammatory-resolving macrophages (Figure 5I), which was not observed in macaques with productive viral infection but undetectable NAb responses (AD0518) or in macaques with detectable NAbs but undetectable viral replication (AD0515) (Figure 5D and Supplemental Table 4). Therefore, persistent viral replication and concomitant NAb detection is associated with increased IMM lung infiltration and reduced wound-healing macrophage numbers.

S-IgG modifies functional response of alternatively but not classically activated macrophages to SARS-CoV infection. To determine whether S-IgG skews wound-healing response through modifying wound-healing macrophage functional response during SARS-CoV infection, we treated in vitro–polarized alternatively activated human monocyte–derived macrophages (MDM) for 20 hours with SARS-CoV pseudovirus and heat-inactivated sera of high-dose S-IgG–treated macaques (S-IgG sera) collected at 2 dpi. We

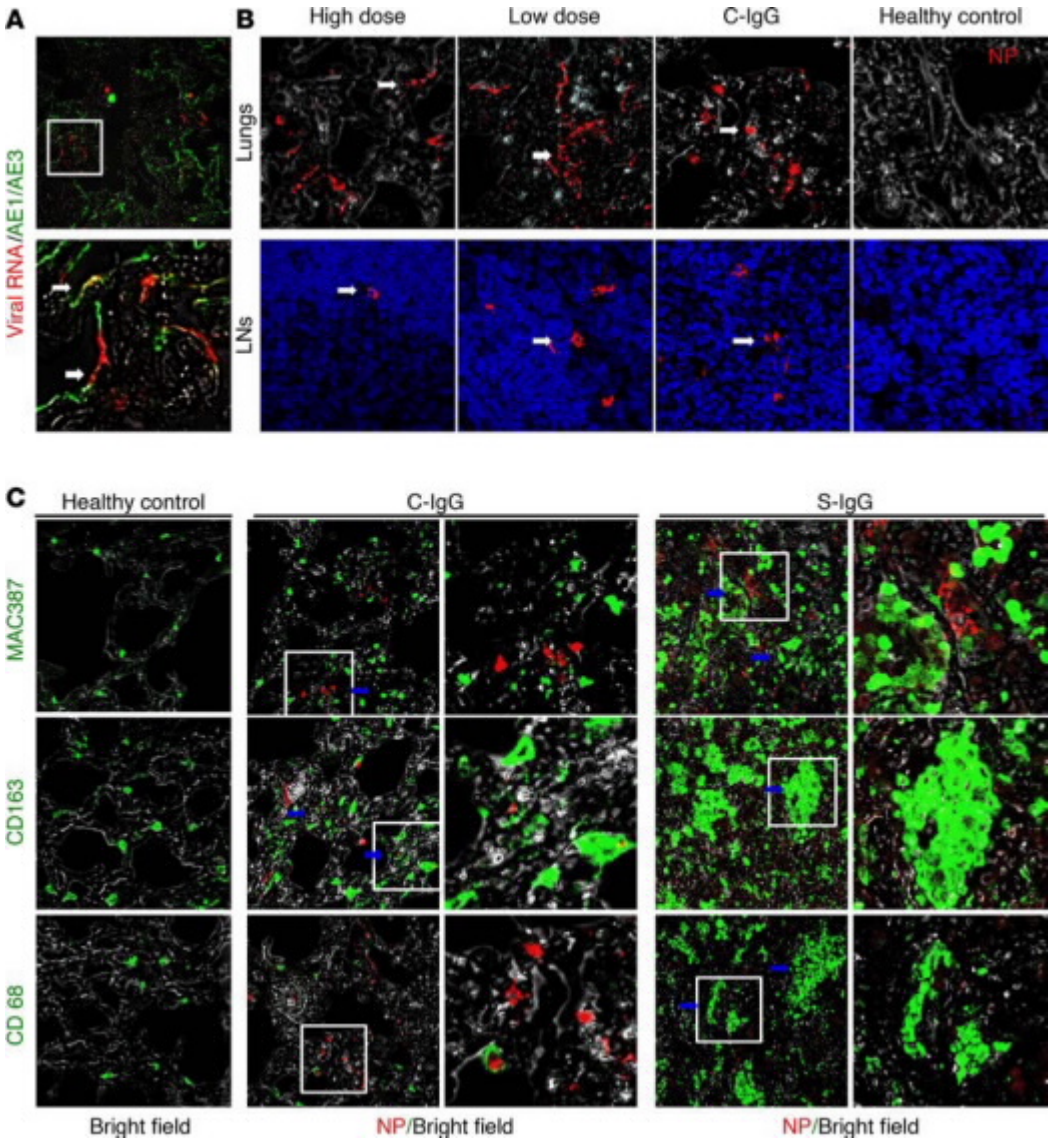

Figure 3. SARS-CoV infection and monocytes/macrophages infiltration in the lungs of C-IgG– and S-IgG–treated macaques at 2 dpi. (**A**) Represen images of SARS-CoV RNA (TRITC) and AE1/AE3 (FITC) cells in the lungs of infected macaques (white arrows). The upper photo shows a low magnification overview (200×); the bottom photo shows the boxed area in the upper photo. (**B**) Representative images of viral protein (NP) immunostaining of the lungs and hilar lymph nodes (LN) of 7 infected and 3 uninfected animals (TRITC, white arrows) (original magnification, 200×). (**C**) Representative images of viral NP and monocytes/macrophages. These sections showed significantly increased IMMs in the lungs of the S-IgG group compared with the C-IgG group (MAC387, CD163, or CD68, blue arrows). Tissue samples are double-immunostained for the SARS-CoV NP (TRITC) and markers for macrophages, including MAC387 (FITC), CD163 (FITC), and CD68 (FITC). Within the panel of representative images for the C-IgG and S-IgG groups, the left panel shows low magnification overview; the right panel shows the boxed area in the left panel (original magnification, 200×).

then measured the concentrations of 13 inflammatory cytokines in cell culture supernatants, including IL-1β, IFN-α, IFN-γ, TNF-α, MCP1, IL-6, IL-8, IL-10, IL-12p70, IL-17A, IL-18, IL-23, and IL-33. Sera from C-IgG recipients or healthy macaques were included as controls. In vitro–polarized classically activated MDM was also studied and compared with alternatively activated MDM in parallel. Consistent with previous report, unstimulated classically activated MDM produced high levels of IL-8 and IL-6; alternatively activated MDM only produced minimal levels of those cytokines (Figure 6A). Addition of SARS-CoV pseudovirus induced IL-8 production in alternatively activated MDM to levels comparable with those found in unstimulated, classically activated MDM, as well as in low-level MCP1 and IL-6 production (Figure 6B). By contrast, SARS-CoV pseudovirus caused less than a 1-fold increase in IL-8 secretion, but not other cytokine secretion, by classically activated MDM (Figure 6C). Strikingly, while none of the sera samples induced cytokine production when they were administered into MDMs alone,

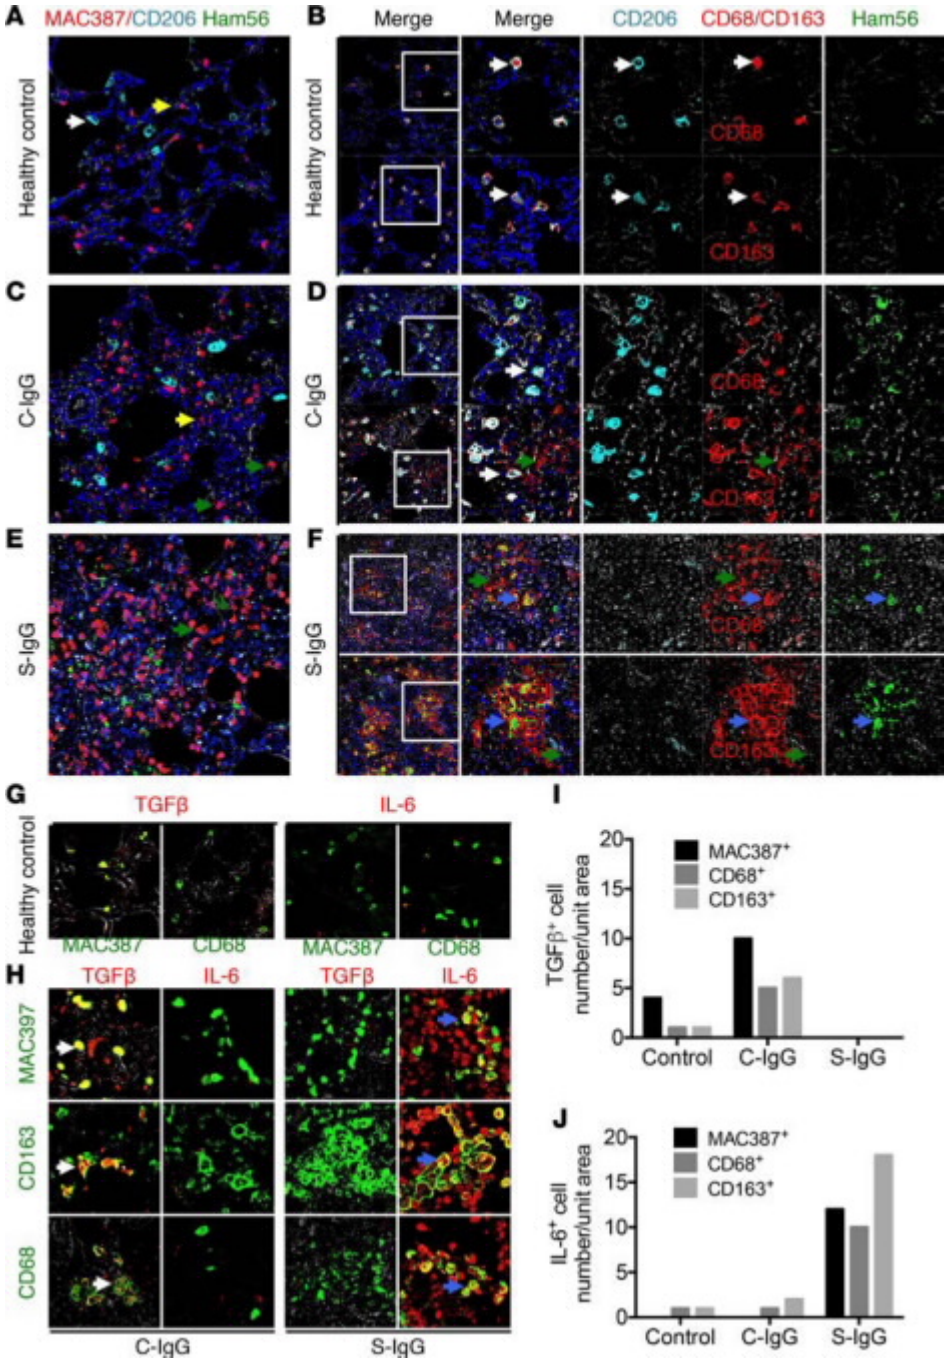

Figure 4. Comparison of monocyte/macrophage phenotype and function in the lungs of S-IgG– and C-IgG–treated macaques. (**A**–**F**) Phenotype of monocytes/macrophages subpopulations in the lungs of healthy, C-IgG–, and S-IgG–treated macaques (original magnification, 200×). These sections were triple-immunostained with antibodies for CD206 (cyan), HAM56 (FITC), and MAC387 (TRITC) (**C**, **E**, and **A**); CD206 (cyan), HAM56 (FITC), and CD68 (TRITC) (upper panel, **D**, **B**, and **F**); or CD163 (TRITC) (lower panel, **D**, **B**, and **F**). **A** and **B** show 2 subpopulations at steady states, including interstitial macrophages (IM) (MAC387$^+$HAM56$^-$CD206$^+$) (yellow arrow), and resident alveolar macrophages (AM) (CD68$^+$CD163$^+$CD206$^+$HAM56$^-$) (white arrows). **C** and **D** show the presence of alternatively activated resident AM and accumulated IMMs in the C-IgG group. Alternatively activated AMs are CD206$^+$CD68$^+$CD163$^+$HAM56$^-$ (**D**, white arrows). IM are MAC387$^+$HAM56$^-$CD206$^+$ (**C**, yellow arrow). IMMs include newly infiltrating monocytes/macrophages (MAC387$^+$) (**C**, green arrow); and inflammatory macrophages (CD68$^+$CD206$^-$HAM56$^-$) (**D**, green arrow). **E** and **F** show significantly increased number of IMMs and decreased number of alternatively activated macrophages in the S-IgG group. IMMs include newly infiltrating monocytes/macrophages (MAC387$^+$) (**E**, green arrow) and inflammatory macrophages that are CD68$^+$HAM56$^-$ (green arrow, **F**, upper panel) and CD163$^+$CD206$^+$HAM56$^-$ (green arrow, **F**, lower panel). Resident AMs are no longer expressing CD206$^+$ (CD68$^+$CD163$^+$CD206$^-$) (blue arrow, **F**, upper panel). (**G**–**J**) TGF-β and IL-6 expression in macrophages in the lungs. These sections were double-immunostained with antibodies for TGF-β (TRITC) and MAC387, CD163, or CD68 (FITC). (**G**) shows low expression levels of TGF-β and IL-6 in IMs (MAC387$^+$) and AMs (CD68$^+$) in healthy macaques. **H** shows increased TGF-β expression in the C-IgG group (white arrows) but increased IL-6 in the S-IgG group (blue arrows). (**I** and **J**) show the numbers of TGF-β$^+$ and IL-6$^+$ monocytes/macrophages in 3 groups in a 200× field.

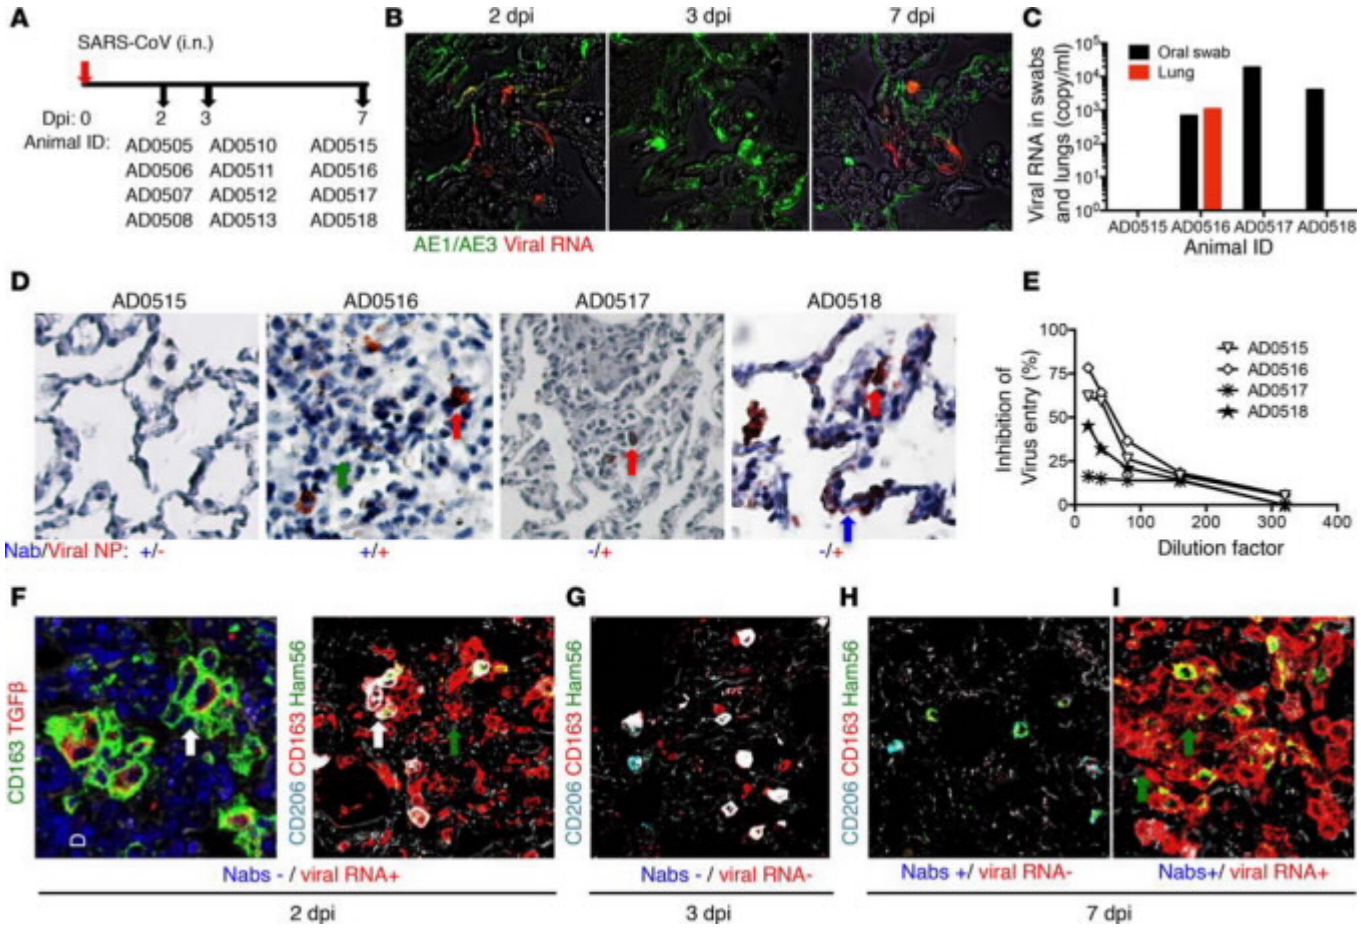

Figure 5. Dynamics of the viral replication, antibody response, and macrophage activation during acute SARS-CoV infection. (**A**) Experimental scheme. A total of 12 Chinese rhesus macaques were challenged i.n. with SARS-CoV ($\times 10^{6}$ $TCID_{50}$). Four animals each were sacrificed at 2, 3, and 7 dpi. (**B**) SARS-CoV RNA detection by ISH in the lungs at 2, 3, and 7 dpi (original magnification, 200 ×). Viral RNA in type I pneumocytes (FITC) was found at 2 dpi ($n = 2$) and 7 dpi ($n = 1$). (**C**) Viral RNA in the swabs and lung homogenates on 7 dpi. SARS-CoV RNA was detected using nested RT-PCR in swabs from 3 macaques (AD0516, AD0517, and AD0518) and lung homogenates from macaque AD0516 and AD0518. (**D**) Alveolar antigen and inflammatory infiltrates in the lungs at 7 dpi (200×). These sections were stained for SARS-CoV NP (red) and nucleus (blue) by IHC, showing NP signal in macrophage-like cells in AD0516 and AD0517 (red arrows), and type I pneumocytes in AD0518 (blue arrows), but substantial inflammatory infiltrates were only observed in AD0516 (green arrows). (**E**) Serum neutralizing activity. Serum neutralizing activity was detected in macaques AD0515 and AD0516 at 7 dpi. (**F**–**I**) Decreased wound-healing response in macaques with productive pulmonary viral infection and serum neutralizing activity (200×). These sections were double-immunostained for TGF-β (TRITC) and CD163 (FITC) or triple stained for CD206 (cyan), HAM56 (FITC), and CD163 (TRITC). The figure shows that wound-healing response took place within 2 dpi, with alternatively activated monocytes/macrophages (TGF-β, CD206, white arrows) and IMMs (CD163, CD206, green arrows) coexisting in the lungs (**F**). After viral clearance, IMMs diminish at 3 dpi (**G**), and the homeostasis was restored at 7 dpi (AD0515) (**H**). When pulmonary viral infection persists, IMM (CD163, CD206, green arrows) infiltration and accumulation is enhanced, and wound-healing macrophages (CD206) are reduced in macaques that have faster NAb response (AD0516) (**I**).

administration of S-IgG sera caused a dose-dependent increase in the production of all 3 inflammatory cytokines in SARS-CoV–stimulated alternatively activated MDM, resulted in a greater than 10-fold increase in IL-6, an 8-fold increase in MCP1, and a 5-fold increase in IL-8 (Figure 6, D and E). This enhancement, however, was not observed when S-IgG sera were replaced with sera from C-IgG recipients or healthy macaques (Figure 6, F, G, and H), suggesting that S-IgG, but not other sera components, enhanced SARS-CoV–stimulated cytokine production by alternatively activated MDM. Administration of S-IgG sera had no effect on cytokine production by SARS-CoV–treated classically activated MDM (Figure 6, I, J, and K), indicating that S-IgG do not modulate virus-mediated classically activated macrophage functional response. MCP1 and IL-8 are key cytokines that regulate monocytes/macrophages migration and promote neutrophils infiltration, while IL-6 promotes persistent inflammation and injury. These results suggest that, in response to SARS-CoV infection, wound-healing macrophages produce IL-8 and low amounts of MCP1 to recruit neutrophils and blood monocytes, whereas the presence

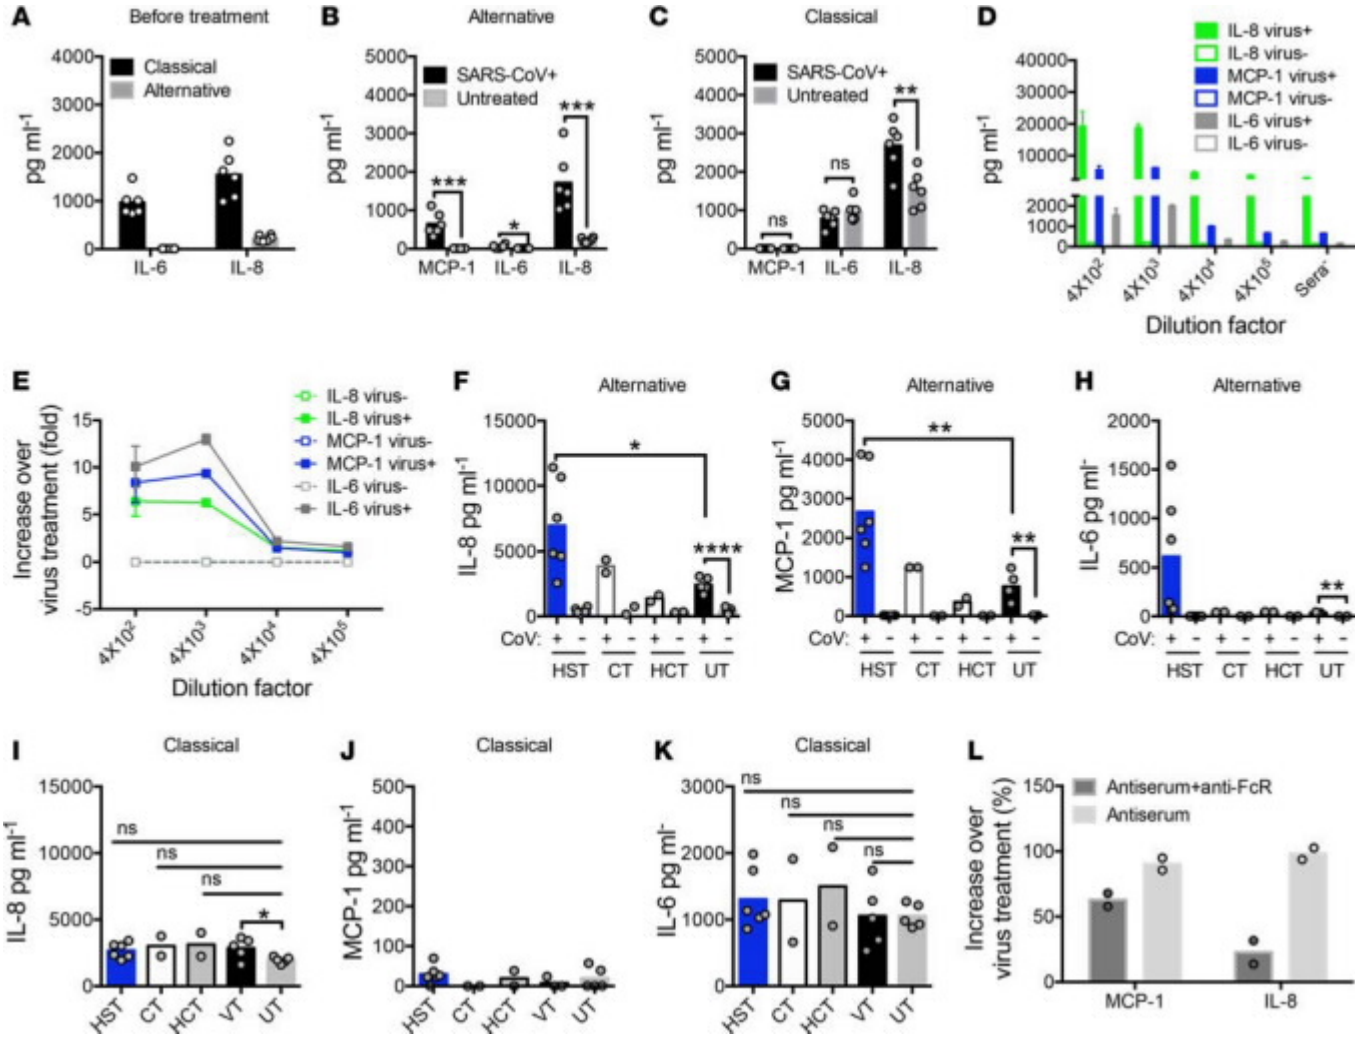

Figure 6. S-IgG significantly amplified proinflammatory cytokine production by SARS-CoV–treated alternatively activated macrophages. In vit polarized alternatively activated macrophages were either left unstimulated or were incubated with SARS-CoV pseudovirus alone or cocultured with SARS-CoV pseudovirus and diluted sera from the high-dose S-IgG group (n = 6) or C-IgG group (n = 2) collected at 2 dpi or from healthy macaques (n = 2) for 20 hours. Secreted cytokine and chemokine levels were measured in the culture supernatant and are shown in data represented as a column graph (**A–D** and **F–K**) and fold or percentage over supernatants from macrophages treated with virus alone and (**E**). **A** shows the levels of IL-8 and IL-6 in the supernatant of classically activated and alternatively activated MDM before treatment and **B** and **C** show that SARS-CoV treatment induced MCP1, IL-8, and very low levels of IL-6 production by alternatively activated MDM, as well as enhanced IL-8 production by classically activated MDM. **D** and **E** show that sera from S-IgG recipients caused dose-dependent increase in cytokine production from SARS-CoV–treated alternatively activated MDM. **F–H** show that virus treated alternatively activated MDM (VT), but not sera treated or untreated cells (UT), secreted proinflammatory cytokines IL-8 (**F**), MCP1 (**G**), and very low levels of IL-6 (**H**). Addition of sera (1:4,000 dilutions) from high-dose S-IgG (HST), but not C-IgG treated macaques (CT) or healthy controls (HCT), significantly amplified IL-8 (**F**), MCP1 (**G**), and IL-6 (**H**) production. **I–K** show that addition of sera (1:4,000 diluted) from high-dose S-IgG–treated (HST), C-IgG treated macaques (CT), or healthy controls (HCT) had no effect on MCP-1 (**J**), and IL-6 (**K**) production by SARS-CoV–treated classically activated MDM. **L** shows that blockade of FcγR significantly reduced antiserum-enhanced IL-8 secretion and partially reduced MCP1 secretion. Data represent mean values or mean values ± SEM of at least 3 independent experiments. Two-tailed unpaired Student's t test was used for statistical analysis. *P ≤ 0.05; **P < 0.01; ***P < 0.001; ****P < 0.0001.

of S-IgG can result in 5- to 10-fold increases in IL-8, MCP1, and IL-6 production by wound-healing macrophages, leading to significantly enhanced and persistent monocytes infiltration and tissue injury. Critically, in the presence of Fcγ receptor (FcγR) blocking antibody, IL-8 was significantly reduced when cells were treated with SARS-CoV pseudovirus and sera from high-dose S-IgG–treated macaques (diluted 1:4,000), indicating that anti–SARS-CoV antibody modifies wound-healing response partially through FcγRs (Figure 6L). Therefore, we conclude that S-IgG directly modifies functional response of alternatively activated macrophages during acute infection, thus skewing wound-healing response, leading to hypercytokinemia, aggressive inflammation and severe lung injury.

Deceased SARS patients displayed higher levels of serum NAbs, accumulated proinflammatory macrophage infiltration, and absence of wound-healing macrophages in the lungs. To examine the role of S-IgG in promoting ALI in a clinical setting, we investigated antibody responses during the early stage of infection in 2 groups of deceased patients or individuals recovered from SARS and characterized the heterogeneity of monocytes/macrophages in the lungs of 3 deceased SARS patients. H&E staining of lung specimens derived from 3 deceased SARS patients revealed severe ALI (Figure 7A). Consistent with the macaque findings, IHC analysis revealed significant infiltration of $CD163^+$ monocytes/macrophages into the lungs of patients, with little TGF-β expression and loss of the wound-healing marker $CD206^+$, indicating predominantly proinflammatory macrophage activation and reduced inflammatory-resolving response (Figure 7B). Moreover, significantly higher levels of anti-S NAbs were detected in the sera of deceased patients (n = 6) during acute infection compared with recovered patients (n = 8) (Figure 7C). These results, therefore, are consistent with findings in experimental macaques.

Antisera from deceased SARS patients skewed wound-healing response during SARS-CoV infection partially through the FcγR. To examine whether human anti–SARS-CoV antibody modifies wound-healing response during SARS-CoV infection, we treated in vitro–polarized alternatively activated MDM with SARS-CoV pseudovirus for 20 hours in the presence of sera collected from SARS patients during acute infection. Macrophages treated with SARS-CoV pseudovirus or sera alone were included as controls. We then examined the protein levels of cytokines/chemokines in the cell culture supernatant. Consistent with findings in macaques, administration of sera from a deceased SARS patient (D1; Supplemental Table 5) into SARS-CoV–treated alternatively activated MDM caused a dose-dependent increase in the production of cytokines, leading to a 2- to 3-fold increase in MCP1 and IL-8 after 20 hours (Figure 8, A and B). This enhancement, however, was not observed in cells treated with sera alone (Figure 8, A–D). Administration of sera from recovered patients (n = 8; Supplemental Table 5) had no effect on cytokine production except 1 sample (Figure 8, C and D). These differences may be explained, at least in part, by their lower NAb titers, although it is also possible that sera from recovered patients contain different antibody populations. Consistently, the only serum sample — R2, which enhanced chemokine production — has a relatively higher NAb titer among the samples tested (Supplemental Table 5). Moreover, statistical analysis shows that IL-8 production strongly correlates with NAb titer of sera from deceased patients (Figure 8E). Furthermore, IL-8 production was significantly reduced when cells were treated with SARS-CoV pseudovirus and sera from deceased SARS patient (diluted 1:4,000) in the presence of FcγR blocking antibody, indicating that anti–SARS-CoV antibody modifies wound-healing response in humans partially through FcγRs (Figure 8F).

Discussion

Here, we present evidence of a detrimental role of anti–S-IgG in ALI during SARS-CoV infection. Respiratory CoVs infection poses a unique challenge to the immune system: not only must the virus be rapidly eliminated, but lung inflammation must also be controlled to prevent acute respiratory failure (33). In the present study, we show that, despite markedly reducing virus titers, anti–S-IgG caused lung injury during the early stages of infection by abrogating a wound-healing macrophage response and TGF-β production, while promoting proinflammatory cytokine IL-8 and MCP1 production and inflammatory macrophage accumulation. To our knowledge, our data demonstrate a previously unrecognized mechanism underlying virus-mediated ALI and suggest that modulation of the anti-S antibody response or blockage of Fcγ receptors during acute infection might be needed for effective treatment for respiratory CoV infection.

Many studies have demonstrated the role of NAbs induced by the S glycoproteins in protecting viral replication in susceptible hosts, including mice, ferrets, hamsters, and macaques (24, 34, 35). However, the effect of S-specific immunity in protecting against pulmonary immunopathology has been controversial. In some cases, vaccination-induced immunity assists the viral clearance and protects mice or ferrets against lethal challenge (36–39), whereas in many other situations, multiple vaccine platforms appear to induce increased eosinophilic proinflammatory pulmonary response upon challenge (18, 23, 40). These differences may be explained, in part, by the characteristics of the vaccine being studied, the infectious dose, and the viral strain employed, as well as by the type or quality of immune response elicited. Recent studies suggest that $CD8^+$ T cell response plays a crucial role in viral clearance and protection of mice against eosinophilic immunopathology and lethal SARS-CoV infection, whereas immunopathology predominantly reflects an inadequate vaccine-induced Th1 response (20–23).

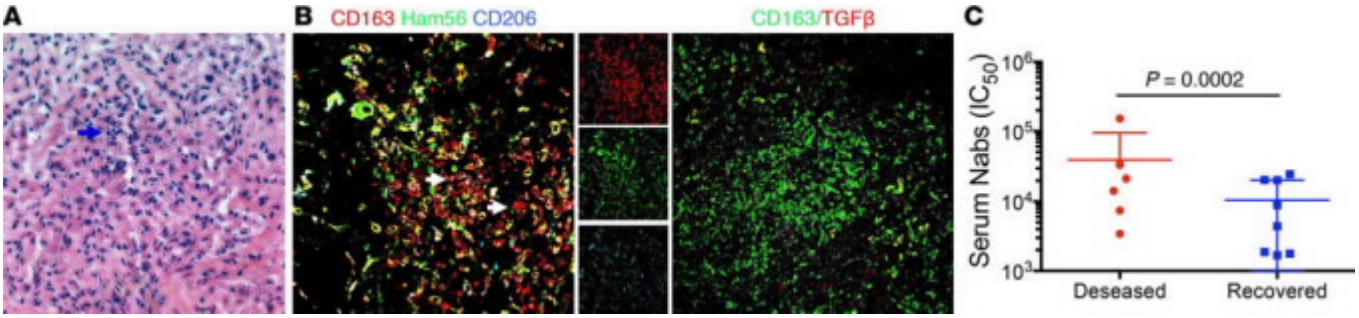

Figure 7. NAb response and phenotype analysis of accumulating monocytes/macrophages in the lungs in deceased SARS patients. (**A**) Pathological changes of the lung tissue. Sections from deceased SARS patients were stained with H&E. A representative of 3 patients (original magnification, 100×), showing symptom of acute DAD with massive cell infiltration in alveolar cavities (blue arrow). (**B**) Massive accumulation of IMMs and absence of wound-healing macrophage response in the lungs of deceased patients. These sections were triple-immunostained with antibodies for CD206 (cyan), HAM56 (FITC), and CD163 (TRITC) or double-immunostained with TGF-β (FITC) and CD163 (FITC) (original magnification, 200×). The right panel in the left image shows single colors from the left image (200×). These representative images show accumulation of IMMs (CD163+HAM56+, white arrows) and the absence of wound-healing response, indicated by loss of the signal for CD206 (cyan, B1) and TGF-β (B2) in the lungs. (**C**) Serum-neutralizing activity against SARS-CoV. Sera collected from deceased ($n = 6$), or recovered (blue, $n = 8$) SARS patients at the early stage of infection were tested for the capacity to neutralize SARS-CoV pseudotype virus. Two-tailed unpaired Student's *t* test was used for statistical analysis.

In fact, a protective effect against pulmonary immunopathology mediated by full length S protein–based vaccine in SARS-CoV–infected nonhuman primate models has not been described, to our knowledge. Although several vaccine candidates protected macaques against viral replication in the lungs, pulmonary immunopathology was not evaluated in these studies (24, 41, 42). By contrast, it was shown that SARS-CoV–specific immune memory induced by prior infection enhanced lung inflammation following homologous challenge in African green monkeys (17). Similarly, augmentation of disease by vaccination has also been described in studies of atypical measles and dengue hemorrhagic fever, as well as several respiratory diseases, including respiratory syncytial virus (RSV) and pandemic influenza (16, 43). In the study of RSV vaccine conducted in 1966 and 1967, 80% of RSV vaccinees needed hospitalization, whereas only 5% of RSV-infected children in the control vaccine group required admission, although the underlying mechanisms remain incompletely understood. Using Chinese rhesus macaques, we show that an ADS-MVA–based vaccine protected macaques against viral replication but significantly enhanced acute DAD at both 7 and 35 dpi compared with the control ADC-MVA group, suggesting that S-specific but not MVA-specific immunity promotes ALI (Figure 1). Until now, it remains unknown if SARS vaccine candidates with a focus on the receptor-binding domain (RBD) of S protein can avoid the induction of ALI in nonhuman primates. These vaccines have been shown to induce highly potent NAb responses and elicit long-term protective immunity in immunized small animals (38).

SARS-CoV infection of Chinese macaques is often characterized by the rapid control of viral replication with mild lung lesions in most macaques (25). The mechanisms underlying why Chinese macaques do not often develop ALI, as observed in most SARS patients, are largely unknown. Our data suggest that these effects, in part, reflect the rapid control of viral replication in the lungs, which peaked between 24 and 48 hours after inoculation (hpi) and diminished within 7 days, thus creating an interval between lung inflammation and high titer antibody production in most macaques. Indeed, although SARS-CoV infection resulted in significant infiltration of macrophages in the lungs, the number of macrophages was rapidly reduced following virus clearance at 3 dpi (Figure 5). At 7 dpi, inflammation appeared to be mostly resolved (Figure 5). By contrast, control of virus replication is less efficient in SARS patients, and the peak in viral load coincides with the first appearance of an antibody response, approximately 10 days after the onset of symptoms (6).

The low rate of ALI and interval between lung inflammation resolution and antibody production, however, makes Chinese macaques an ideal animal model for the present study. Using vaccination and passive immunization, we conditioned anti-S antibody titers in macaques during the early stage of infection when ALI was not typically observed. We found that prior administration of anti–S-IgG led to massive accumulation of monocytes/macrophages in the lungs within 2 dpi. This result is consistent with previous reports, in which mice given the SARS vaccine exhibited an immunopathologic lung reaction after the subsequent challenge with SARS-CoV (18, 19). Moreover, in SARS patients, clinical course and outcome are more favorable in children younger than 12 years of age compared with adolescents and adults (44), indicating that prior alternative CoV infection might

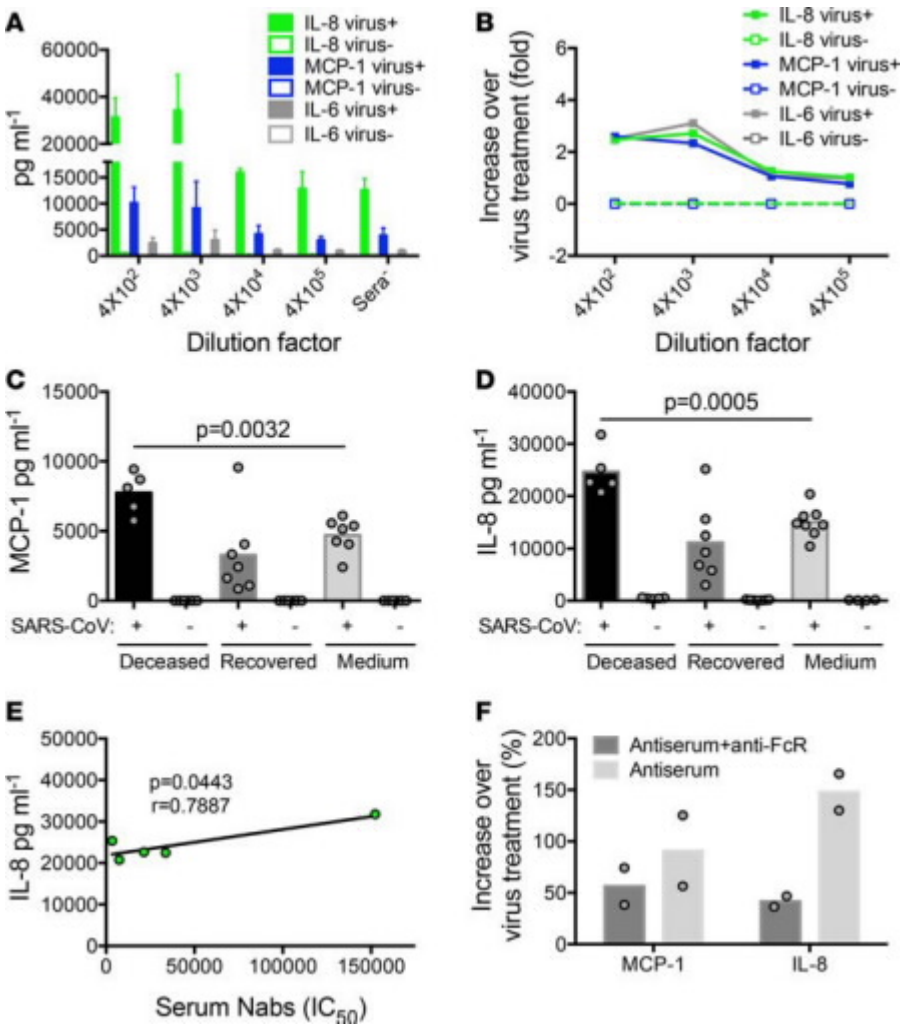

Figure 8. Sera from deceased SARS patients skewed wound-healing macrophage response partially through FcγR. In vitro–polarized alternatively activated MDM were either left unstimulated or were incubated with SARS-CoV pseudovirus alone or cocultured with SARS-CoV pseudovirus and 1–400,000 serials diluted or 1/4,000 diluted sera from deceased (n = 5) or recovered SARS patients (n = 7) for 20 hours. Cells treated with sera from patients alone served as controls. Secreted cytokine and chemokine levels were measured in the culture supernatant and are shown in data represented as a column graph (**A**, **C**, and **D**) and fold or percentage over supernatants from macrophages treated with virus alone (**B** and **F**). **A** and **B** show that addition of sera from deceased patient (D1) dose-dependently enhanced production of IL-8, IL-6, and MCP-1 by SARS-CoV–treated alternatively activated MDM. **C** and **D** show significantly enhanced IL-8 and MCP-1 production by alternatively activated macrophages treated with sera from deceased SARS patients and virus compared with cells treated with virus alone. Sera treatment alone did not induce IL-8 or MCP-1 production. (**E**) Correlation of IL-8 production with NAb titers of sera of deceased patients. Solid lines denote the relationship between histopathology scores and serum neutralizing activity. (**F**) Blockade of human FcγR significantly reduced antiserum-enhanced IL-8 secretion and partially reduced MCP-1 secretion. In vitro–polarized alternatively activated human monocyte–derived macrophages were cocultured with SARS-CoV pseudovirus and 1–4,000 diluted sera from deceased patient (D1) with or without FcγR blocking antibody for 20 hours. Secreted cytokine and chemokine levels were measured in the culture supernatant and are shown in data represented as increase over supernatants from macrophages treated with virus alone. Data represent mean values or mean values ± SEM of at least 3 independent experiments. Two-tailed unpaired Student's t test and Spearman's rank correlation test were used for statistical analysis.

play a role in driving enhanced pulmonary inflammation. A recent study reported that pathogenic immune complexes promoted lung injury during the 2009 H1N1 pandemic (16). It remains unknown whether immune complexes may also play a role in driving ALI during SARS-CoV infection.

Detailed analyses of macrophage heterogeneity at different stages of infection and in lungs with severe injury or mild lesion revealed distinct roles for proinflammatory and wound-healing macrophages in SARS disease progression. We observed that the early transition of macrophage responses from proinflammatory

to wound healing with increased TGF-β expression is associated with inflammation resolution and mild lung injury. By contrast, abrogated wound healing by S-IgG resulted in decreased TGF-β production and prolonged classical macrophage activation, and it promoted severe lung injury. Our findings are primarily based on imaging of formalin-fixed tissues of infected macaques, which may have technical limitations. A detailed flow cytometric analysis would be helpful to further characterize macrophage subpopulations in infected lungs. Unfortunately, we were not allowed to obtain any live cells, including macrophages, for analysis by flow cytometry outside the BSL-3 laboratory in China, which is in line with "WHO biosafety guidelines for handling of SARS specimens" (https://www.who.int/csr/sars/biosafety2003_04_25/en/). Having said this, TGF-β is mainly derived from wound-healing macrophages but not from classically activated macrophages. Therefore, by staining both TGF-β and CD206 (another biomarker of wound-healing macrophages), we believe that the finding of reduction of this type of macrophages in the S-IgG–treated lungs is convincing.

Patients who received convalescent plasma from recovered SARS patients had shorter hospital stays and lower mortality rates without evident adverse effects (45–47). These results might reflect a different quality of antibodies in recovered patients from deceased patients during early infection. Indeed, we previously observed that deceased patients had significantly higher NAbs with a very low level of anti-N antibodies in serum during the early stage of infection (14). In contrast, recovered patients had more rapid anti-N antibody and slower NAb development (14). Consistently, serum from deceased patients — but not SARS survivors during early stages of infection — enhanced IL-6, IL-8, and MCP1 production by wound-healing macrophages (Figure 8). We previously identified epitopes in S protein that elicited NAbs and antibodies that enhanced SARS-CoV infection (48, 49). Further studies that will attempt to identify antibodies and epitopes that mediate prevention or enhancement of ALI might be needed for future vaccine design and immunotherapy.

Lastly, blockade of FcγRs reduced proinflammatory cytokine production, suggesting a potential role of FcγRs for the postulated reprogramming of alternatively activated macrophage FcγRs are functionally divided into activating and inhibitory receptors. Activating FcγRs, such as FcγRI, FcγRIIA, and FcγRIII, triggers production of proinflammatory chemokines and cytokines through an immunoreceptor tyrosine–based activation motif (ITAM) in their intracytoplasmic domain and SRC family kinases and spleen tyrosine kinase (SYK), whereas the inhibitory FcγR, FcγRIIB, has an immunoreceptor tyrosine–based inhibition motif (ITIM) in its intracytoplasmic domain and counteracts the signals that are mediated by activating FcγRs. Based on literature and our experiments, human monocyte–derived wound-healing macrophages express higher levels of CD16 (FcγRIII) and CD32A (FcγRIIA) (50). Therefore, it is likely that S-IgG promoted proinflammatory cytokine production through FcγRI and/or FcγRIIA. S-IgG did not affect classically activated macrophage function in vitro. This difference can be possibly explained by the high baseline level of proinflammatory cytokines before infection and the downregulated expression of FcγRs on classically activated MDM by SARS-CoV treatment.

Methods

Immunization of animals. We vaccinated Chinese rhesus macaques as previously described (51). Briefly, 16 Chinese rhesus monkeys were immunized twice on days 0 and 28. Eight of these animals received ADS-MVA, whereas the other 8 animals received ADC-MVA. ADS-MVA and ADC-MVA vectors encoding SARS-CoV S protein or HCV E1E2 were constructed and produced as previously described (51). The dose for both immunizations was 5×10^8 $TCID_{50}$. The vaccine strain SARS-CoV HKU39849 (AY278491) shares 100% sequence homology of the S gene with the challenge strain $SARS\text{-}CoV_{PUMC}$ (AY350750).

Animals, tissues, and SARS-CoV infection. SARS-CoV–infected animals and control animals were all adult female Chinese rhesus macaques. A total of 42 Chinese rhesus macaques were challenged i.n. with a live pathogenic SARS-CoV (PUM, $TCID_{50}$ = 50) as previously described (25). An additional 3 uninfected macaques were inoculated with PBS as negative controls. Animals were subjected to daily measurement of anal temperature, routine blood assays, and chest radiography. Animals were euthanized at 2, 3, 7, 21, and 35 days after inoculation (Figure 1, Figure 2, and Figure 6). All animals were humanely euthanized with an i.v. overdose of pentobarbital and were immediately necropsied. Lung tissues (left and right cranial, middle and caudal lobes, and right accessory lobe) were collected and fixed in 10% neutral-buffered formalin, embedded in paraffin, and sectioned at 5 μm.

Passive transfer of IgG. SARS-CoV S protein–immune serum was generated by vaccination with ADS-MVA vectors. IgG was purified from pooled sera by protein G affinity chromatography to >95% purity. IgG was depyrogenated, concentrated to 20–30 mg protein ml^{-1}, and administered i.v. Recipients received 200 mg or 5 mg of purified IgG per kg body weight at 48 hours before the viral challenge.

Neutralization. A neutralization assay was established to determine the humoral immune responses generated by the vaccine as previously described (51). The neutralizing activity of heat-inactivated animal sera was determined using a pseudotype viral entry assay. The pseudotype virus was generated through cotransfection of 293T cells with 2 plasmids, pcDNA-Sopt9 and pNL4-3Luc_Env_Vpr_, carrying the optimized S gene and a human immunodeficiency virus type 1 backbone, respectively. The serial diluted serum samples were incubated with equal amounts of pseudotype virus at 37°C for 1 hour. The serum-virus mixtures were subsequently added into preseeded HEK 293T-ACE2 cells. After 56 hours, infected cells were lysed to measure luciferase activity.

Nested RT-PCR and isolation of SARS-CoV. Pharyngeal swab samples were collected from infected monkeys on the first day after inoculation and subsequently tested for SARS-CoV using nested RT-PCR as previously described (25). Briefly, RNA was isolated using TRIZOL (Invitrogen). RT-PCR was performed in a 50 μl reaction volume with outer primer pair (5′-GCTGCATTGGTTTGTTATATCGTTA-TGC-3′) and (5′-ATACAGAATACAT-AGATTGCTGTTATCC-3′), inner primer pair (5′-TCACTTGCTTC-CGTTGAGGTAGC-CAGCGTGGT-GGTTCATACAA-3′) and (5′-GGTTTCGGATGTTACAGC-GTCTCCCGG-CAGAAAGCTGTAAGCT-3′). All PCR products were verified by nucleotide sequencing. SARS-CoV was isolated as previously described. Briefly, pharyngeal swab samples from the infected macaques were inoculated onto Vero-E6 cells and cultured in DMEM (Thermo Fisher Scientific). Both cytopathic effect (CPE) and immunofluorescence assay (IFA) (incubation with 1:10 dilution of SARS patient serum) were used to determine the infection status of the animals.

Double and triple immunofluorescence staining on paraffin sections. The samples were deparaffinized and rehydrated. After blocking with normal goat serum for 30 minutes at room temperature, a rabbit anti–SARS-CoV nucleocapsid antibody (ss-006-0100, ENZYME) was applied at 4°C overnight, followed by an Alexa Fluor 448 conjugated goat anti–rabbit IgG antibody for 1 hour at room temperature. Additional immunofluorescence staining was subsequently performed by overnight incubation with primary antibodies, followed by the detection of signals using appropriate fluorescent secondary antibodies (MilliporeSigma) for 1 hour at room temperature.

Primary antibodies for immunofluresence staining. The following primary antibodies were used in this study: SARS-CoV NP (ss-006-0100, ENZYME); MAC387 (clone MAC387, AbD, Serotec); CD68 (clone KPI, DAKO; ab125047, Abcam); CD163 (clone EDHu1, AbD and ab183476, Abcam); HAM56 (clone HAM56, DAKO); CD206 (HPA004114, MilliporeSigma); TGF-β (sc-146, Santa Cruz Biotechnology Inc.); IL-6 (sc-1265, Santa Cruz Biotechnology Inc.); AE1/AE3 (clone AE1/AE3, DAKO).

ISH studies. ISH was developed for the detection of SARS-CoV. DNA fragments of N and S proteins from the SARS-CoV strain from Hong Kong (AY278491) were used as templates to generate RNA probes. The probes were labeled with digoxigenin (GENEWIZ Inc.). After deparaffinization and rehydration, the sections were treated with microwave heating in an 800 W domestic microwave oven (NN-ST556M, Panasonic) at medium power for 10 minutes in 0.01 M sodium citrate buffer. Hybridization was performed at high stringency with 150 ng/ml of denatured probe at 45°C for 16 hours in 50 μl of hybridization mix (50% formamide, 10% dextran sulfate in 2× saline sodium citrate [SSC]) in a moist chamber. Excess probe was removed by washing twice in 2× SSC for 20 minutes at 45°C, followed by 2 washes in 1× SSC and 0.1× SSC for 20 minutes at 45°C. Immunological detection was conducted using the DIG Nuclear Acid Detection Kit (Roche Diagnostics) according to the manufacturer's instructions. Briefly, after incubation with 1% blocking reagent for 30 minutes, the sections were incubated with sheep anti-digoxigenin alkaline phosphatase conjugate (11093274910, Roche Diagnostics) diluted at 1: 500 for 2 hours at room temperature. After 3 separate washes with washing buffer (0.1 M maleic acid, 0.15 M NaCl [pH 7.5], 0.3% Tween 20), the signal was developed using 200 μl of a HNPP/Fast Red TR mix (1758888, Roche Diagnostics) in the dark for 45 minutes. The sections were counterstained with DAPI. Tissue sections incubated with sense RNA probe were used as a negative control.

Confocal microscopy. Confocal microscopy was performed using a Carl Zeiss LSM 700 confocal microscope equipped with 4 lasers (Zeiss). ZEN (Zeiss) was used to assign colors to the 4 channels collected: Alexa Fluor 568 and HNPP/Fast Red, which fluoresces when exposed to a 568-nm wavelength laser and appears red; Alexa Fluor 488 (Molecular Probes), which appears green; Alexa Fluor 647 (Molecular Probes), which appears cyan; and the differential interference contrast (DIC) image, which is in gray scale. The 4 channels were simultaneously collected. To differentiate between individual cells, Hoechst 33258 (nuclear marker; Molecular Probes) was used at 1 μg/ml and incubated for 5 minutes, followed by rinsing with water. The colocalization of antigens was demonstrated by the addition of colors as indicated in the figure legend.

Monocyte isolation, differentiation, and polarization of macrophages. Monocytes were purified from peripheral blood mononuclear cells obtained from blood buffy coats (provided by Red Cross, Hong Kong, China) or monkey peripheral blood, as we previously described (52). Monkey peripheral blood was obtained in heparinized vacutainer collection tubes from healthy female rhesus monkeys. To generate M1 macrophages, monocytes were differentiated in RPMI 1640 medium (Thermo Fisher Scientific) supplemented with GM-CSF (400 IU/ml), 2 mM glutamine, 10% decomplemented FCS, 100 IU/ml penicillin, and 100 μg/ml streptomycin (Thermo Fisher Scientific) for 4 days, followed by exposure to fresh medium supplemented with 5% FCS and containing GM-CSF and LPS (100 ng/ml) + IFN-γ (20 ng/ml) for an additional 72 hours. To generate M2 macrophages, monocytes were differentiated in RPMI 1640 medium (Thermo Fisher Scientific) supplemented with M-CSF (50 ng/ml), 2 mM glutamine, 10% decomplemented FCS, 100 IU/ml penicillin, and 100 μg/ml streptomycin for 4 days, followed by exposure to fresh medium supplemented with 5% FCS and containing M-CSF (50 ng/ml) + IL-4 (20 ng/ml) for an additional 72 hours.

Quantification of cytokine levels. A panel of 13 cytokines, including IL-1β, IFN-α, IFN-γ, TNF-α, MCP1, IL-6, IL-8, IL-10, IL-12p70, IL-17A, IL-18, IL-23, and IL-33 in monkey sera and in culture medium were quantified using multiplexing laser bead technology (BioLegend). To assess the cytokine production of macrophages, in vitro–polarized cells were washed 3 times with PBS and were subsequently activated with SARS-CoV pseudotype virus in RPMI 1640 medium (Thermo Fisher Scientific) with or without administration of highly diluted and heat-inactivated (56°C) sera from macaques or SARS patients. FcγR-specific mouse monoclonal antibody (5 μg, clone 3G8, anti-hCD16, 16016682; clone FLI8.26, anti-hCD32, 16032981; and clone 10.1, anti-hCD64, 16064981 [BD Pharmingen]) was used for blockade of human FcγR. The supernatant of these cultures was recovered after 20 hours of stimulation, and the cytokine levels were measured and analyzed.

Statistics. All statistical analyses were performed using the 2-tailed Student's *t* test. *P* values less than 0.05 were considered statistically significant. Data are presented as the mean values ± SEM of at least 3 independent experiments unless otherwise indicated.

Study approval. The experiment was conducted in a Biosafety Level 3 animal facility. Handling and experimental procedures, including injections, blood collection, virus challenge, and sacrificing were approved and performed according to the animal welfare committee on the Use of Live Animals in Teaching and Research of Institute of Laboratory Animal Science, Beijing, China. All study subjects gave informed consent, and procedures were reviewed and approved by the University of Hong Kong Research Ethics Committee.

Author contributions

ZC, LL, and QW designed the study. LL and QW analyzed the data. LL, ZC, KYY, SP, and AL contributed to drafting the manuscript. ZC is the principal investigator, with overall responsibility for the design of the study. QW and CQ coordinated the autopsy organization and collection of autopsy materials of Chinese macaques. QW was involved in the development and performance of the RT-PCR assay. LL, HT, TW, and KWC performed the neutralization assay. LL, XA, and AL were involved in the development of the H&E, SARS-CoV IHC, and ISH assays. HW performed the ISH assay and the IHC staining of NP and calculation of the mean florescence intensity in the lungs. LL, HK, and KN performed the H&E and double- or triple-IHC staining. JF and HT performed culture of monocyte-derived macrophages. QL, HT, JP, and ZT performed analysis of cytokine production in cell culture supernatant and monkey sera. KHC and KYY coordinated the collection of sera and tissue sample from SARS patients. All authors were involved in the correlative interpretation of the pathological and molecular data.

Acknowledgments

A SARS-like cluster of circulating bat coronaviruses shows potential for human emergence

Vineet D Menachery[1], Boyd L Yount Jr[1], Kari Debbink[1,2], Sudhakar Agnihothram[3], Lisa E Gralinski[1], Jessica A Plante[1], Rachel L Graham[1], Trevor Scobey[1], Xing-Yi Ge[4], Eric F Donaldson[1], Scott H Randell[5,6], Antonio Lanzavecchia[7], Wayne A Marasco[8,9], Zhengli-Li Shi[4] & Ralph S Baric[1,2]

The emergence of severe acute respiratory syndrome coronavirus (SARS-CoV) and Middle East respiratory syndrome (MERS)-CoV underscores the threat of cross-species transmission events leading to outbreaks in humans. Here we examine the disease potential of a SARS-like virus, SHC014-CoV, which is currently circulating in Chinese horseshoe bat populations[1]. Using the SARS-CoV reverse genetics system[2], we generated and characterized a chimeric virus expressing the spike of bat coronavirus SHC014 in a mouse-adapted SARS-CoV backbone. The results indicate that group 2b viruses encoding the SHC014 spike in a wild-type backbone can efficiently use multiple orthologs of the SARS receptor human angiotensin converting enzyme II (ACE2), replicate efficiently in primary human airway cells and achieve *in vitro* titers equivalent to epidemic strains of SARS-CoV. Additionally, *in vivo* experiments demonstrate replication of the chimeric virus in mouse lung with notable pathogenesis. Evaluation of available SARS-based immune-therapeutic and prophylactic modalities revealed poor efficacy; both monoclonal antibody and vaccine approaches failed to neutralize and protect from infection with CoVs using the novel spike protein. On the basis of these findings, we synthetically re-derived an infectious full-length SHC014 recombinant virus and demonstrate robust viral replication both *in vitro* and *in vivo*. Our work suggests a potential risk of SARS-CoV re-emergence from viruses currently circulating in bat populations.

The emergence of SARS-CoV heralded a new era in the cross-species transmission of severe respiratory illness with globalization leading to rapid spread around the world and massive economic impact[3,4]. Since then, several strains—including influenza A strains H5N1, H1N1 and H7N9 and MERS-CoV—have emerged from animal populations, causing considerable disease, mortality and economic hardship in the afflicted regions[5]. Although public health measures were able to stop the SARS-CoV outbreak[4], recent metagenomics studies have identified sequences of closely related SARS-like viruses circulating in Chinese bat populations that may pose a future threat[1,6–11]. However, sequence data alone provides minimal insights to identify and prepare for future prepandemic viruses. Therefore, to examine the emergence potential (that is, the potential to infect humans) of circulating bat CoVs, we built a chimeric virus encoding a novel, zoonotic CoV spike protein—from the RsSHC014-CoV sequence that was isolated from Chinese horseshoe bats[1]—in the context of the SARS-CoV mouse-adapted backbone. The hybrid virus allowed us to evaluate the ability of the novel spike protein to cause disease independently of other necessary adaptive mutations in its natural backbone. Using this approach, we characterized CoV infection mediated by the SHC014 spike protein in primary human airway cells and *in vivo*, and tested the efficacy of available immune therapeutics against SHC014-CoV. Together, the strategy translates metagenomics data to help predict and prepare for future emergent viruses.

The sequences of SHC014 and the related RsWIV1-CoV show that these CoVs are the closest relatives to the epidemic SARS-CoV strains (**Fig. 1a**,**b**); however, there are important differences in the 14 residues that bind human ACE2, the receptor for SARS-CoV, including the five that are critical for host range: Y442, L472, N479, T487 and Y491 (ref. 7). In WIV1, three of these residues vary from the epidemic SARS-CoV Urbani strain, but they were not expected to alter binding to ACE2 (**Supplementary Fig. 1a** and **Supplementary Table 1**). This fact is confirmed by both pseudotyping experiments that measured the ability of lentiviruses encoding WIV1 spike proteins to enter cells expressing human ACE2 (**Supplementary Fig. 1**) and by *in vitro* replication assays of WIV1-CoV (ref. 1). In contrast, 7 of 14 ACE2-interaction residues in SHC014 are different from those in SARS-CoV, including all five residues critical for host range (**Supplementary Fig. 1c** and **Supplementary Table 1**). These changes, coupled with

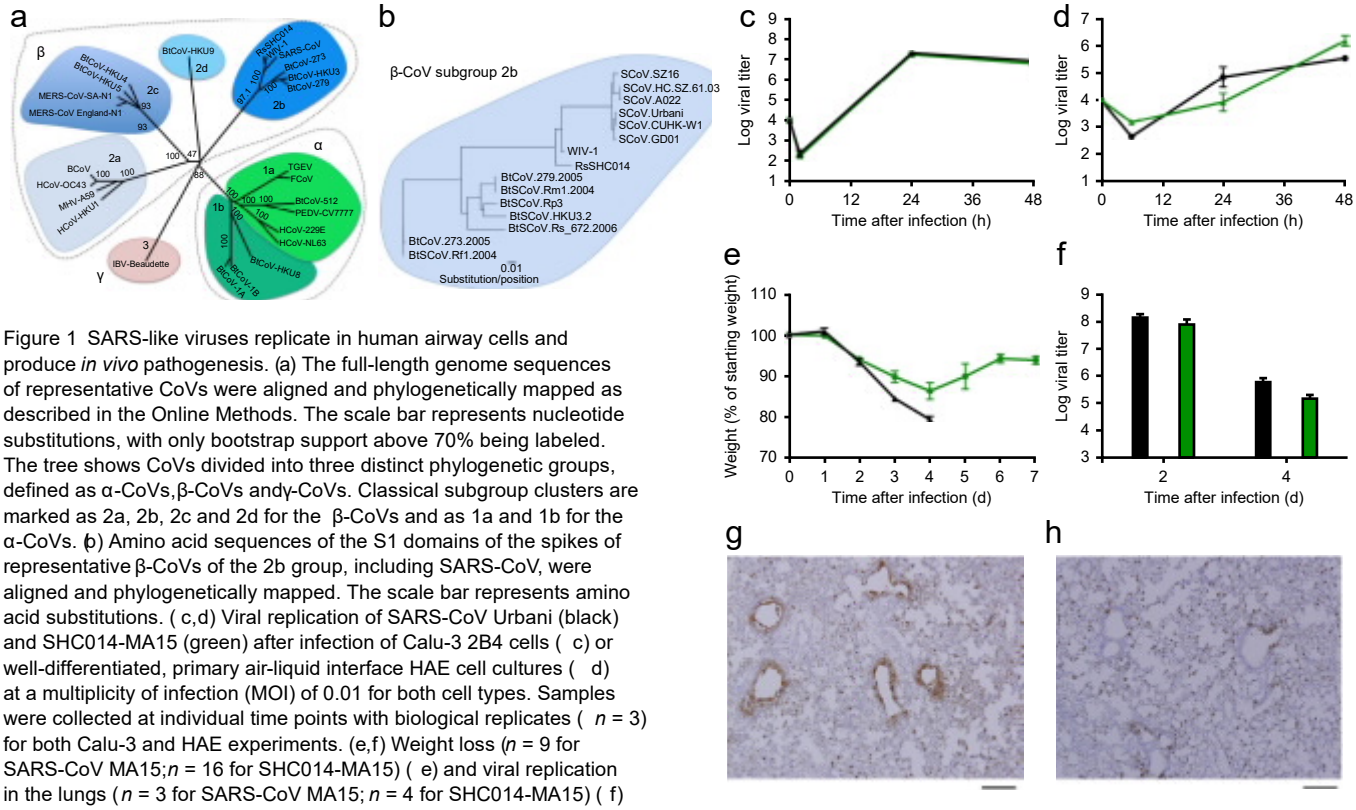

Figure 1 SARS-like viruses replicate in human airway cells and produce *in vivo* pathogenesis. (a) The full-length genome sequences of representative CoVs were aligned and phylogenetically mapped as described in the Online Methods. The scale bar represents nucleotide substitutions, with only bootstrap support above 70% being labeled. The tree shows CoVs divided into three distinct phylogenetic groups, defined as α-CoVs, β-CoVs and γ-CoVs. Classical subgroup clusters are marked as 2a, 2b, 2c and 2d for the β-CoVs and as 1a and 1b for the α-CoVs. (b) Amino acid sequences of the S1 domains of the spikes of representative β-CoVs of the 2b group, including SARS-CoV, were aligned and phylogenetically mapped. The scale bar represents amino acid substitutions. (c,d) Viral replication of SARS-CoV Urbani (black) and SHC014-MA15 (green) after infection of Calu-3 2B4 cells (c) or well-differentiated, primary air-liquid interface HAE cell cultures (d) at a multiplicity of infection (MOI) of 0.01 for both cell types. Samples were collected at individual time points with biological replicates ($n = 3$) for both Calu-3 and HAE experiments. (e,f) Weight loss ($n = 9$ for SARS-CoV MA15; $n = 16$ for SHC014-MA15) (e) and viral replication in the lungs ($n = 3$ for SARS-CoV MA15; $n = 4$ for SHC014-MA15) (f) of 10-week-old BALB/c mice infected with 1×10^4 p.f.u. of mouse-adapted SARS-CoV MA15 (black) or SHC014-MA15 (green) via the intranasal (i.n.) route. (g,h) Representative images of lung sections stained for SARS-CoV N antigen from mice infected with SARS-CoV MA15 ($n = 3$ mice) (g) or SHC014-MA15 ($n = 4$ mice) (h) are shown. For each graph, the center value represents the group mean, and the error bars define the s.e.m. Scale bars, 1 mm.

the failure of pseudotyped lentiviruses expressing the SHC014 spike to enter cells (**Supplementary Fig. 1d**), suggested that the SHC014 spike is unable to bind human ACE2. However, similar changes in related SARS-CoV strains had been reported to allow ACE2-binding[7,8], suggesting that additional functional testing was required for verification. Therefore, we synthesized the SHC014 spike in the context of the replication-competent, mouse-adapted SARS-CoV backbone (we hereafter refer to the chimeric CoV as SHC014-MA15) (**Fig. 1g**) to maximize the opportunity for pathogenesis and vaccine studies in mice (**Supplementary Fig. 2a**). Despite predictions from both structure-based modeling and pseudotyping experiments, SHC014-MA15 was viable and replicated to high titers in Vero cells (**Supplementary Fig. 2b**). Similarly to SARS, SHC014-MA15 also required a functional ACE2 molecule for entry and could use human, civet and bat ACE2 orthologs (**Supplementary Fig. 2c**). To test the ability of the SHC014 spike to mediate infection of the human airway, we examined the sensitivity of the human epithelial airway cell line Calu-3 2B4 (ref. 9) to infection and found robust SHC014-MA15 replication, comparable to that of SARS-CoV Urbani (**Fig. 1c**). To extend these findings, primary human airway epithelial (HAE) cultures were infected and showed robust replication of both viruses (**Fig. 1d**). Together, the data confirm the ability of viruses with the SHC014 spike to infect human airway cells and underscore the potential threat of cross-species transmission of SHC014-CoV.

To evaluate the role of the SHC014 spike in mediating infection *in vivo*, we infected 10-week-old BALB/c mice with 10^4 plaque-forming units (p.f.u.) of either SARS-MA15 or SHC014-MA15 (**Fig. 1e–h**). Animals infected with SARS-MA15 experienced rapid weight loss and lethality by 4 d post infection (d.p.i.); in contrast, SHC014-MA15 infection produced substantial weight loss (10%) but no lethality in mice (**Fig. 1e**). Examination of viral replication revealed nearly equivalent viral titers from the lungs of mice infected with SARS-MA15 or SHC014-MA15 (**Fig. 1f**). Whereas lungs from the SARS-MA15–infected mice showed robust staining in both the terminal bronchioles and the lung parenchyma 2 d.p.i. (**Fig. 1g**), those of SHC014-MA15–infected mice showed reduced airway antigen staining (**Fig. 1h**); in contrast, no deficit in antigen staining was observed in the parenchyma or in the overall histology scoring, suggesting differential infection of lung tissue for SHC014-MA15 (**Supplementary Table 2**). We next analyzed infection in more susceptible, aged (12-month-old) animals. SARS-MA15–infected animals rapidly lost weight and succumbed to infection (**Supplementary Fig. 3a**). SHC014-MA15 infection induced robust and sustained weight loss, but had minimal lethality. Trends in the histology and antigen staining patterns that we observed in young mice were conserved in the older animals (**Supplementary Table 3**). We excluded the possibility that SHC014-MA15 was mediating infection through an alternative receptor on the basis of experiments using *Ace2*$^{-/-}$ mice, which did not show weight loss or antigen staining after SHC014-MA15 infection (**Supplementary Fig. 4a** and **Supplementary Table 2**). Together, the data indicate that viruses with the SHC014 spike are capable of inducing weight loss in mice in the context of a virulent CoV backbone.

Given the preclinical efficacy of Ebola monoclonal antibody therapies, such as ZMApp[10], we next sought to determine the efficacy of SARS-CoV monoclonal antibodies against infection with

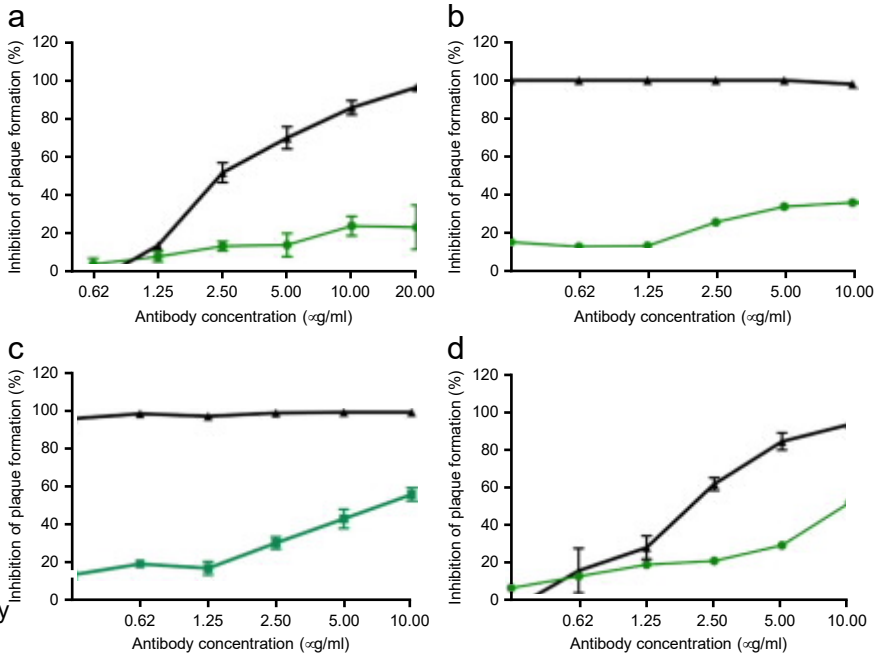

Figure 2 SARS-CoV monoclonal antibodies have marginal efficacy against SARS-like CoVs. (a–d) Neutralization assays evaluating efficacy (measured as reduction in the number of plaques) of a panel of monoclonal antibodies, which were all originally generated against epidemic SARS-CoV, against infection of Vero cells with SARS-CoV Urbani (black) or SHC014-MA15 (green). The antibodies tested were fm6 (n = 3 for Urbani; n = 5 for SHC014-MA15)[11,12] (a), 230.15 (n = 3 for Urbani; n = 2 for SHC014-MA15) (b), 227.15 (n = 3 for Urbani; n = 5 for SHC014-MA15) (c) and 109.8 (n = 3 for Urbani; n = 2 for SHC014-MA15)[13] (d). Each data point represents the group mean and error bars define the s.e.m. Note that the error bars in SARS-CoV Urbani–infected Vero cells in b,c are overlapped by the symbols and are not visible.

SHC014-MA15. Four broadly neutralizing human monoclonal antibodies targeting SARS-CoV spike protein had been previously reported and are probable reagents for immunotherapy[11–13]. We examined the effect of these antibodies on viral replication (expressed as percentage inhibition of viral replication) and found that whereas wild-type SARS-CoV Urbani was strongly neutralized by all four antibodies at relatively low antibody concentrations (**Fig. 2a–d**), neutralization varied for SHC014-MA15. Fm6, an antibody generated by phage display and escape mutants[11,12], achieved only background levels of inhibition of SHC014-MA15 replication (**Fig. 2a**). Similarly, antibodies 230.15 and 227.14, which were derived from memory B cells of SARS-CoV-infected patients[13], also failed to block SHC014-MA15 replication (**Fig. 2b,c**). For all three antibodies, differences between the SARS and SHC014 spike amino acid sequences corresponded to direct or adjacent residue changes found in SARS-CoV escape mutants (fm6 N479R; 230.15 L443V; 227.14 K390Q/E), which probably explains the absence of the antibodies' neutralizing activity against SHC014. Finally, monoclonal antibody 109.8 was able to achieve 50% neutralization of SHC014-MA15, but only at high concentrations (>10 μg/ml) (**Fig. 2d**). Together, the results demonstrate that broadly neutralizing antibodies against SARS-CoV may only have marginal efficacy against emergent SARS-like CoV strains such as SHC014.

To evaluate the efficacy of existing vaccines against infection with SHC014-MA15, we vaccinated aged mice with double-inactivated whole SARS-CoV (DIV). Previous work showed that DIV could neutralize and protect young mice from challenge with a homologous virus[14]; however, the vaccine failed to protect aged animals in which augmented immune pathology was also observed, indicating the possibility of the animals being harmed because of the vaccination[15]. Here we found that DIV did not provide protection from challenge with SHC014-MA15 with regards to weight loss or viral titers (**Supplementary Fig. 5a,b**). Consistent with a previous report with other heterologous group 2b CoVs[15], serum from DIV-vaccinated, aged mice also failed to neutralize SHC014-MA15 (**Supplementary Fig. 5c**). Notably, DIV vaccination resulted in robust immune pathology (**Supplementary Table 4**) and eosinophilia (**Supplementary Fig. 5d–f**). Together, these results confirm that the DIV vaccine would not be protective against infection with SHC014 and could possibly augment disease in the aged vaccinated group.

In contrast to vaccination of mice with DIV, the use of SHC014-MA15 as a live, attenuated vaccine showed potential cross-protection against challenge with SARS-CoV, but the results have important caveats. We infected young mice with 10^4 p.f.u. of SHC014-MA15 and observed them for 28 d. We then challenged the mice with SARS-MA15 at day 29 (**Supplementary Fig. 6a**). The prior infection of the mice with the high dose of SHC014-MA15 conferred protection against challenge with a lethal dose of SARS-MA15, although there was only a minimal SARS-CoV neutralization response from the sera elicited 28 d after SHC014-MA15 infection (**Supplementary Fig. 6b**, 1:200). In the absence of a secondary antigen boost, 28 d.p.i. represents the expected peak of antibody titers and implies that there will be diminished protection against SARS-CoV over time[16,17]. Similar results showing protection against challenge with a lethal dose of SARS-CoV were observed in aged BALB/c mice with respect to weight loss and viral replication (**Supplementary Fig. 6c**). However, the SHC014-MA15 infection dose of 10^4 p.f.u. induced >10% weight loss and lethality in some aged animals (**Fig. 1** and **Supplementary Fig. 3**). We found that vaccination with a lower dose of SHC014-MA15 (10^2 p.f.u.), did not induce weight loss, but it also failed to protect aged animals from a SARS-MA15 lethal dose challenge (**Supplementary Fig. 6e,f**). Together, the data suggest that SHC014-MA15 challenge may confer cross-protection against SARS-CoV through conserved epitopes, but the required dose induces pathogenesis and precludes use as an attenuated vaccine.

Having established that the SHC014 spike has the ability to mediate infection of human cells and cause disease in mice, we next synthesized a full-length SHC014-CoV infectious clone based on the approach used for SARS-CoV (**Fig. 3a**)[2]. Replication in Vero cells revealed no deficit for SHC014-CoV relative to that for SARS-CoV (**Fig. 3b**); however, SHC014-CoV was significantly ($P < 0.01$) attenuated in primary HAE cultures at both 24 and 48 h after infection (**Fig. 3c**). *In vivo* infection of mice demonstrated no significant weight loss but showed reduced viral replication in lungs of full-length SHC014-CoV infection, as compared to SARS-CoV Urbani (**Fig. 3d,e**). Together, the results establish the viability of full-length

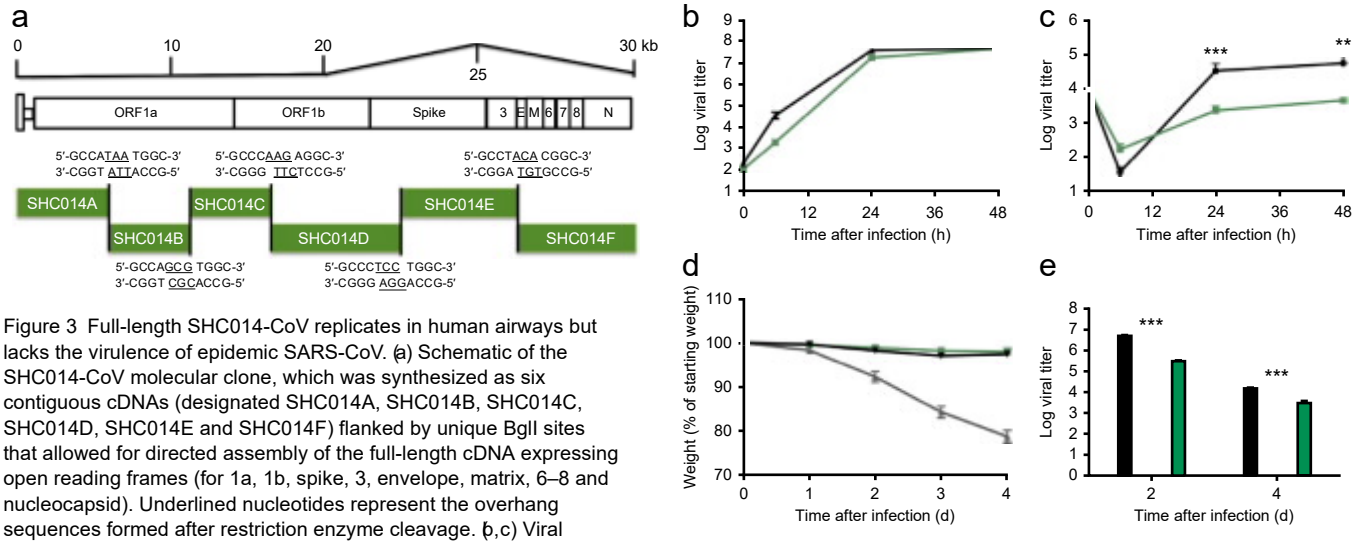

Figure 3 Full-length SHC014-CoV replicates in human airways but lacks the virulence of epidemic SARS-CoV. (a) Schematic of the SHC014-CoV molecular clone, which was synthesized as six contiguous cDNAs (designated SHC014A, SHC014B, SHC014C, SHC014D, SHC014E and SHC014F) flanked by unique BglI sites that allowed for directed assembly of the full-length cDNA expressing open reading frames (for 1a, 1b, spike, 3, envelope, matrix, 6–8 and nucleocapsid). Underlined nucleotides represent the overhang sequences formed after restriction enzyme cleavage. (b,c) Viral replication of SARS-CoV Urbani (black) or SHC014-CoV (green) after infection of Vero cells (b) or well-differentiated, primary air-liquid interface HAE cell cultures (c) at an MOI of 0.01. Samples were collected at individual time points with biological replicates ($n = 3$) for each group. Data represent one experiment for both Vero and HAE cells. (d,e) Weight loss ($n = 3$ for SARS-CoV MA15, $n = 7$ for SHC014-CoV; $n = 6$ for SARS-Urbani) (d) and viral replication in the lungs ($n = 3$ for SARS-Urbani and SHC014-CoV) (e) of 10-week-old BALB/c mice infected with 1×10^5 p.f.u. of SARS-CoV MA15 (gray), SHC014-CoV (green) or SARS-CoV Urbani (black) via the i.n. route. Each data point represents the group mean, and error bars define the s.e.m. ** $P < 0.01$ and *** $P < 0.001$ using two-tailed Student's *t*-test of individual time points.

SHC014-CoV, but suggest that further adaptation is required for its replication to be equivalent to that of epidemic SARS-CoV in human respiratory cells and in mice.

During the SARS-CoV epidemic, links were quickly established between palm civets and the CoV strains that were detected in humans[4]. Building on this finding, the common emergence paradigm argues that epidemic SARS-CoV originated as a bat virus, jumped to civets and incorporated changes within the receptor-binding domain (RBD) to improve binding to civet Ace2 (ref. 8). Subsequent exposure to people in live-animal markets permitted human infection with the civet strain, which, in turn, adapted to become the epidemic strain (**Fig. 4a**). However, phylogenetic analysis suggests that early human SARS strains appear more closely related to bat strains than to civet strains[18]. Therefore, a second paradigm argues that direct bat-human transmission initiated SARS-CoV emergence and that palm civets served as a secondary host and reservoir for continued infection (**Fig. 4b**)[19]. For both paradigms, spike adaptation in a secondary host is seen as a necessity, with most mutations expected to occur within the RBD, thereby facilitating improved infection. Both theories imply that pools of bat CoVs are limited and that host-range mutations are

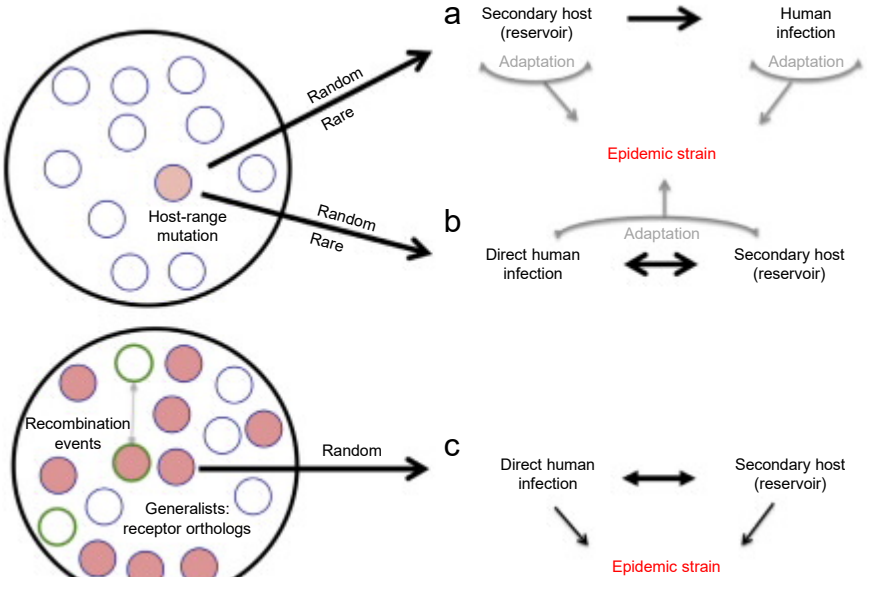

Figure 4 Emergence paradigms for coronaviruses. Coronavirus strains are maintained in quasi-species pools circulating in bat populations. (a,b) Traditional SARS-CoV emergence theories posit that host-range mutants (red circle) represent random and rare occurrences that permit infection of alternative hosts. The secondary-host paradigm (a) argues that a nonhuman host is infected by a bat progenitor virus and, through adaptation, facilitates transmission to humans; subsequent replication in humans leads to the epidemic viral strain. The direct paradigm (b) suggests that transmission occurs between bats and humans without the requirement of an intermediate host; selection then occurs in the human population with closely related viruses replicating in a secondary host, permitting continued viral persistence and adaptation in both. (c) The data from chimeric SARS-like viruses argue that the quasi-species pools maintain multiple viruses capable of infecting human cells without the need for mutations (red circles). Although adaptations in secondary or human hosts may be required for epidemic emergence, if SHC014 spike–containing viruses recombined with virulent CoV backbones (circles with green outlines), then epidemic disease may be the result in humans. Existing data support elements of all three paradigms.

both random and rare, reducing the likelihood of future emergence events in humans.

Although our study does not invalidate the other emergence routes, it does argue for a third paradigm in which circulating bat CoV pools maintain 'poised' spike proteins that are capable of infecting humans without mutation or adaptation (**Fig. 4c**). This hypothesis is illustrated by the ability of a chimeric virus containing the SHC014 spike in a SARS-CoV backbone to cause robust infection in both human airway cultures and in mice without RBD adaptation. Coupled with the observation of previously identified pathogenic CoV backbones[3,20], our results suggest that the starting materials required for SARS-like emergent strains are currently circulating in animal reservoirs. Notably, although full-length SHC014-CoV probably requires additional backbone adaption to mediate human disease, the documented high-frequency recombination events in CoV families underscores the possibility of future emergence and the need for further preparation.

To date, genomics screens of animal populations have primarily been used to identify novel viruses in outbreak settings[21]. The approach here extends these data sets to examine questions of viral emergence and therapeutic efficacy. We consider viruses with the SHC014 spike a potential threat owing to their ability to replicate in primary human airway cultures, the best available model for human disease. In addition, the observed pathogenesis in mice indicates a capacity for SHC014-containing viruses to cause disease in mammalian models, without RBD adaptation. Notably, differential tropism in the lung as compared to that with SARS-MA15 and attenuation of full-length SHC014-CoV in HAE cultures relative to SARS-CoV Urbani suggest that factors beyond ACE2 binding—including spike processivity, receptor bio-availability or antagonism of the host immune responses—may contribute to emergence. However, further testing in nonhuman primates is required to translate these findings into pathogenic potential in humans. Importantly, the failure of available therapeutics defines a critical need for further study and for the development of treatments. With this knowledge, surveillance programs, diagnostic reagents and effective treatments can be produced that are protective against the emergence of group 2b–specific CoVs, such as SHC014, and these can be applied to other CoV branches that maintain similarly heterogeneous pools.

In addition to offering preparation against future emerging viruses, this approach must be considered in the context of the US government–mandated pause on gain-of-function (GOF) studies[22]. On the basis of previous models of emergence (**Fig. 4a,b**), the creation of chimeric viruses such as SHC014-MA15 was not expected to increase pathogenicity. Although SHC014-MA15 is attenuated relative to its parental mouse-adapted SARS-CoV, similar studies examining the pathogenicity of CoVs with the wild-type Urbani spike within the MA15 backbone showed no weight loss in mice and reduced viral replication[23]. Thus, relative to the Urbani spike–MA15 CoV, SHC014-MA15 shows a gain in pathogenesis (**Fig. 1**). On the basis of these findings, scientific review panels may deem similar studies building chimeric viruses based on circulating strains too risky to pursue, as increased pathogenicity in mammalian models cannot be excluded. Coupled with restrictions on mouse-adapted strains and the development of monoclonal antibodies using escape mutants, research into CoV emergence and therapeutic efficacy may be severely limited moving forward. Together, these data and restrictions represent a crossroads of GOF research concerns; the potential to prepare for and mitigate future outbreaks must be weighed against the risk of creating more dangerous pathogens. In developing policies moving forward, it is important to consider the value of the data generated by these studies and whether these types of chimeric virus studies warrant further investigation versus the inherent risks involved.

Overall, our approach has used metagenomics data to identify a potential threat posed by the circulating bat SARS-like CoV SHC014. Because of the ability of chimeric SHC014 viruses to replicate in human airway cultures, cause pathogenesis *in vivo* and escape current therapeutics, there is a need for both surveillance and improved therapeutics against circulating SARS-like viruses. Our approach also unlocks the use of metagenomics data to predict viral emergence and to apply this knowledge in preparing to treat future emerging virus infections.

Note: Any Supplementary Information and Source Data files are available in the online version of the paper.

ACKNOWLEDGMENTS

Research in this manuscript was supported by grants from the National Institute of Allergy & Infectious Disease and the National Institute of Aging of the US National Institutes of Health (NIH) under awards U19AI109761 (R.S.B.), U19AI107810 (R.S.B.), AI085524 (W.A.M.), F32AI102561 (V.D.M.) and K99AG049092 (V.D.M.), and by the National Natural Science Foundation of China awards 81290341 (Z.-L.S.) and 31470260 (X.-Y.G.), and by USAID-EPT-PREDICT funding from EcoHealth Alliance (Z.-L.S.). Human airway epithelial cultures were supported by the National Institute of Diabetes and Digestive and Kidney Disease of the NIH under award NIH DK065988 (S.H.R.). We also thank M.T. Ferris (Dept. of Genetics, University of North Carolina) for the reviewing of statistical approaches and C.T. Tseng (Dept. of Microbiology and Immunology, University of Texas Medical Branch) for providing Calu-3 cells. Experiments with the full-length and chimeric SHC014 recombinant viruses were initiated and performed before the GOF research funding pause and have since been reviewed and approved for continued study by the NIH. The content is solely the responsibility of the authors and does not necessarily represent the official views of the NIH.

AUTHOR CONTRIBUTIONS

V.D.M. designed, coordinated and performed experiments, completed analysis and wrote the manuscript. B.L.Y. designed the infectious clone and recovered chimeric viruses; S.A. completed neutralization assays; L.E.G. helped perform mouse experiments; T.S. and J.A.P. completed mouse experiments and plaque assays; X.-Y.G. performed pseudotyping experiments; K.D. generated structural figures and predictions; E.F.D. generated phylogenetic analysis; R.L.G. completed RNA analysis; S.H.R. provided primary HAE cultures; A.L. and W.A.M. provided critical monoclonal antibody reagents; and Z.-L.S. provided SHC014 spike sequences and plasmids. R.S.B. designed experiments and wrote manuscript.

COMPETING FINANCIAL INTERESTS

The authors declare no competing financial interests.

ONLINE METHODS

Viruses, cells and *in vitro* infection and plaque assays. Wild-type SARS-CoV (Urbani), mouse-adapted SARS-CoV (MA15) and chimeric SARS-like CoVs were cultured on Vero E6 cells (obtained from United States Army Medical Research Institute of Infectious Diseases), grown in Dulbecco's modified Eagle's medium (DMEM) (Gibco, CA) and 5% fetal clone serum (FCS) (Hyclone, South Logan, UT) along with antibiotic/antimycotic (Gibco, Carlsbad, CA). DBT cells (Baric laboratory, source unknown) expressing *ACE2* orthologs have been previously described for both human and civet; *Ace2* sequence was based on that from *Rhinolophus leschenaulti* and DBT cells expressing bat *Ace2* were established as described previously[8]. Pseudotyping experiments were similar to those using an HIV-based pseudovirus, prepared as previously described[10], and examined on HeLa cells (Wuhan Institute of Virology) that expressed *ACE2* orthologs. HeLa cells were grown in minimal essential medium (MEM) (Gibco, CA) supplemented with 10% FCS (Gibco, CA) as previously described[34]. Growth curves in Vero E6, DBT, Calu-3 2B4 and primary human airway epithelial cells were performed as previously described[8,25]. None of the working cell line stocks were authenticated or tested for mycoplasma recently, although the original seed stocks used to create the working stocks are free from contamination. Human lungs for HAE cultures were procured under University of North Carolina at Chapel Hill Institutional Review Board–approved protocols. HAE cultures represent highly differentiated human airway epithelium containing ciliated and non-ciliated epithelial cells as well as goblet cells. The cultures are also grown on an air-liquid interface for several weeks before use, as previously described[26]. Briefly, cells were washed with PBS and inoculated with virus or mock-diluted in PBS for 40 min at 37 °C. After inoculation, cells were washed three times and fresh medium was added to signify time 0. Three or more biological replicates were harvested at each described time point. No blinding was used in any sample collections nor were samples randomized. All virus cultivation was performed in a biosafety level (BSL) 3 laboratory with redundant fans in the biosafety cabinets, as described previously by our group[7]. All personnel wore powered air purifying respirators (Breathe Easy, 3M) with Tyvek suits, aprons and booties and were double-gloved.

Sequence clustering and structural modeling. The full-length genomic sequences and the amino acid sequences of the S1 domains of the spike of representative CoVs were downloaded from Genbank or Pathosystems Resource Integration Center (PATRIC), aligned with ClustalX and phylogenetically compared by using maximum likelihood estimation using 100 bootstraps or by using the PhyML[1] (https://code.google.com/p/phyml/) package, respectively. The tree was generated using maximum likelihood with the PhyML package. The scale bar represents nucleotide substitutions. Only nodes with bootstrap support above 70% are labeled. The tree shows that CoVs are divided into three distinct phylogenetic groups defined as α-CoVs, β-CoVs and γ-CoVs. Classical subgroup clusters are marked as 2a, 2b, 2c and 2d for β-CoVs, and 1a and 1b for the α-CoVs. Structural models were generated using Modeller (Max Planck Institute Bioinformatics Toolkit) to generate homology models for SHC014 and Rs3367 of the SARS RBD in complex with ACE2 based on crystal structure 2AJF (Protein Data Bank). Homology models were visualized and manipulated in MacPyMol (version 1.3).

Construction of SARS-like chimeric viruses. Both wild-type and chimeric viruses were derived from either SARS-CoV Urbani or the corresponding mouse-adapted (SARS-CoV MA15) infectious clone (ic) as previously described[37]. Plasmids containing spike sequences for SHC014 were extracted by restriction digest and ligated into the E and F plasmid of the MA15 infectious clone. The clone was designed and purchased from Bio Basic as six contiguous cDNAs using published sequences flanked by unique class IIS restriction endonuclease sites (BglI). Thereafter, plasmids containing wild-type, chimeric SARS-CoV and SHC014-CoV genome fragments were amplified, excised, ligated and purified. *In vitro* transcription reactions were then preformed to synthesize full-length genomic RNA, which was transfected into Vero E6 cells as previously described[2]. The medium from transfected cells was harvested and served as seed stocks for subsequent experiments. Chimeric and full-length viruses were confirmed by sequence analysis before use in these studies. Synthetic construction of chimeric mutant and full-length SHC014-CoV was approved by the University of North Carolina Institutional Biosafety Committee and the Dual Use Research of Concern committee.

Ethics statement. This study was carried out in accordance with the recommendations for the care and use of animals by the Office of Laboratory Animal Welfare (OLAW), NIH. The Institutional Animal Care and Use Committee (IACUC) of The University of North Carolina at Chapel Hill (UNC, Permit Number A-3410-01) approved the animal study protocol (IACUC #13-033) used in these studies.

Mice and *in vivo* infection. Female, 10-week-old and 12-month-old BALB/cAnNHsD mice were ordered from Harlan Laboratories. Mouse infections were done as previously described[29]. Briefly, animals were brought into a BSL3 laboratory and allowed to acclimate for 1 week before infection. For infection and live-attenuated virus vaccination, mice were anesthetized with a mixture of ketamine and xylazine and infected intranasally, when challenged, with 50 µl of phosphate-buffered saline (PBS) or diluted virus with three or four mice per time point, per infection group per dose as described in the figure legends. For individual mice, notations for infection including failure to inhale the entire dose, bubbling of inoculum from the nose, or infection through the mouth may have led to exclusion of mouse data at the discretion of the researcher; post-infection, no other pre-established exclusion or inclusion criteria are defined. No blinding was used in any animal experiments, and animals were not randomized. For vaccination, young and aged mice were vaccinated by footpad injection with a 20-µl volume of either 0.2 µg of double-inactivated SARS-CoV vaccine with alum or mock PBS; mice were then boosted with the same regimen 22 d later and challenged 21 d thereafter. For all groups, as per protocol, animals were monitored daily for clinical signs of disease (hunching, ruffled fur and reduced activity) for the duration of the experiment. Weight loss was monitored daily for the first 7 d, after which weight monitoring continued until the animals recovered to their initial starting weight or displayed weight gain continuously for 3 d. All mice that lost greater than 20% of their starting body weight were group-fed and further monitored multiple times per day as long as they were under the 20% cutoff. Mice that lost greater than 30% of their starting body weight were immediately sacrificed as per protocol. Any mouse deemed to be moribund or unlikely to recover was also humanely sacrificed at the discretion of the researcher. Euthanasia was performed using an isoflurane overdose and death was confirmed by cervical dislocation. All mouse studies were performed at the University of North Carolina (Animal Welfare Assurance #A3410-01) using protocols approved by the UNC Institutional Animal Care and Use Committee (IACUC).

Histological analysis. The left lung was removed and submerged in 10% buffered formalin (Fisher) without inflation for 1 week. Tissues were embedded in paraffin and 5-µm sections were prepared by the UNC Lineberger Comprehensive Cancer Center histopathology core facility. To determine the extent of antigen staining, sections were stained for viral antigen using a commercially available polyclonal SARS-CoV anti-nucleocapsid antibody (Imgenex) and scored in a blinded manner by for staining of the airway and parenchyma as previously described[29]. Images were captured using an Olympus BX41 microscope with an Olympus DP71 camera.

Virus neutralization assays. Plaque reduction neutralization titer assays were performed with previously characterized antibodies against SARS-CoV, as previously described[11–13]. Briefly, neutralizing antibodies or serum was serially diluted twofold and incubated with 100 p.f.u. of the different infectious clone SARS-CoV strains for 1 h at 37 °C. The virus and antibodies were then added to a 6-well plate with 5×10^5 Vero E6 cells/well with multiple replicates ($n \geq 2$). After a 1-h incubation at 37 °C, cells were overlaid with 3 ml of 0.8% agarose in medium. Plates were incubated for 2 d at 37 °C, stained with neutral red for 3 h and plaques were counted. The percentage of plaque reduction was calculated as (1 − (no. of plaques with antibody/no. of plaques without antibody)) × 100.

© 2015 Nature America, Inc. All rights reserved.

Statistical analysis. All experiments were conducted contrasting two experimental groups (either two viruses, or vaccinated and unvaccinated cohorts). Therefore, significant differences in viral titer and histology scoring were determined by a two-tailed Students *t* test at individual time points. Data was normally distributed in each group being compared and had similar variance.

Biosafety and biosecurity. Reported studies were initiated after the University of North Carolina Institutional Biosafety Committee approved the experimental protocol (Project Title: Generating infectious clones of bat SARS-like CoVs; Lab Safety Plan ID: 20145741; Schedule G ID: 12279). These studies were initiated before the US Government Deliberative Process Research Funding Pause on Selected Gain-of-Function Research Involving Influenza, MERS and SARS Viruses (http://www.phe.gov/s3/dualuse/Documents/gain-of-function.pdf). This paper has been reviewed by the funding agency, the NIH. Continuation of these studies was requested, and this has been approved by the NIH.

SARS-CoV is a select agent. All work for these studies was performed with approved standard operating procedures (SOPs) and safety conditions for SARS-CoV, MERs-CoV and other related CoVs. Our institutional CoV BSL3 facilities have been designed to conform to the safety requirements that are recommended in the Biosafety in Microbiological and Biomedical Laboratories (BMBL), the US Department of Health and Human Services, the Public Health Service, the Centers for Disease Control (CDC) and the NIH. Laboratory safety plans were submitted to, and the facility has been approved for use by, the UNC Department of Environmental Health and Safety (EHS) and the CDC. Electronic card access is required for entry into the facility. All workers have been trained by EHS to safely use powered air purifying respirators (PAPRs), and appropriate work habits in a BSL3 facility and active medical surveillance plans are in place. Our CoV BSL3 facilities contain redundant fans, emergency power to fans and biological safety cabinets and freezers, and our facilities can accommodate SealSafe mouse racks. Materials classified as BSL3 agents consist of SARS-CoV, bat CoV precursor strains, MERS-CoV and mutants derived from these pathogens. Within the BSL3 facilities, experimentation with infectious virus is performed in a certified Class II Biosafety Cabinet (BSC). All members of the staff wear scrubs, Tyvek suits and aprons, PAPRs and shoe covers, and their hands are double-gloved. BSL3 users are subject to a medical surveillance plan monitored by the University Employee Occupational Health Clinic (UEOHC), which includes initially physical, annual influenza vaccination and mandatory reporting of any symptoms associated with CoV infection during periods when working in the BSL3. All BSL3 users are trained in exposure management and reporting protocols, are prepared to self-quarantine and have been trained for safe delivery to a local infectious disease management department in an emergency situation. All potential exposure events are reported and investigated by EHS and UEOHC, with reports filed to both the CDC and the NIH.

ReFRAME Workflow

To improve efficiency and limit excess compound usage, ReFRAME screening follows a strict workflow. A well-defined protocol helps to reduce or eliminate time-consuming and sometimes confusing email exchanges. To ensure a successful screen, please make sure you understand the process before engaging in a ReFRAME screen.

You should have received this document as a Zip Package. To keep the hyperlinks working (example Assay Description), unzip the package to one location and do not move again.

Before Screening Begins

1	MTA or Collaboration Agreement Signed (provided by Kelli Kuhen, Director of Global Health)
2	Final *Assay Description* form for ReFRAMEDB.org delivered to *reframescreens@scripps.edu*
3	Final *Plate Layout* form delivered to *reframescreens@scripps.edu*
4	By default, partner agrees to a standard primary screen (singlicate) and two dose response sets for initial follow-up on. Dose sets are provided as replicate plates. Plates are prepared as 10-point 1:3 serial dilutions, starting at 10 µM unless otherwise discussed. Exceptions must be approved by the ReFRAME committee. For these the partner must complete the *Quantity Exception* form. More information on standard usage can be found *here*.
5	Optional: Partner sends Calibr controls dissolved in DMSO. Active concentration adjusted to match volume of the screening compounds whenever possible.

Screening Round 1

1	Calibr sends partner pre-spotted plates and compound keys (as blinded RFM IDs) for primary screen.
2	Partner performs screen and select hits (up to 1% of the library)
3	Partner sends hitlist as RFM IDs using the *Primary Screening* form.
4	Calibr sends partner two sets of pre-spotted dose response plates.
5	Collaborator sends Calibr dose response data via *Dose Response Data* form
6	Calibr sends collaborator structure and identities of confirmed hits

Additional Counter Screens (On ReFRAME committee approval)

1	In some cases, additional material for counter screen assays can be provided by Calibr. Requests for additional material or other resources will be reviewed by the ReFRAME committee. Partners are asked to complete *Screening Round 1* before additional requests for compounds.

Post Screening Begins

1	Dose response data uploaded to ReFRAMEdb.org by Calibr 1 year after partner receives structure identities. Partner can contact Calibr to request a delay under some circumstances.
2	Public success is the best way for our partners to support the ReFRAME project. Please notify Calibr of any publications, grants or studies that resulted from the ReFRAME screen using the *Milestone* document.

Calibr
at Scripps Research

How to access the ReFRAME Library

ReFRAME partnerships are determined on a case-by-case basis to avoid redundant screens, minimize compound consumption and ensure proposed assays have the requisite quality. Successful partner screens will meet the following requirements:

- Relevant to Global Health
- Execute a Material Transfer Agreement that ensures global access to data generated by the screen (12-month delay before deposition of data onto a public database maintained by Calibr (reframedb.org)
- Differentiated assay from prior or on-going screens (e.g. Pathogen species tested, clinical isolate vs. lab-adapted strain, lifecycle stage, assay readout (proliferation vs viability, etc.)
- Miniaturized and optimized to suit limited compound supply
    - Assay volume less than 50 µL (384- or 1536-well format)
    - Assay amenable to a single point screen and <1% hit rate follow-up

If approved, the typical screening partner receives ~0.5 nanomoles of each compound during primary screening (i.e., **50 nL @ 10 mM**) and up to 4 nanomoles for “hits” during the entire campaign (includes primary screen, dose response reconfirmation and counter screen).

For more information contact *reframescreens@scripps.edu*

Calibr ReFrame Assay Form

*A screening library of 12,000 molecules assembled by combining three databases (Clarivate Integrity, GVK Excelra GoStar and Citeline Pharmaprojects) to facilitate drug repurposing. **Information provided in this form will be posted on the public reframe portal website. Example of a completed form is at the end of page. Please visit https://reframedb.org/#/assays to see more examples.*

Screening Workflow: After MTA is signed, collaborator will provide plates and control. Primary screen of compounds will be pre-spotted and sent on assay ready plates. Collaborator will determine hits up to 1%. Hits will be pre-spotted in dose response in two sets. Structures and identities of the hits from dose response will be revealed. Any deviations from typical workflow require approval from the ReFrame Committee.

Click or tap here to enter text.

Pre-screening Notes

Previous experiments showed a 10 fold decrease with positive control. Assay underwent several round of optimization to achieve a Z' score of 0.52. After pilot screen and consideration of control, hits will be selected when compounds reduce signal 7 standard deviations below mean. A 0.7% hit-rate was observed in the pilot with a 68% confirmation rate.)

Assay Development Statistics (Z', fold change, CV's of strongest control)

Pilot (triplicate plates) had Z' > 0.5 (10 fold change)

Pre-spotted plate description

Description of pre-potted plates for single assay and corresponding counter screens. If this description is for a secondary or counter screen, please indicate the primary screen and leave the rest blank.

For primary screen 50 nL compound from 10 mM source in singlicate (layout: described in 1_AssayRegistration.PlateLayout.xlsx)

ReFRAME Process

1	MTA Approval and partner completes *Assay Registration Description* Form
2	Partner completes *Plate Layout Form* and finalizes all details (i.e. plate type, volumes, controls, etc.). Typical concentration of compound transferred goes up to 10uM. Typical volume of compound transferred ranges from 2.5nL to 100nL from a 10mM source.
3	Partner sends Calibr plate and controls. Controls are given at 10mM in DMSO.
4	Calibr sends partner pre-spotted plates and compound keys (as blinded RFM IDs) for primary screen. Plates will be in singlicate in the format defined in *Plate Layout Form.*
5	Partner performs screen and select hits (up to 1% of the library)
6	Partner sends hitlist as RFM IDs
7	Calibr sends partner two sets of pre-spotted dose response plates. Sets are provided as replicate plates. Plates are prepared as 8-point 1:3 serial dilutions, starting at 20 uM unless otherwise discussed.
8	Collaborator sends Calibr dose response data via *Dose Response Data* form
9	Calibr sends collaborator structure and identities of confirmed hits
10	Final review of Assay Registration Description and publication date
11	In some cases, additional material for secondary assays can be provided by Calibr. Requests for additional material or other resources will be reviewed by the ReFRAME committee. Request are considered after steps 1 through 10 are complete.

50nL for 50uL assay volume at 10uM

Plate Type. Format: Vendor Catalog number, (description)

384-well Corning 8793 (black solid bottom)

Dose Response Volume (High point and dilution). Dose response delivered as two singlicate dose sets.

Start at 10uM (final), 1:3 dilution, 8pt.

☒ By checking this box, I understand the primary screen of compounds will be pre-spotted and sent on assay ready plates. I, the collaborator will determine hits up to 1%. Then, hits will be pre-spotted in dose response in duplicate.

Calibr
at Scripps Research

Assay Description

Description (Word count between 100-200**. The background biology needed to understand the screen. Should be detailed and specific to the assay. Keep general discussion of a disease to a minimum. Examples: the details and significance of the particular larval stage being studied in the assay; the mechanism of action of the enzyme being targeted by a biochemical screen; the benefits of your screen over other formats, details on cell type and modification if any; how your assay works to detect viability, activity or other factors etc.)**

This is a secondary assay for hits active against C. parvum IOWA (Sterling and Bunch Grass Farm strains). Cryptosporidium parvum and the related species Cryptosporidium hominis cause diarrheal disease in humans. The current standard of care is ineffective in patients most at risk of cryptosporidiosis. This is a confirmatory secondary high-content imaging-based high-throughput screen of the hits from the full deck against the protozoan pathogen Cryptosporidium parvum. The assay measures inhibition of parasite proliferation within the human ileocecal colorectal adenocarcinoma cell line HCT-8 (a commonly used cell line for studying Cryptosporidium spp. in vitro. HCI detection of this cell-based assay allows for concomitant measurement of Cryptosporidium parasite inhibition and host cell cytotoxicity.

Protocol/Workflow (A light-weight materials and methods section, but be as detailed as possible)

This specific ID is for C. hominis (TU502), which has been routinely passaged through neonatal gnotobiotic piglets at Tufts University by the Tzipori lab. For the assay, HCT-8 cells are seeded into 1536-well clear-bottom plates and incubated at 37C. 24 hours later, compounds are transferred (1.88 uM for primary screening and 25 uM top concentration for dose-response), and then excysted Cryptosporidium sporozoites and oocysts are dispensed onto cells. 48 hours later, cells are fixed with 4% paraformaldehyde. Cells are then washed, permeabilized with 0.25% Triton X-100 in PBS, blocked with SuperBlock (Thermo), and finally stained with a 1:10 dilution of Superblock with 1ug/mL FITC-tagged Vicia Villosa lectin and 3uM DAPI nuclear stain. Cells are then washed with PBS-T to remove residual stain and plates are sealed with aluminum adhesive seals. Plates are imaged (10x objective) on the CX5 Cellomics imager using the SpotDetector algorithm. Compounds that inhibit Cryptosporidium proliferation by >= 70% and do not inhibit HCT-8 growth by more than 40% are picked for dose response testing.

Read out and Normalization (Clarify exactly what is being measured and how. Include information on normalization routines)

High-content imaging; normalized to neutral control minus inhibitor.

Indication (Indicate disease that is targeting)

Cryptosporidiosis

Assay Type (Type of assay: cell based, biochemical, phenotypic…)

cell based, High-Content Imaging

AC50 Units (If another metric is used, please specify)

AC50 in Molar

Detection Method (Describe the way the assay is read)

High-Content Imaging; Nitazoxanide and floxuridine are used as positive controls, and DMSO is the neutral control. Spot

Counts are normalized by Neutral Controls Minus Inhibitors.

Detection Reagent (Provide the reagents used for detection)

FITC 485/521

Components (Any species that are involved in the assay)

C. hominis (TU502); HCT-8 cells; Detection reagent

Neutral Control (Position on plate, description, and amount transferred in nL)

100nL of DMSO in column 22

Stimulator or Inhibitor Control (Position on plate, description, source concentration provided by collaborator, final concentration in uM, and volume transferred in nL)

100nL of DMSO (worms added by collaborator) in column 23

DMSO Sensitivity (Highest percentage of DMSO that assay is tolerable at)

1%

Pre-screening Notes

Previous experiments showed a 10 fold decrease with positive control. Assay underwent several round of optimization to achieve a Z' score of 0.52. After pilot screen and consideration of control, hits will be selected when compounds reduce signal 7 standard deviations below mean. A 0.7% hit-rate was observed in the pilot with a 68% confirmation rate.

Assay Development Statistics (Z', fold change, CV's of strongest control)

Pilot (triplicate plates) had Z' > 0.5 (10 fold change)

Summary of Process

Step	Description
1	MTA Approval/Pre-screening meeting
2	Assay Registration Form and Plate Layout completed
3	Collaborator sends plates and controls to be used
4	Calibr sends collaborator prespotted plates and plate ID for primary screening (one assay, singlicate, single concentration)
5	Collaborator performs screen and selects hit (<= 1% of library)
6	Collaborator sends hitlist as RFM IDs
7	Calibr sends collaborator 2 sets of dose response prespotted plates starting at 20uM high
8	Collaborator sends Calibr data from dose response experiment
9	Calibr sends collaborator identities of confirmed hits
10	Discuss for further follow up compounds

Materials Needed from Collaborator

Completet MTA and Assay Registration Form
Plates
Control
Hitlist from Primary Screen
Data from dose response experiment (used for reframe portal)

Materials Provided to Collaborator

Plates with Compounds
File with Plate layout
Stucture and smiles of compounds confirmed in dose response

Assay ready plates will be spotted exactly as defined by the information below. Please verify all calculations and concentrations are correct and match values defined in the assay description form.

Calibr
at Scripps Research

Why “Pre-spotted” Plates?

Calibr has worked with dozens of screening partners to provide the ReFRAME collection for screening and it is intended to fuel hundreds of assays. Because the collection is finite, we provide the collection in nanomole quantities to prevent premature depletion of the library. The typical screening partner receives ~0.5 nanomoles of each compound during primary screening (i.e., **50 nL @ 10 mM**) and up to 4 nanomoles for “hits” during the campaign (includes primary screen, dose response experiments and counter screens). To achieve this, Calibr uses acoustic dispensing to “pre-spot” assay plates or intermediate plates for our partners. In addition to conserving the library, this format limits our partners’ need for automation and information management—all tracking, dosing and compound management are performed at Calibr. After the campaign, we work with our partners to provide larger quantities for the validated hits. However, until then the library is provided in two formats:

Format 1, Pre-spotted Assay plates: Calibr “dry spots” compound directly onto assay plates and ships to partner for assay. Optimal workflow when the assay can accommodate addition of compound at the start of the assay.

Format 2, Pre-spotted Intermediate plates: Calibr “dry spots” compound onto intermediate plates and ships to partner. The partner then resuspends compounds in assay buffer for transfer to the assay plate at the appropriate time. This workflow is necessary when the partner needs to delay addition of the compound to the assay well (e.g. some adherent cell-based assays).

Exceptions can be made. However, exceptions are rare and only made when the assay is considered very high priority with no other options. We typically will not accommodate assay well volumes greater than 50 µL and we expect our partners to conserve compound to the best of their ability. To date, a large majority of ReFRAME screens have been in 384- or 1536-well format.

Summary of Standard Workflow

1	MTA Approval and partner completes *Assay Registration Description* Form
2	Partner completes *Plate Layout Form* and finalizes all details (i.e. plate type, volumes, controls, etc.). Typical concentration of compound transferred goes up to 10uM. Typical volume of compound transferred ranges from 2.5nL to 100nL from a 10mM source.
3	Partner sends Calibr plate and controls. Controls are given at 10mM in DMSO.
4	Calibr sends partner pre-spotted plates and compound keys (as blinded RFM IDs) for primary screen. Plates will be in singlicate in the format defined in *Plate Layout Form.*
5	Partner performs screen and select hits (up to 1% of the library)
6	Partner sends hitlist as RFM IDs
7	Calibr sends partner two sets of pre-spotted dose response plates. Sets are provided as replicate plates. Plates are prepared as 8-point 1:3 serial dilutions, starting at 10 µM unless otherwise discussed.
8	Collaborator sends Calibr dose response data via *Dose Response Data* form
9	Calibr sends collaborator structure and identities of confirmed hits

10	Final review of Assay Registration Description and publication date
11	In some cases, additional material for secondary assays can be provided by Calibr. Requests for additional material or other resources will be reviewed by the ReFRAME committee. Request are considered after steps 1 through 10 are complete.

Primary Screening Stats (average per plate)	example
Z' Factor	0.5
Fold Change	5.5
CV's of DMSO	7.5%
CV's of compound	10%
CV's of control (strongest control)	15%
hit selection method (fold change, Z score, etc.)	z-score
hit selection cut-off	z-score > 5

ReFRAMe IDs of Hits from Primary Screen (Only up to 1%)

RFM-xxx-xxx-x
RFM-xxx-xxx-x
RFM-xxx-xxx-x

Instructions: See examples in grey text. Hover over column headers for more information. Please include one data point of each determined hit from the dose response experiment. Highlighting not necessary, this is to point out and explain exceptions. Please delete examples upon submission.

RFM ID	ac50 (M)	Precision	Normalization Routine	Efficacy	r-squared	Datamode	Note	Examples
RFM-000-077-1	*0.000002*	*EQUAL*	*Neutral Controls Minus Inhibitors*	*-111.97322*	*0.9997*	*DECREASING*		*typical data example 1*
RFM-000-077-2	*5.00E-05*	*EQUAL*	*Neutral Controls Minus Inhibitors*	*-111.97322*	*0.910*	*INCREASING*		*typical data example 2*
RFM-000-077-3	*N/A*	*LESS THAN*	*Neutral Controls Minus Inhibitors*	*N/A*	*N/A*	*SUPER ACTIVE*	*super activity due to toxicity-- no further follow up*	
RFM-000-077-2	*5.00E-06*	*EQUAL*	*Neutral Controls Minus Inhibitors*	*NULL?*	*0.910*	*INCREASING*	*data unable to be characterized via control due to xxxxxx*	
RFM-000-077-2	*5.00E-06*	*EQUAL*	*None*	*-111.97322*	*0.910*	*INCREASING*	*data not normalized due to xxxxxxxxx*	
RFM-000-077-2	*2.00E-05*	*GREATER THAN*	*Neutral Controls Minus Inhibitors*	*-100*	*NULL?*	*INCREASING*	*r-squared vavlue cound not be calculated because of xxxxxxx*	

RFM ID	RFM ID: List RFM compound identifier of every hit. Plate-well to RFM ID keys were provided by Calibr during screening (i.e. RFM-000-077-1)
ac50 (M)	ac50 (M): Half Maximal Activity Concentration AC50, IC50, EC50 or CC50 depending on assay type. Must be a number or blank. Do not use greater than or less than signs. Indicate this in precision column.
Precision	Precision: Describe the precision of the experimental concentration using EQUAL, LESS THAN, or GREATER THAN. The result is nearly always EQUAL. -EQUAL if ac50 was found in the concentration range tested -LESS THAN for super active compounds and ac50 was below the curve -GREATER THAN if ac50 is higher than indicated by curve
Normalization Routine	Normalization Routine: Description of how data was normalized (normalized to compounds, normalized to neutral controls minus inhibitors, Robust Z-score, etc.)
Efficacy	Efficacy: Measurement of efficacy (example: compound identical to control inhibitor would be -100 if data normalized by Neutral Controls Minus Inhibitors). Must be a number or blank. If no value for effiacy, type NULL.
r-squared	r-squared: Must be a number or blank. R squared value of curve
Datamode	Datamode: Direction of the curve: DECREASING, INCREASING, SUPER ACTIVE (see notes in example)
Note	Note: Provide explaination for every exception here and any additional comments that you may want to include.

Calibr ReFrame Portal Form

*A screening library of 12,000 molecules assembled by combining three databases (Clarivate Integrity, GVK Excelra GoStar and Citeline Pharmaprojects) to facilitate drug repurposing. **Information provided in this form will be posted on the public reframe portal website. Example of a filled out form is on the end of page.*

Summary of Screening Workflow

Step 1	MTA is signed and approved
Step 2	Assay Description Form and Plate Layout is filled out
Step 3	Collaborator sends plate and control to be used
Step 4	Calibr sends pre-spotted plates for primary screening at no more than 10uM (one assay, one concentration, single copy)
Step 5	Collaborator performs screen and select hits up to ~1%
Step 6	Calibr receives hitlist as RFM ID and sends 2 sets of pre-spotted 8 point dose response plates (starting at 20uM highest concentration with 1 to 3 dilution)
Step 7	Collaborator sends dose response hits data (ac50, r squared, efficacy, normalization)
Step 8	Calibr sends collaborator identities and structure of confirmed hits
Step 9	Discuss providing larger quantities of final hits
Deviations from Screening Workflow must be approved by Director of Global Health Program	Approval Signature:_____ Approval Date:_____

Author in format "Name, Titles (Location)"	**Jane Doe, PhD (University of California, San Francisco)**
Summary (Brief sentence or two about the type of screen and the target)	**Brugia pahangi worm motility assay**

Assay Description

Description (Word count between 100-200**. The background biology needed to understand the screen. Should be detailed and specific to the assay. Keep general discussion of a disease to a minimum. Examples: the details and significance of the particular larval stage being studied in the assay; the mechanism of action of the enzyme being targeted by a biochemical screen; the benefits of your screen over other formats, details on cell type and modification if any; how your assay works to detect viability, activity or other factors etc.)**

Adult female Brugia pahangi worms are used in the primary screens to identify a macrofilaricidal candidate. Adult female Brugia are initially screened in quadruplicate in 24 well plates at a single concentration from 1-10μM. Worms treated with 1% DMSO only are used as controls. Worms are kept in a 37°C, 5% CO2 incubator for the duration of the assay. Worm motility (phenotypic screening) is assessed on Day 0 (the day worms are treated with compound), Day 1, Day 2, Day 3, and Day 6 using an imaging system called The Worminator. Mean movement units (worms moving are assessed as pixels displaced per second) generated from The Worminator on Day 3 and Day 6 are converted into % inhibitions of worm motility compared to controls treated with 1% DMSO only. A compound hit is defined as one that inhibits the motility of the adult female worm ≥ 75% by Day 6 of the assay. If a compound inhibits motility of the worms consistently in at least two assays at single concentrations, an IC50 is performed using a 6-point serial dilution starting at 30μM. IC50s are calculated using GraphPad Prism.

Protocol/Workflow (A light-weight materials and methods section, but be as detailed as possible)

Adult female Brugia pahangi were shipped from Univ. of Missouri-Columbia and assayed using methods described by Marcellino et al. (2012). Individual females are placed in each well of a 24-well plate with media (RPMI-1640 with 25 mM HEPES, 2.0 g/L NaHCO3, 5% heat inactivated FBS, and 1X Antibiotic/Antimycotic solution). Worms are transferred to new 24-well plates upon arrival with 500 μL of media per well. Initial ReFrame compound screening is conducted at 3 μM per compound, and 1% DMSO is used as a negative control. All drugs are dissolved in DMSO (Sigma-Aldrich, St. Louis, MO) stock solutions are stored at -20°C. Four worms were used as replicates for each concentration and worm plates are kept in a 37°C, 5% CO2 incubator for the duration of the assay except during motility readings. To determine the effect of a compound on worm motility, individual worm movement are counted as the number of pixels displaced per second by

each worm in each well using the Worminator. Each plate of worms is video recorded for approximately 60 seconds, and mean movement units (MMUs) are determined for individual worms. Percent inhibition of motility is calculated by dividing the MMUs of the treated worms by the control average MMUs, subtracting the value from 1.0, flooring the values to zero and multiplying by 100%. Videos are recorded each day, including the first day of the assay (Day 0). Compounds that inhibit worm motility can be tested in IC50 assays. Prism is used to calculate IC50 values using a non-linear regression curve fit.

Detection/measurement (Clarify exactly what is being measure and how. Include information on normalization routines)

Individual worm movements are counted as number of pixels displaced per second by each worm in each well using the Worminator. Each plate of worms is video recorded for approximately 60 seconds, and the mean movement units (MMUs) are determined for individual worms. Percent inhibition of motility is calculated by dividing the MMUs of the treated worms by the control average MMUs, subtracting the value from 1.0, flooring the values to zero and multiplying by 100%. Videos are recorded each day, including the first day of the assay (Day 0). Compounds that inhibit worm motility can be tested in IC50 assays. Prism is used to calculate IC50 values using a non-linear regression curve fit.

Indication (Indicate disease that is targeting)

Calibr ReFrame: Request Format Exception

Because the collection is finite and intended for dozens of partners, each partner is expected to minimize library consumption. A majority of ReFRAME screens are performed in singlicate and miniaturized to a 384 or 1536-well format. However, we recognize this is not always possible (i.e. larger parasites). Please justify your need for an exception. This will be reviewed by the ReFRAME committee and must be approved by Calibr's Director of Global Health.

In vitro promise of Aplidin for COVID- 19 sends PharmaMar upwards

13-03-2020

A bolstering of hopes that Spanish drugmaker PharmaMar (MSE: PHM) might have an answer for the COVID-19 coronavirus sent the comp share price spiralling upwards on Friday.

PharmaMar was 38% higher later on Friday, having earlier in the day shown gains of more than 50%, as markets digested an update on a d that the company sees as a potential treatment for the virus.

The firm reported that *in vitro* studies results of Aplidin (plitidepsin) on the human coronavirus HCoV-229E, which has a multiplication and propagation mechanism very similar to Covid-19, have been positive with a potency of the nanomolar order.

These studies have been carried out at the National Biotechnology Centre of the Spanish National Research Council. They confirm the hypothesis that the therapeutic target of Aplidin (plitidepsin), which is EF1A, is key to the multiplication and spread of the virus.

PharmaMar has said that it will contact regulatory authorities to analyze the possibilities of studies on patients infected with Covid-19.

Aplidin (plitidepsin) is a compound that is currently approved in Australia for the treatment of multiple myeloma, having been rejected by the European Medicines Agency (EMA) in 2017. That decision is being appealed in the European Court of Justice. And, in January 2019, Pharn

Calibr ReFrame Assay Form

*A screening library of 12,000 molecules assembled by combining three databases (Clarivate Integrity, GVK Excelra GoStar and Citeline Pharmaprojects) to facilitate drug repurposing. **Information provided in this form will be posted on the public reframe portal website. Example of a completed form is at the end of page. Please visit https://reframedb.org/#/assays to see more examples.*

Screening Workflow: After MTA is signed, collaborator will provide plates and control. Primary screen of compounds will be pre-spotted and sent on assay ready plates. Collaborator will determine hits up to 1%. Hits will be pre-spotted in dose response in two sets. Structures and identities of the hits from dose response will be revealed. Any deviations from typical workflow require approval from the ReFrame Committee.

Summary Brief sentence or two about the type of screen and the target. If secondary assay start with "Secondary assay for <assay title short>"	*Click or tap here to enter text.*

Compound Transfer Description

Assay Volume (uL of volume at time of compound exposure)

Ex: 50uL

Primary Screening Volume Transfer from 10mM Source Plates. (For cell-based assays, consider toxicity. A higher concentration (i.e. 10 µM) can lead to false negatives in many assays.)

Ex: 50nL for 50uL assay volume at 10uM.

Plate Type. Format: Vendor Catalog number, (description)

Ex: 384-well Corning 8793 (black solid bottom)

Calibr
at Scripps Research

Dose Response Volume (High point and dilution). Dose response delivered as two singlicate dose sets.

Ex: Start at 10uM (final), 1:3 dilution, 8pt.

☐ By checking this box, I understand the primary screen of compounds will be pre-spotted and sent on assay ready plates. I, the collaborator, will determine hits up to 1%. Then, hits will be pre-spotted in dose response in duplicate.

Assay Description

Description (Word count between 100-200**. The background biology needed to understand the screen. Should be detailed and specific to the assay. Keep general discussion of a disease to a minimum. Examples: the details and significance of the particular larval stage being studied in the assay; the mechanism of action of the enzyme being targeted by a biochemical screen; the benefits of your screen over other formats, details on cell type and modification if any; how your assay works to detect viability, activity or other factors etc.)**

Pre-screening Notes

Previous experiments showed a 10 fold decrease with positive control. Assay underwent several round of optimization to achieve a Z' score of 0.52. After pilot screen and consideration of control, hits will be selected when compounds reduce signal 7 standard deviations below mean. A 0.7% hit-rate was observed in the pilot with a 68% confirmation rate.)

Assay Development Statistics (Z', fold change, CV's of strongest control)

Pilot (triplicate plates) had Z' > 0.5 (10 fold change)

Pre-spotted plate description

Description of pre-potted plates for single assay and corresponding counter screens. If this description is for a secondary or counter screen, please indicate the primary screen and leave the rest blank.

For primary screen 50 nL compound from 10 mM source in singlicate (layout: described in 1_AssayRegistration.PlateLayout.xlsx)

ReFRAME Process

1	MTA Approval and partner completes *Assay Registration Description* Form
2	Partner completes *Plate Layout Form* and finalizes all details (i.e. plate type, volumes, controls, etc.). Typical concentration of compound transferred goes up to 10uM. Typical volume of compound transferred ranges from 2.5nL to 100nL from a 10mM source.
3	Partner sends Calibr plate and controls. Controls are given at 10mM in DMSO.
4	Calibr sends partner pre-spotted plates and compound keys (as blinded RFM IDs) for primary screen. Plates will be in singlicate in the format defined in *Plate Layout Form.*
5	Partner performs screen and select hits (up to 1% of the library)
6	Partner sends hitlist as RFM IDs
7	Calibr sends partner two sets of pre-spotted dose response plates. Sets are provided as replicate plates. Plates are prepared as 8-point 1:3 serial dilutions, starting at 20 uM unless otherwise discussed.
8	Collaborator sends Calibr dose response data via *Dose Response Data* form
9	Calibr sends collaborator structure and identities of confirmed hits
10	Final review of Assay Registration Description and publication date
11	In some cases, additional material for secondary assays can be provided by Calibr. Requests for additional material or other resources will be reviewed by the ReFRAME committee. Request are considered after steps 1 through 10 are complete.

Mailing Address	11119 N Torrey Pines Rd, La Jolla, CA 92037
Assay Title	Crypto-C. hominis high-content imaging proliferation
Assay Title Short (less than 50 characters)	Crypto-C. hominis proliferation
Author In format "Name, Titles (Location)"	Jane Doe, PhD (California Institute for Biomedical Research (Calibr), La Jolla, CA)
Summary Brief sentence or two about the type of screen and the target. If secondary assay start with "Secondary assay for <assay title short>"	Secondary assay for Crypto-C. hominis proliferation. Phenotypic high-content imaging-based high-throughput screen against the protozoan pathogen C. parvum to find new small molecule inhibitors of Cryptosporidium, which causes diarrheal disease in humans.

Compound Transfer Description

Assay Volume (uL of volume at time of compound exposure)

50uL

Primary Screening Volume Transfer from 10mM Source Plates.

50nL for 50uL assay volume at 10uM

Plate Type. Format: Vendor Catalog number, (description)

384-well Corning 8793 (black solid bottom)

Dose Response Volume (High point and dilution). Dose response delivered as two singlicate dose sets.

Start at 10uM (final), 1:3 dilution, 8pt.

☒ By checking this box, I understand the primary screen of compounds will be pre-spotted and sent on assay ready plates. I, the collaborator will determine hits up to 1%. Then, hits will be pre-spotted in dose response in duplicate.

Assay Description

Description (Word count between 100-200**. The background biology needed to understand the screen. Should be detailed and specific to the assay. Keep general discussion of a disease to a minimum. Examples: the details and significance of the particular larval stage being studied in the assay; the mechanism of action of the enzyme being targeted by a biochemical screen; the benefits of your screen over other formats, details on cell type and modification if any; how your assay works to detect viability, activity or other factors etc.)**

This is a secondary assay for hits active against C. parvum IOWA (Sterling and Bunch Grass Farm strains). Cryptosporidium parvum and the related species Cryptosporidium hominis cause diarrheal disease in humans. The current standard of care is ineffective in patients most at risk of cryptosporidiosis. This is a confirmatory secondary high-content imaging-based high-throughput screen of the hits from the full deck against the protozoan pathogen Cryptosporidium parvum. The assay measures inhibition of parasite proliferation within the human ileocecal colorectal adenocarcinoma cell line HCT-8 (a commonly used cell line for studying Cryptosporidium spp. in vitro. HCI detection of this cell-based assay allows for concomitant measurement of Cryptosporidium parasite inhibition and host cell cytotoxicity.

Protocol/Workflow (A light-weight materials and methods section, but be as detailed as possible)

This specific ID is for C. hominis (TU502), which has been routinely passaged through neonatal gnotobiotic piglets at Tufts University by the Tzipori lab. For the assay, HCT-8 cells are seeded into 1536-well clear-bottom plates and incubated at 37C. 24 hours later, compounds are transferred (1.88 uM for primary screening and 25 uM top concentration for dose-response), and then excysted Cryptosporidium sporozoites and oocysts are dispensed onto cells. 48 hours later, cells are fixed with 4% paraformaldehyde. Cells are then washed, permeabilized with 0.25% Triton X-100 in PBS, blocked with SuperBlock (Thermo), and finally stained with a 1:10 dilution of Superblock with 1ug/mL FITC-tagged Vicia Villosa lectin and 3uM DAPI nuclear stain. Cells are then washed with PBS-T to remove residual stain and plates are sealed with aluminum adhesive seals. Plates are imaged (10x objective) on the CX5 Cellomics imager using the SpotDetector algorithm. Compounds that inhibit Cryptosporidium proliferation by >= 70% and do not inhibit HCT-8 growth by more than 40% are picked for dose response testing.

Read out and Normalization (Clarify exactly what is being measured and how. Include information on normalization routines)

High-content imaging; normalized to neutral control minus inhibitor.

Indication (Indicate disease that is targeting)

Cryptosporidiosis

Assay Type (Type of assay: cell based, biochemical, phenotypic…)

cell based, High-Content Imaging

AC50 Units (If another metric is used, please specify)

AC50 in Molar

Detection Method (Describe the way the assay is read)

High-Content Imaging; Nitazoxanide and floxuridine are used as positive controls, and DMSO is the neutral control. Spot

Counts are normalized by Neutral Controls Minus Inhibitors.

Detection Reagent (Provide the reagents used for detection)

FITC 485/521

Components (Any species that are involved in the assay)

C. hominis (TU502); HCT-8 cells; Detection reagent

Neutral Control (Position on plate, description, and amount transferred in nL)

100nL of DMSO in column 22

Stimulator or Inhibitor Control (Position on plate, description, source concentration provided by collaborator, final concentration in uM, and volume transferred in nL)

100nL of DMSO (worms added by collaborator) in column 23

DMSO Sensitivity (Highest percentage of DMSO that assay is tolerable at)

1%

Pre-screening Notes

Previous experiments showed a 10 fold decrease with positive control. Assay underwent several round of optimization to achieve a Z' score of 0.52. After pilot screen and consideration of control, hits will be selected when compounds reduce signal 7 standard deviations below mean. A 0.7% hit-rate was observed in the pilot with a 68% confirmation rate.

Assay Development Statistics (Z', fold change, CV's of strongest control)

Pilot (triplicate plates) had Z' > 0.5 (10 fold change)

Summary of Process

Step	Description
1	MTA Approval/Pre-screening meeting
2	Assay Registration Form and Plate Layout completed
3	Collaborator sends plates and controls to be used
4	Calibr sends collaborator prespotted plates and plate ID for primary screening (one assay, singlicate, single concentration)
5	Collaborator performs screen and selects hit (<= 1% of library)
6	Collaborator sends hitlist as RFM IDs
7	Calibr sends collaborator 2 sets of dose response prespotted plates starting at 20uM high
8	Collaborator sends Calibr data from dose response experiment
9	Calibr sends collaborator identities of confirmed hits
10	Discuss for further follow up compounds

Materials Needed from Collaborator

Completet MTA and Assay Registration Form
Plates
Control
Hitlist from Primary Screen
Data from dose response experiment (used for reframe portal)

Materials Provided to Collaborator

Plates with Compounds
File with Plate layout
Stucture and smiles of compounds confirmed in dose response

Assay ready plates will be spotted exactly as defined by the information below. Please verify all calculations and concentrations are correct and match values defined in the assay description form.

Calibr
at Scripps Research

Why “Pre-spotted” Plates?

Calibr has worked with dozens of screening partners to provide the ReFRAME collection for screening and it is intended to fuel hundreds of assays. Because the collection is finite, we provide the collection in nanomole quantities to prevent premature depletion of the library. The typical screening partner receives ~0.5 nanomoles of each compound during primary screening (i.e., **50 nL @ 10 mM**) and up to 4 nanomoles for “hits” during the campaign (includes primary screen, dose response experiments and counter screens). To achieve this, Calibr uses acoustic dispensing to “pre-spot” assay plates or intermediate plates for our partners. In addition to conserving the library, this format limits our partners’ need for automation and information management—all tracking, dosing and compound management are performed at Calibr. After the campaign, we work with our partners to provide larger quantities for the validated hits. However, until then the library is provided in two formats:

Format 1, Pre-spotted Assay plates: Calibr “dry spots” compound directly onto assay plates and ships to partner for assay. Optimal workflow when the assay can accommodate addition of compound at the start of the assay.

Format 2, Pre-spotted Intermediate plates: Calibr “dry spots” compound onto intermediate plates and ships to partner. The partner then resuspends compounds in assay buffer for transfer to the assay plate at the appropriate time. This workflow is necessary when the partner needs to delay addition of the compound to the assay well (e.g. some adherent cell-based assays).

Exceptions can be made. However, exceptions are rare and only made when the assay is considered very high priority with no other options. We typically will not accommodate assay well volumes greater than 50 µL and we expect our partners to conserve compound to the best of their ability. To date, a large majority of ReFRAME screens have been in 384- or 1536-well format.

Summary of Standard Workflow

1	MTA Approval and partner completes *Assay Registration Description* Form
2	Partner completes *Plate Layout Form* and finalizes all details (i.e. plate type, volumes, controls, etc.). Typical concentration of compound transferred goes up to 10uM. Typical volume of compound transferred ranges from 2.5nL to 100nL from a 10mM source.
3	Partner sends Calibr plate and controls. Controls are given at 10mM in DMSO.
4	Calibr sends partner pre-spotted plates and compound keys (as blinded RFM IDs) for primary screen. Plates will be in singlicate in the format defined in *Plate Layout Form.*
5	Partner performs screen and select hits (up to 1% of the library)
6	Partner sends hitlist as RFM IDs
7	Calibr sends partner two sets of pre-spotted dose response plates. Sets are provided as replicate plates. Plates are prepared as 8-point 1:3 serial dilutions, starting at 10 µM unless otherwise discussed.
8	Collaborator sends Calibr dose response data via *Dose Response Data* form
9	Calibr sends collaborator structure and identities of confirmed hits

10	Final review of Assay Registration Description and publication date
11	In some cases, additional material for secondary assays can be provided by Calibr. Requests for additional material or other resources will be reviewed by the ReFRAME committee. Request are considered after steps 1 through 10 are complete.

Primary Screening Stats (average per plate)	example
Z' Factor	0.5
Fold Change	5.5
CV's of DMSO	7.5%
CV's of compound	10%
CV's of control (strongest control)	15%
hit selection method (fold change, Z score, etc.)	z-score
hit selection cut-off	z-score > 5

ReFRAMe IDs of Hits from Primary Screen (Only up to 1%)

RFM-xxx-xxx-x
RFM-xxx-xxx-x
RFM-xxx-xxx-x

Instructions: See examples in grey text. Hover over column headers for more information. Please include one data point of each determined hit from the dose response experiment. Highlighting not necessary, this is to point out and explain exceptions. Please delete examples upon submission.

RFM ID	ac50 (M)	Precision	Normalization Routine	Efficacy	r-squared	Datamode	Note	Examples
RFM-000-077-1	*0.000002*	*EQUAL*	*Neutral Controls Minus Inhibitors*	*-111.97322*	*0.9997*	*DECREASING*		*typical data example 1*
RFM-000-077-2	*5.00E-05*	*EQUAL*	*Neutral Controls Minus Inhibitors*	*-111.97322*	*0.910*	*INCREASING*		*typical data example 2*
RFM-000-077-3	*N/A*	*LESS THAN*	*Neutral Controls Minus Inhibitors*	*N/A*	*N/A*	*SUPER ACTIVE*	*super activity due to toxicity-- no further follow up*	
RFM-000-077-2	*5.00E-06*	*EQUAL*	*Neutral Controls Minus Inhibitors*	*NULL?*	*0.910*	*INCREASING*	*data unable to be characterized via control due to xxxxxx*	
RFM-000-077-2	*5.00E-06*	*EQUAL*	*None*	*-111.97322*	*0.910*	*INCREASING*	*data not normalized due to xxxxxxxxx*	
RFM-000-077-2	*2.00E-05*	*GREATER THAN*	*Neutral Controls Minus Inhibitors*	*-100*	*NULL?*	*INCREASING*	*r-squared vavlue cound not be calculated because of xxxxxxx*	

RFM ID	RFM ID: List RFM compound identifier of every hit. Plate-well to RFM ID keys were provided by Calibr during screening (i.e. RFM-000-077-1)
ac50 (M)	ac50 (M): Half Maximal Activity Concentration AC50, IC50, EC50 or CC50 depending on assay type. Must be a number or blank. Do not use greater than or less than signs. Indicate this in precision column.
Precision	Precision: Describe the precision of the experimental concentration using EQUAL, LESS THAN, or GREATER THAN. The result is nearly always EQUAL. -EQUAL if ac50 was found in the concentration range tested -LESS THAN for super active compounds and ac50 was below the curve -GREATER THAN if ac50 is higher than indicated by curve
Normalization Routine	Normalization Routine: Description of how data was normalized (normalized to compounds, normalized to neutral controls minus inhibitors, Robust Z-score, etc.)
Efficacy	Efficacy: Measurement of efficacy (example: compound identical to control inhibitor would be -100 if data normalized by Neutral Controls Minus Inhibitors). Must be a number or blank. If no value for effiacy, type NULL.
r-squared	r-squared: Must be a number or blank. R squared value of curve
Datamode	Datamode: Direction of the curve: DECREASING, INCREASING, SUPER ACTIVE (see notes in example)
Note	Note: Provide explaination for every exception here and any additional comments that you may want to include.

Calibr ReFrame Portal Form

*A screening library of 12,000 molecules assembled by combining three databases (Clarivate Integrity, GVK Excelra GoStar and Citeline Pharmaprojects) to facilitate drug repurposing. **Information provided in this form will be posted on the public reframe portal website. Example of a filled out form is on the end of page.*

Summary of Screening Workflow

Step 1	MTA is signed and approved
Step 2	Assay Description Form and Plate Layout is filled out
Step 3	Collaborator sends plate and control to be used
Step 4	Calibr sends pre-spotted plates for primary screening at no more than 10uM (one assay, one concentration, single copy)
Step 5	Collaborator performs screen and select hits up to ~1%
Step 6	Calibr receives hitlist as RFM ID and sends 2 sets of pre-spotted 8 point dose response plates (starting at 20uM highest concentration with 1 to 3 dilution)
Step 7	Collaborator sends dose response hits data (ac50, r squared, efficacy, normalization)
Step 8	Calibr sends collaborator identities and structure of confirmed hits
Step 9	Discuss providing larger quantities of final hits
Deviations from Screening Workflow must be approved by Director of Global Health Program	Approval Signature:_____ Approval Date:_____

Summary (Brief sentence or two about the type of screen and the target)	**Brugia pahangi worm motility assay**

Assay Description

Description (Word count between 100-200**. The background biology needed to understand the screen. Should be detailed and specific to the assay. Keep general discussion of a disease to a minimum. Examples: the details and significance of the particular larval stage being studied in the assay; the mechanism of action of the enzyme being targeted by a biochemical screen; the benefits of your screen over other formats, details on cell type and modification if any; how your assay works to detect viability, activity or other factors etc.)**

Adult female Brugia pahangi worms are used in the primary screens to identify a macrofilaricidal candidate. Adult female Brugia are initially screened in quadruplicate in 24 well plates at a single concentration from 1-10μM. Worms treated with 1% DMSO only are used as controls. Worms are kept in a 37°C, 5% CO2 incubator for the duration of the assay. Worm motility (phenotypic screening) is assessed on Day 0 (the day worms are treated with compound), Day 1, Day 2, Day 3, and Day 6 using an imaging system called The Worminator. Mean movement units (worms moving are assessed as pixels displaced per second) generated from The Worminator on Day 3 and Day 6 are converted into % inhibitions of worm motility compared to controls treated with 1% DMSO only. A compound hit is defined as one that inhibits the motility of the adult female worm ≥ 75% by Day 6 of the assay. If a compound inhibits motility of the worms consistently in at least two assays at single concentrations, an IC50 is performed using a 6-point serial dilution starting at 30μM. IC50s are calculated using GraphPad Prism.

Protocol/Workflow (A light-weight materials and methods section, but be as detailed as possible)

Adult female Brugia pahangi were shipped from Univ. of Missouri-Columbia and assayed using methods described by Marcellino et al. (2012). Individual females are placed in each well of a 24-well plate with media (RPMI-1640 with 25 mM HEPES, 2.0 g/L NaHCO3, 5% heat inactivated FBS, and 1X Antibiotic/Antimycotic solution). Worms are transferred to new 24-well plates upon arrival with 500 μL of media per well. Initial ReFrame compound screening is conducted at 3 μM per compound, and 1% DMSO is used as a negative control. All drugs are dissolved in DMSO (Sigma-Aldrich, St. Louis, MO) stock solutions are stored at -20°C. Four worms were used as replicates for each concentration and worm plates are kept in a 37°C, 5% CO2 incubator for the duration of the assay except during motility readings. To determine the effect of a compound on worm motility, individual worm movement are counted as the number of pixels displaced per second by

each worm in each well using the Worminator. Each plate of worms is video recorded for approximately 60 seconds, and mean movement units (MMUs) are determined for individual worms. Percent inhibition of motility is calculated by dividing the MMUs of the treated worms by the control average MMUs, subtracting the value from 1.0, flooring the values to zero and multiplying by 100%. Videos are recorded each day, including the first day of the assay (Day 0). Compounds that inhibit worm motility can be tested in IC50 assays. Prism is used to calculate IC50 values using a non-linear regression curve fit.

Detection/measurement (Clarify exactly what is being measure and how. Include information on normalization routines)

Individual worm movements are counted as number of pixels displaced per second by each worm in each well using the Worminator. Each plate of worms is video recorded for approximately 60 seconds, and the mean movement units (MMUs) are determined for individual worms. Percent inhibition of motility is calculated by dividing the MMUs of the treated worms by the control average MMUs, subtracting the value from 1.0, flooring the values to zero and multiplying by 100%. Videos are recorded each day, including the first day of the assay (Day 0). Compounds that inhibit worm motility can be tested in IC50 assays. Calibr ReFrame: Request Format Exception

Because the collection is finite and intended for dozens of partners, each partner is expected to minimize library consumption. A majority of ReFRAME screens are performed in singlicate and miniaturized to a 384 or 1536-well format. However, we recognize this is not always possible (i.e. larger parasites). Please justify your need for an exception. This will be reviewed by the ReFRAME committee and must be approved by Calibr's Director of Global Health.

Routine Venous Thromboembolism Prophylaxis May Be Inadequate in the Hypercoagulable State of Severe Coronavirus Disease 2019

Thomas K. Maatman, MD[1]; Farid Jalali, MD[2]; Cyrus Feizpour, MD[1]; Anthony Douglas II, BS[3]; Sean P. McGuire, MD[1]; Gabriel Kinnaman, BS[3]; Jennifer L. Hartwell, MD[1]; Benjamin T. Maatman, MD[4]; Rolf P. Kreutz, MD[4]; Rajat Kapoor, MD[5]; Omar Rahman, MD[5]; Nicholas J. Zyromski, MD[1]; Ashley D. Meagher, MD, MPH

Objectives: The aim of this study was to determine the frequency of venous thromboembolism in critically ill coronavirus disease 2019 patients and associate a degree of inflammatory marker elevation to venous thromboembolism development.

Design: An observational study that identified patients with severe coronavirus disease 2019 between March 12, 2020, and March 31, 2020. Data reported are those available through May 6, 2020.

Setting: A multicenter study including three Indianapolis area academic hospitals.

Patients: Two-hundred forty consecutive patients with confirmed severe acute respiratory syndrome coronavirus 2 infection were admitted to one of three hospitals. One-hundred nine critically ill coronavirus disease 2019 patients admitted to the ICU were included in the analysis.

Interventions: All patients received routine subcutaneous chemical venous thromboembolism prophylaxis.

Measurements and Main Results: The primary outcome of this study was to determine the frequency of venous thromboembolism and the degree of inflammatory and coagulation marker elevation associated with venous thromboembolism development. Descriptive statistics outlined the frequency of venous thromboembolism at any time during severe coronavirus disease 2019. Clinical course and laboratory metrics were compared between patients that developed venous thromboembolism and patients that did not develop venous thromboembolism. Hypercoagulable thromboelastography was defined as two or more hypercoagulable parameters.

Main Results: One-hundred nine patients developed severe coronavirus disease 2019 requiring ICU care. The mean (± sd) age was 61 ± 16 years and 57% were male. Seventy-five patients (69%) were discharged home, 7 patients (6%) remain in the hospital, and 27 patients (25%) died. Venous thromboembolism was diagnosed in 31 patients (28%) 8 ± 7 days after hospital admission, including two patients diagnosed with venous thromboembolism at presentation to the hospital. Elevated admission $_d$-dimer and peak $_d$-dimer were associated with venous thromboembolism development ($p < 0.05$). $_d$-dimer greater than 2,600 ng/mL predicted venous thromboembolism with an area under the receiver operating characteristic curve of 0.760 (95% CI, 0.661–0.858; $p < 0.0001$), sensitivity of 89.7%, and specificity of 59.5%. Twelve patients (11%) had thromboelastography performed and 58% of these patients had a hypercoagulable study. The calculated coagulation index was hypercoagulable in 50% of patients with thromboelastography.

Conclusions: These data show that coronavirus disease 2019 results in a hypercoagulable state. Routine chemical venous thromboembolism prophylaxis may be inadequate in preventing venous thromboembolism in severe coronavirus disease 2019. (*Crit Care Med* 2020; XX:00–00)

Key Words: deep vein thrombosis; low-molecular-weight heparin; novel coronavirus; pulmonary embolism; venous thromboembolism

The novel severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has resulted in a pandemic passing three million worldwide cases of coronavirus disease 2019 (COVID-19) with an associated case-fatality rate of 6.9% (1). The first death from COVID-19 in the state of Indiana was reported on March 16; 65 deaths and 2,565 cases were confirmed by March 31 (2). Severe COVID-19 is

characterized by acute respiratory failure often culminating in the need for mechanical ventilation (3–6). Studies have associated increased acute phase reactants and inflammatory markers with severe COVID-19 (3–5,7–10). Abnormal coagulation parameters have additionally been associated with severe or fatal COVID-19 (11–13). These reports describe a biochemical profile suspicious for a prothrombotic and hypercoagulable state characterized by significant elevations in fibrinogen and a rapid unexpected ascent of serum d-dimer. This degree of profound systemic inflammation has a well-known association to a hypercoagulable state (14). These findings, and anecdotal clinical experience, have generated the hypothesis that a prothrombotic state may play a dominant pathophysiologic role in severe or fatal COVID-19. Supporting this thesis is a study from China describing decreased mortality in critically ill patients receiving prophylactic anticoagulation with low-molecular-weight heparin (15).

Profound systemic inflammation, critical illness, immobility, and organ failure are documented risk factors for a prothrombotic and hypercoagulable state (16–18). Recent autopsy reports in patients with COVID-19 identified cardiac and pulmonary microvascular thrombosis (19), supporting clinical suspicion for this pathophysiologic mechanism in COVID-19 shared among physicians on preprint platforms and social media. The frequency of venous thromboembolism (VTE) in critically ill patients with COVID-19, including deep vein thrombosis (DVT) and pulmonary embolism (PE), is becoming better understood, ranging from 25% to 27% in recent publications (12,13). Thromboelastography is a dynamic evaluation of the viscoelastic properties of whole blood throughout the clot formation and lysis process, allowing for quantitative measurement of clot formation kinetics (20, 21). In various clinical circumstances including critical illness, a hypercoagulable thromboelastography profile has been associated with increased thrombotic risk; however, thromboelastography has not been explored in patients with severe COVID-19.

The aim of this study was to determine the frequency of VTE in critically ill COVID-19 patients and associate a degree of inflammatory marker elevation to VTE development.

MATERIALS AND METHODS

Study Population

All patients with laboratory-confirmed SARS-CoV-2 infection admitted to three Indianapolis area hospitals between March 12 and March 31 were evaluated in this study. Patients less than 18 years old, imprisoned patients, pregnant patients, and patients who elected for comfort care on arrival were excluded from analysis. All data available through May 6, 2020, were included.

Two-hundred forty adult patients were admitted; 122 patients had mild/moderate COVID-19 and 118 patients had severe/fatal COVID-19. Definitions of COVID-19 severity are defined in subsequent text. Nine patients with severe COVID-19 elected for comfort care only and were excluded from the analysis, resulting in 109 patients meeting inclusion criteria (**Fig. 1**). Twelve patients with thromboelastography were included in a subgroup analysis. The Indiana University (IU) Institutional Review Board (IRB) approved the conduct of this study (IRB Study Number 2004134287) and deemed it exempt. Informed consent was waived, and anonymized data were analyzed.

The severity of COVID-19 is defined in subsequent text. All patients admitted with COVID-19 receive VTE chemoprophylaxis including either 5,000 U subcutaneous heparin every 8 hours, 40 mg enoxaparin daily, or 30 mg enoxaparin bid. Mild COVID-19 patients received best supportive treatment. Moderate and severe COVID-19 patients, in addition to best supportive care, were treated with hydroxychloroquine 400 mg orally every 12 hours for two doses, then 400 mg orally daily for four doses and azithromycin 500 mg IV daily for three doses. Acute respiratory distress syndrome (ARDS) was defined according to the Berlin criteria (22). In patients with low pulmonary compliance, similar to traditional ARDS, standard ARDS Network strategy was used (23). Although standardized treatment protocols were applied generally, clinical judgment in individual cases dictated treatment strategies.

Study Definitions

Coexisting medical conditions and medications were recorded according to physician documentation at the time of hospital admission. Individual patient's clinical examination findings, laboratory results, diagnostic imaging, treatment, and outcomes were retrospectively reviewed.

Testing for COVID-19 was obtained in accordance with the Centers for Disease Control and Prevention (CDC) guidelines and clinical specimens were tested using the CDC's assay (24). Testing occurred at the Indiana State Department of Health Laboratory from March 1 to March 19. All testing on and after March 20 was performed at the IU Health Pathology Laboratory.

Per institutional guidelines, mild COVID-19 was defined as Spo_2 greater than 94% on room air with or without radiographic evidence of pneumonia. Moderate COVID-19 was defined as a measured peripheral oxygen saturation (Spo_2) less than or equal to 94% on room air with or without radiographic evidence of pneumonia. Severe COVID-19 was defined as Spo_2 less than or equal to 94% with respiratory rate greater than or equal to 30 breaths per minute and Pao_2/Fio_2 ratio less than or equal to 300 mm Hg. Any patient requiring mechanical ventilation was considered to have severe COVID-19.

Extremity DVT was diagnosed on four-extremity duplex ultrasound performed for clinical suspicion for venous thrombosis and defined as a loss of compressibility of the vein and abnormal or absent blood flow. PE was diagnosed on contrast-enhanced cross-sectional imaging and defined as a filling defect within the lumen of the pulmonary artery or its branches. All patients developing VTE at any time period during their illness were included in this analysis.

Kaolin activated thromboelastography was performed with the TEG5000 hemostasis analyzer (Haemonetics, Braintree, MA) and used heparinase coated cups. Each

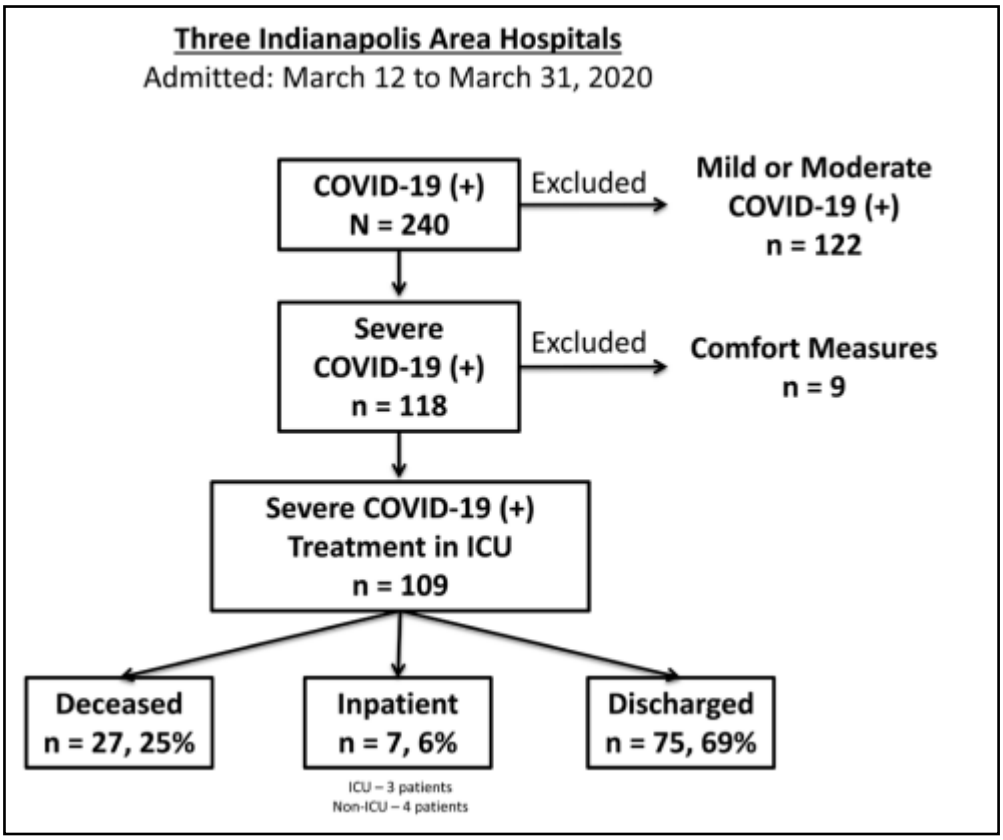

Figure 1. Flow chart of study patients. COVID-19 = coronavirus disease 2019.

thromboelastography assay included reaction time (R), kinetics (K), alpha angle (α), maximum amplitude (MA), and fibrinolytic activity 30 minutes after MA (LY30). A hypercoagulable thromboelastography was defined as two or more thromboelastography parameters beyond one sd of the age- and gender-matched controls (25). Of the individual thromboelastography parameters, a decreased R-time and K-time and an increased alpha angle and MA were considered hypercoagulable. A coagulation index (CI) was calculated for each thromboelastography and considered hypercoagulable if elevated beyond the laboratory reference range.

Statistical Analysis

Statistical analysis was performed using IBM SPSS Statistics Version 25.0 with deidentified data (IBM, Armonk, NY). Categorical variables are summarized as number with percentages. Variables with greater than 50% of patients missing data were not reported or included in the analysis. Continuous variables are reported as mean values with sd or median values with interquartile range (IQR). No imputation was made for missing data. As appropriate, the chi-square test and Mann-Whitney *U* tests were performed to evaluate the bivariate relationship between variables of interest and COVID-19 outcomes. Receiver operator characteristic curves were plotted and Youden Index was used to determine optimal laboratory cutoff points. The discriminatory ability of these cutoff points to predict VTE was assessed by calculating the area under the curve (AUC), sensitivity, and specificity. *p* values of less than 0.05 were accepted as statistically significant.

RESULTS

Demographic and Clinical Characteristics

One-hundred nine patients with confirmed SARS-CoV-2 infection were treated for severe COVID-19 requiring intensive care. Demographic and clinical characteristics are shown in **Table 1**. Fifty-five patients (50%) were black, the mean age was 61 ± 16 years, and 57% of patients were male. The mean body mass index was 34.8 ± 11.8 kg/m^2. Sixty-one patients (56%) were admitted directly to the ICU. The mean duration of symptoms prior to ICU admission was 8 ± 5 days. Respiratory failure requiring mechanical ventilation developed in 103 patients (94%), cardiovascular failure requiring vasopressors developed in 70 patients (64%), and renal failure requiring renal replacement therapy (RRT) developed in 16 patients (15%).

As of May 6, 7 patients (6%) continue to receive inpatient treatment (non-ICU, *n* = 4; ICU, *n* = 3), 75 patients (69%) had been discharged from the hospital, and 27 patients (22%) died (Fig. 1). Patients discharged from the ICU had a median duration of 13 days (IQR, 9–17 d) of intensive care. Of the patients discharged from the hospital, the median hospital length of stay was 20 days (IQR, 16–27 d). Death occurred a median of 11 days (IQR, 8–16 d) after hospital admission.

The median time to routine chemical VTE prophylaxis was hospital day 0 (IQR, 0–1 d) and included subcutaneous heparin every 8 hours (*n* = 61, 56%), enoxaparin daily (*n* = 26, 24%), or enoxaparin every 12 hours (*n* = 14, 13%). Seven patients (6%) were treated with full anticoagulation immediately upon admission for existing medical comorbidities (*n* = 4, 4%) or VTE diagnosed at presentation (*n* = 2, 2%). One patient was transferred from an outside hospital in which the timing of VTE prophylaxis initiation was unable to be determined.

Venous Thromboembolism

Of the 109 patients with severe COVID-19, 31 patients (28%) developed VTE. Two patients were diagnosed with VTE upon presentation to the hospital; the remaining 29 patients developed VTE while on routine chemical VTE chemoprophylaxis (*n* = 26) or on full anticoagulation for medical comorbidities (*n* = 3). Isolated DVT was diagnosed in 26 patients (84%) and isolated PE was diagnosed in one patient (3%); four patients

had both DVT and PE (13%). Five DVT were associated with central venous catheters (CVCs) in the internal jugular vein (n = 3) and femoral vein (n = 2); however, in four of these patients, additional DVT were detected in locations remote from the CVC. The number of DVT identified per patient was 3 ± 2. Of the 30 patients with DVT, the location of the DVT was most commonly the lower extremities (n = 18, 60%); however, upper extremity DVT and both upper and lower extremity DVT were diagnosed in six each (20%). The mean time from hospital admission to VTE diagnosis was 8 ± 7 days. Initial treatment for VTE included unfractionated heparin IV infusion (n = 13, 42%), weight-based enoxaparin subcutaneously bid (n = 13, 42%), oral apixaban (n = 2, 6%), and unfractionated heparin IV infusion with alteplase infusion (n = 2, 6%). In one patient, anticoagulation was contraindicated due to recent cerebrovascular accident.

On univariate analysis, the development of VTE was significantly associated with higher serum platelet count, aspartate aminotransferase, lactate dehydrogenase, d-dimer, and troponin concentrations at admission (Table 1). The frequency of VTE was no different in patients without or with respiratory failure requiring mechanical ventilation (33% vs 28%; p = 0.785), cardiovascular failure requiring vasopressors (26% vs 30%; p = 0.629), or renal failure requiring RRT (31% vs 12.5%; p = 0.126). When comparing the peak serum concentration of laboratory values in patients prior to VTE diagnosis to patients that did not develop VTE, increased d-dimer concentration and decreased platelet counts were observed (**Table 2**).

Admission d-dimer concentration, peak d-dimer concentration, and peak platelet count were plotted on a receiver-operating characteristic curve; the AUC, ideal laboratory cutoff points to detect VTE, and associated sensitivity and specificity are shown in **Figure 2**. A serum d-dimer concentration greater than 2,600 ng/mL (normal range, 0–292 ng/mL) was the test with the best discriminatory ability to detect VTE with an AUC of 0.760 (p < 0.0001) and a sensitivity and specificity of 89.7% and 59.5%, respectively. Patients developing VTE had no difference in mortality (8/31, 26%) when compared with patients that did not develop VTE (19/78, 24%; p = 0.875).

Thromboelastography

Twelve patients (11%) had thromboelastography analyzed during their hospital stay and the mean value of each thromboelastography parameter is shown in **Figure 3**. Thromboelastography was performed a median of 3.5 days (IQR, 1–6 d) after hospital admission and was performed for significantly elevated d-dimer (n = 8, 67%) or as a baseline prior to extracorporeal membrane oxygenation initiation (n = 3, 25%). In one patient (8%), thromboelastography was ordered due to persistent clotting of the RRT filter. Hypercoagulable thromboelastography (≥ 2 hypercoagulable thromboelastography parameters) were observed in 58% of patients and at least one thromboelastography parameter was hypercoagulable in 83% of patients. The most common hypercoagulable feature of thromboelastography was a decreased R-time in 67% of patients. The calculated CI was hypercoagulable in 50% of patients. The individual patterns of patients with hypercoagulable and nonhypercoagulable thromboelastography are shown in Figure 3. The mean d-dimer in patients with a hypercoagulable thromboelastography was 2,240 ± 599 ng/mL. Three patients (43%) with a hypercoagulable thromboelastography developed VTE; however, one patient with a normal thromboelastography developed VTE.

DISCUSSION

In this series of 109 critically ill COVID-19 patients among three Indianapolis area hospitals, we report an extremely high frequency of VTE despite the prompt initiation of routine chemical VTE prophylaxis. Risk factors associated with VTE development included an elevated d-dimer at hospital presentation and an elevated d-dimer or decreased platelet count during intensive care. Thromboelastography documented hypercoagulability in the majority of patients in which it was

TABLE 2. Peak Inflammatory and Coagulation Markers Prior to Venous Thromboembolism Diagnosis

Laboratory Value	No VTE (n = 80), n, Median (IQR)	VTE (n = 29), n, Median (IQR)	p
Platelet count (per mm^3)	**78, 383,000 (291,000–472,000)**	**31, 294,000 (223,000–340,000)**	**0.001**
Neutrophil-to-lymphocyte ratio	74, 12.2 (8.6–23.7)	29, 16.0 (9.3–21.0)	0.695
Lactate dehydrogenase (U/L)	75, 541 (401–708)	26, 534 (495–721)	0.870
Fibrinogen (mg/dL)	46, 680 (521–872)	23, 651 (465–771)	0.243
d-dimer (ng/mL)	**74, 1,934 (695–3,573)**	**29, 4,046 (3,071–13,324)**	**0.00004**
Ferritin (ng/mL)	70, 910 (447–1,775)	26, 1,022 (459–1,643)	0.882
C-reactive protein (mg/dL)	73, 24.3 (17.3–32.3)	27, 26.4 (13.6–33.4)	0.877
Procalcitonin (ng/mL)	63, 0.34 (0.20–1.93)	25, 0.66 (0.15–3.98)	0.554

IQR = interquartile range, VTE = venous thromboembolism.
Unless otherwise stated, median values are reported with IQR.
Bold values represent statistical significance with p < 0.05.

performed. Mortality was not significantly different in patients developing VTE when compared with patients who did not develop VTE.

We report a frequency of VTE of 28% in critically ill patients with COVID-19 and identified an elevated d-dimer at presentation and an elevated d-dimer or thrombocytopenia

during intensive care as risk factors for VTE development. About 5–10% of critically ill patients develop VTE; thus, the risk for VTE in critically ill patients with COVID-19 is about 2.5–5 times higher than the general ICU population (26, 27). The frequency of VTE identified in the current study is similar to that reported in two recent studies from China (25%) and the Netherlands (27%) (12, 13) and similar to that reported in critically ill patients with severe acute respiratory syndrome (24%) during the outbreak in the early 2000s (28). COVID-19 is associated with a profound systemic inflammatory response, hypercoagulable serum coagulation profile, organ failure, and immobility; thus, it is no surprise that the frequency of VTE is significant and higher than expected despite prompt initiation of routine chemical VTE prophylaxis. This study likely underestimates the true frequency of VTE in this population, as diagnostic evaluation for VTE was deferred to prevent untoward risk to healthcare workers and inpatients.

The mechanism by which critically ill patients with COVID-19 develop VTE at a higher frequency than the general ICU population remains unclear, specifically whether a hypercoagulable state is induced by the degree of viremia and the virus itself, or if this is simply in response to the profound systemic inflammation and critical illness, which are known risk factors for VTE development (14, 16, 26, 27). The association between elevated d-dimer and VTE development is likely representative of both the degree of systemic inflammation in critically ill COVID-19 patients and inappropriate activation of the coagulation cascade; however, the degree to which each of these components contribute to VTE development was not possible to determine in this study. The frequency of VTE in severe COVID-19, its risk factors, and outcomes warrant ongoing worldwide investigation, as COVID-19 will likely continue to contribute to worldwide morbidity and mortality for some years. Given the documented hypercoagulability and frequency of VTE in this population, consideration should be given to an escalated dose of chemical VTE prophylaxis using either weight-based or anti-factor-Xa guided dosing in COVID-19 patients with d-dimer greater than 728 ng/mL at presentation. In addition to this increased dosing of chemical VTE prophylaxis, critically ill patients with a d-dimer greater than 2,600 ng/mL (or > 10 times the upper limit of laboratory normal) should be evaluated with four-extremity duplex ultrasound; empiric anticoagulation in the setting of elevated d-dimer and presumptive diagnosis of VTE should be made on a case-by-case basis. Early detection of VTE and prevention of PE in patients with severe COVID-19 is paramount given the mounting clinical and autopsy evidence of lung microvascular and macrovascular thrombosis (12, 13, 19, 29), which plausibly may be contributing to the progressive and fatal hypoxemic respiratory failure in these patients without prompt initiation of adequate anticoagulation.

In this series of 12 patients with severe COVID-19 undergoing thromboelastography analysis, 58% met objective criteria for hypercoagulability and 83% of patients had at least one hypercoagulable thromboelastography parameter. The most common hypercoagulable parameter was the reaction (R) time in 67% of patients. This suggests that SARS-CoV-2 infection and the associated systemic inflammation, in the most severe cases, results in activation of the coagulation cascade. Three of seven patients with a hypercoagulable thromboelastography went on to develop VTE; thus, larger volume, prospective studies may be warranted to evaluate this association further and define the utility of thromboelastography in COVID-19. Given the degree of inflammatory and coagulation marker elevation in severe COVID-19, serial thromboelastography analysis may provide useful insights as to which patients are at highest risk for microvascular and macrovascular thrombosis, potentially offering a window for improved and effective microvascular and macrovascular thrombosis prophylaxis. Our study corroborates a recently published study that reported hypercoagulable thromboelastography in COVID-19 patients (30). Thromboelastography represents an objective metric (thromboelastography) to describe the hypercoagulability encountered in COVID-19 and provides a more complete picture of the coagulation cascade compared with traditional laboratory values. Large, prospective studies evaluating thromboelastography could provide detailed insight into the abnormal coagulation in COVID-19. Further, the potential role of platelet activation and aggregation in VTE development can be evaluated with thromboelastography, providing an additional target for improved VTE prophylaxis with antiplatelet therapy. The current study and the study published by Panigada et al (30) were unable to evaluate platelet function in COVID-19, as thromboelastography with platelet mapping was not routinely performed. A multi-institutional observational study evaluating the utility of serial thromboelastography in COVID-19 is currently underway. Future investigation may evaluate for an association between thromboelastography parameters and anti-factor Xa guided VTE prophylaxis, as thromboelastography may not be available at all institutions treating COVID-19 patients.

Given the gravity and scope of the COVID-19 pandemic, rapid dissemination of significant clinical observations is paramount to improving patient outcomes; however, several limitations of this study deserve mention. Although this is a relatively large series it is an observational study and the inherent bias introduced by a retrospective evaluation of any patient population is a limitation. The retrospective nature of this study precludes the ability to establish any causal relationship between d-dimer concentration or platelet count and VTE development. Critically ill COVID-19 patients often had multiple CVCs simultaneously and/or at different time points throughout their treatment and the location of CVC as a risk factor for VTE development was unable to be evaluated. Measurement of prothrombin time was not included in the institutional protocol at the time of this study and not routinely performed, thereby preventing the ability of this study to evaluate disseminated intravascular coagulation. Only critically ill COVID-19 patients were included in this study; therefore, this study lacked a comparator group of ICU patients without COVID-19 in which to compare VTE frequency. The current study did not evaluate the degree of viremia as a risk factor for

VTE and this should be considered in future studies. The small number of patients with thromboelastography analysis may not accurately reflect the trends of the entire cohort and more detailed analysis is warranted. Given the number of patients with thromboelastography data, we were unable to associate thromboelastography parameters to VTE. The number of comparisons was intentionally kept to a minimum to avoid the introduction of type II error. Finally, Patients with sudden clinical deterioration and death were not evaluated postmortem for the development of VTE.

CONCLUSIONS

These data show that SARS-CoV-2 infection results in systemic hypercoagulability resulting in VTE. Although current data on outcomes in patients receiving therapeutic anticoagulation in COVID-19 are lacking, it is apparent that routine chemical VTE prophylaxis may be inadequate in preventing thrombotic complications in severe COVID-19.

Coagulopathy of Coronavirus Disease 2019

Toshiaki Iba, MD[1]; Jerrold H. Levy, MD[2]; Marcel Levi, MD[3]; Jean Marie Connors, MD[4]; Jecko Thachil, MD[5]

Downloaded from https://journals.lww.com/ccmjournal by A1V36RY5v17t+yzsxkVM6HA7rlTGhx+v6vG6mv+q3Yq0hk3sgJeRTu8Fog1CW3yGJhnBpPdv0x6ErC7OktRrYkAN3zR0G9NFeklLvfC2XrnPK5L4K6bRDr5o4GpBEVP on 05/29/2020

Objectives: Recent studies have reported a high prevalence of thrombotic events in coronavirus disease 2019. However, the significance of thromboembolic complications has not been widely appreciated. The purpose of this review is to provide current knowledge of this serious problem.

Design: Narrative review.

Data Sources: Online search of published medical literature through PubMed using the term "COVID-19," "SARS," "acute respiratory distress syndrome," "coronavirus," "coagulopathy," "thrombus," and "anticoagulants."

Study Selection and Data Extraction: Articles were chosen for inclusion based on their relevance to coagulopathy and thrombosis in coronavirus disease 2019, and anticoagulant therapy. Reference lists were reviewed to identify additional relevant articles.

Data Synthesis: Coronavirus disease 2019 is associated with a strikingly high prevalence of coagulopathy and venous thromboembolism that may contribute to respiratory deterioration. Monitoring coagulation variables is important, as abnormal coagulation tests are related to adverse outcomes and may necessitate adjuvant antithrombotic interventions. In the initial phase of the infection, d-dimer and fibrinogen levels are increased, while activated partial prothrombin time, prothrombin time, and platelet counts are often relatively normal. Increased d-dimer levels three times the upper limit of normal may trigger screening for venous thromboembolism. In all hospitalized patients, thromboprophylaxis using low-molecular-weight heparin is currently recommended. The etiology of the procoagulant responses is complex and thought to be a result of specific interactions between host defense mechanisms and the coagulation system. Although the coagulopathy is reminiscent of disseminated intravascular coagulation and thrombotic microangiopathy, it has features that are markedly distinct from these entities.

Conclusions: Severe acute respiratory syndrome coronavirus 2/coronavirus disease 2019 frequently induces hypercoagulability with both microangiopathy and local thrombus formation, and a systemic coagulation defect that leads to large vessel thrombosis and major thromboembolic complications, including pulmonary embolism in critically ill hospitalized patients. d-dimers and fibrinogen levels should be monitored, and all hospitalized patients should undergo thromboembolism prophylaxis with an increase in therapeutic anticoagulation in certain clinical situations. (*Crit Care Med* 2020; XX:00–00)

Key Words: coagulopathy; coronavirus; coronavirus disease 2019; disseminated intravascular coagulation; hypercoagulability; thromboembolism

Increasing communications worldwide have reported that hospitalized, critically ill coronavirus disease 2019 (COVID-19) patients are frequently developing laboratory abnormalities compatible with hypercoagulability and clinically a high prevalence of thromboembolic events (1). In addition to deep vein thrombosis (DVT) and pulmonary embolism (PE), thrombosis in extracorporeal circuits and arterial thrombosis have been reported (2). Patients with COVID-19 often present with dyspnea, hypoxemia, and hemodynamic instability with acute respiratory distress syndrome (ARDS), and in such clinical condition, venous thromboembolism (VTE) may be overlooked (3, 4). Standard imaging in critically ill patients utilizing contrast-enhanced CT may not always be feasible, and additionally, concerns exist with disease transmission to health-care staff.

Ranucci et al (5) recently reported comprehensive coagulation analyses including d-dimers, fibrinogen levels, and viscoelastic testing in the COVID-19 patients with ARDS, and reported the procoagulant profile on ICU admission with median d-dimer levels of 5.5 mg/L (10 times the upper limit of normal), fibrinogen levels of 7.8 g/L, and increased clot strength by thromboelastometry. Panigada et al (6) performed a similar analysis and also noted increased fibrinogen levels, enhanced platelet activation, and increased viscoelastic variables. Beyond

VTE, the relevance of microthrombus formation to organ dysfunction and acro-ischemic change has also been suggested (7–9). Although the number of postmortem pathologic reports are limited, Luo et al (10) described vascular wall thickening, stenosis of the vascular lumen, and microthrombus formation accompanying the findings of ARDS. Similar pathologic findings are found in small vessels of other organs (8–11). Magro et al (12) reported the deposition of C5b-9 (membrane attack complex), C4d, and mannose-binding lectin-associated serine protease-2 in the lung capillaries and the skin microvasculature. Notably, the deposition was co-localized with the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) spike glycoprotein. A recent report also noted mononuclear and polymorphonuclear leukocyte infiltration and pulmonary microcirculation along with apoptosis as induced by caspase-3 staining (13).

In critically ill COVID-19 patients, there appear to be at least two separate pathologic coagulation pathologic processes that are important in producing clinical manifestations. In the microcirculation of the lung and potentially other organs, there is local direct vascular and endothelial injury producing microvascular clot formation and angiopathy (13, 14). Postmortem biopsy of the lung revealed mononuclear and polymorphonuclear infiltration along with apoptosis of endothelial and mononuclear cells (13). In the systemic circulation, due to hypercoagulability with hyperfibrinogenemia, there is also the potential for large vessel thrombosis and major thromboembolic sequelae including PE that is reported in 20–30% of ICU patients (15–17) (**Fig. 1**). Because of the important role of coagulation activation in critically ill COVID-19 patients, this review summarizes the current knowledge about the coagulopathy and role of anticoagulation in these patients.

PREVALENCE OF COAGULOPATHY AND DISSEMINATED INTRAVASCULAR COAGULATION

Coagulopathy is a common feature of SARS-CoV-2 infection, and an increase in d-dimer is the most common finding. One of the larger initial studies found abnormally elevated d-dimer levels in 260 of 560 cases (46.4%) with a prevalence of 43% in nonsevere patients compared with 60% in critically ill ICU patients (18). In another series, elevated d-dimers were associated with a poor prognosis (19). More recently, Zhang et al (20) examined 343 cases and showed that d-dimer levels of over 2.0 mg/L could predict mortality with a sensitivity of 92.3% and a specificity of 83.3%. Tang et al (21) reported increased d-dimers and fibrin degradation products along with mildly to moderately increased prothrombin times (PTs) and activated partial thromboplastin times (aPTT) in COVID-19. Of note is they reported that 71.4% of nonsurvivors fulfilled the criteria of sepsis-induced coagulopathy, while 0.6% of the survivors met the criteria.

Platelet counts in COVID-19 patients are variable depending on the reported studies. A meta-analysis reported significantly lower platelet counts in critically ill COVID-19 patients with weighted mean difference of -31×10^9/L (95% CI, -35 to -29×10^9/L), and thrombocytopenia defined as below the lower limit of the reference range was associated with more than five-fold higher risk of severe disease, which may reflects secondary infections (22). However, as noted above, thrombocytopenia is not a significant finding initially in COVID-19 (23). Huang et al (24) reported platelet counts of less than 100×10^9/L in only 8% of ICU and 4% in non-ICU patients initially at admission. Yin et al (25) compared the platelet count between COVID-19–associated ARDS patients and non-COVID-19 ARDS patients and reported minor clinical differences in platelet counts (215 ± 100 vs $188 \pm 98 \times 10^9$/L). The lack of thrombocytopenia reflects that this is not a consumptive coagulopathy typical of disseminated intravascular coagulation (DIC). The potential for increases in platelet counts in COVID-19 patients is suspected to be caused by increased proinflammatory cytokines such as interleukin (IL)-1β and IL-6 produced by the macrophages and monocytes in the lung (26), and activated platelets may contribute to the lung injury (27). Interestingly, only 6.4% of COVID-19 patients who died met DIC criteria of the International Society on Thrombosis and Haemostasis (ISTH) (28). More recent data suggests the COVID-19

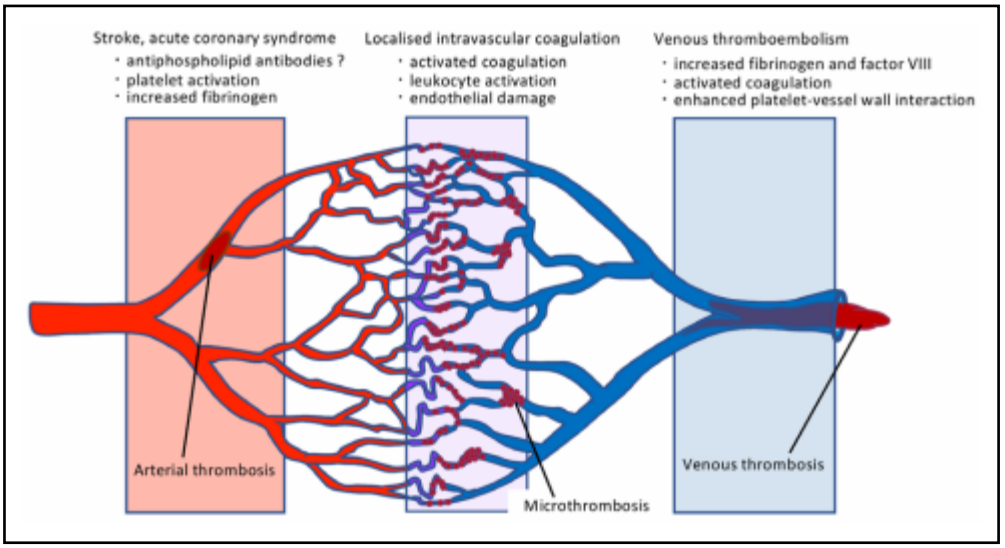

Figure 1. Various types of thrombus formation in coronavirus disease 2019 (COVID-19). Venous thrombosis and pulmonary thromboembolism are common complications in COVID-19. Increased fibrinogen and factor VIII, activated coagulation, direct viral endothelial infection and endothelial injury, and increased platelet-vessel wall interaction activation play roles in the development of thrombotic complications. In addition, there may be pulmonary microvascular coagulation in COVID-19. The prevalence of arterial thrombosis is also high and involvement of antiphospholipid antibodies has been suggested.

Copyright © 2020 by the Society of Critical Care Medicine and Wolters Kluwer Health, Inc. All Rights Reserved.

coagulopathy is different from common bacterial infection-induced DIC with relatively minimal changes in platelet counts, antithrombin levels, PT, and aPTT (21, 29).

The association with increased microvascular thrombosis, increased levels of lactate dehydrogenase (LDH) and ferritin, and mild increase in PT and aPTT are reminiscent of thrombotic microangiopathy (30). Although thrombocytopenia and hemolytic anemia are uncommon in COVID-19, clinical presentations of increased d-dimers, vascular endothelial injury, and multiple organ damage are also common features of atypical hemolytic uremic syndrome (12).

CHANGES IN COAGULATION AND FIBRINOLYSIS

The coagulation cascade is activated in viral infections as a host defense to limit the spread of the pathogens (31). Initially, an adaptive hemostasis response occurs that is associated with a systemic inflammatory response. As a result of increased inflammatory activity, fibrinogen is significantly increased, and thrombin generation occurs (32). The enhanced cytokine production during virus infection also stimulates additional procoagulant reactions, with increased tissue factor expression, a major initiator of the activation in coagulation. However, other factors such as phosphatidylserine on the cellular membrane, neutrophil extracellular traps, and damage-associated molecular patterns (DAMPs) may also be involved in the procoagulant profile in COVID-19 (33). In some cases, the presence of antiphospholipid antibodies that can induce arterial thrombosis is reported (2), and the relevance to stroke and acute coronary disease should be examined in future studies.

There is an association between bronchoalveolar coagulation/fibrinolysis and the pathogenesis of ARDS that enhances intrapulmonary deposition of fibrin (34). In cases of bacterial infection, measurement of coagulation and fibrinolysis factors in bronchoalveolar lavage fluid (BALF) have demonstrated enhanced intrapulmonary thrombin generation, insufficiently balanced physiologic anticoagulation, and suppressed fibrinolysis mediating the pathogenesis of ARDS (35). In COVID-19, procoagulant activity is increased through tissue factor pathway, and plasmin activity suppressed by the reduced urokinase-type plasminogen activator and increased plasminogen activator inhibitor-1 (36, 37). By contrast, Ji et al (38) reported activated plasmin and increased fibrinolytic activity resulting in d-dimer elevation in COVID-19 and reported that the preexisting increased plasmin activity recognized in hypertension, diabetes, and cardiovascular disease enhances the virulence and infectivity of the SARS-CoV-2 virus by cleaving its spike proteins. The pathologic findings of ARDS in COVID-19 suggest the inflammation and diffuse alveolar damage with exudates that mimic sepsis-induced ARDS are lymphocyte predominant (39).

Gattinoni et al (40) hypothesized that there are two distinct types of lung damage in ARDS. Type-L is characterized by the low elastance and high compliance, which is rarely seen in ARDS, while type-H shows high elastance and low compliance that is the typical style of ARDS. They explain the primary cause of hypoxemia in type-L is perfusion defects presumably caused by vasoconstriction and high shunt fraction. In contrast, the high elastance in type-H is thought to be induced by lung edema. We hypothesize that the intravascular coagulation and clot formation, in addition to the vasoconstriction, contribute to the disturbance of perfusion. The findings as mentioned above suggest that the procoagulant changes are present in both intra-alveolar and intravascular spaces (**Fig. 2**). Indeed, Dolhnikoff et al (41) reported the fibrinous thrombi in pulmonary arteriole in areas of both damaged and preserved lung parenchyma. The endothelial damage in the pulmonary capillary is also accelerated by the vascular endothelial damage. SARS-CoV-2 infects endothelial cells through an angiotensin-converting enzyme 2 receptor (42); the rapid viral replication causes massive endothelial cell apoptosis and triggers the loss of anticoagulant function of the vascular lumen. In addition to the derangement of coagulation/fibrinolysis and platelet function, endothelial dysfunction contributes to the procoagulant change in COVID-19 (**Fig. 3**).

INFLAMMATORY THROMBUS, MICROCIRCULATORY INJURY, AND ORGAN DYSFUNCTION

Various proinflammatory cytokines are known to be elevated in COVID-19, and a "cytokine storm" is estimated to be relevant in the progression and modification of the disease. Tumor necrosis factor-α, IL-1β, IL-6, interferon-γ, and granulocyte-colony stimulating factor are the representative cytokines that mediate inflammation and coagulation. Elevation in the circulating blood cytokine levels is also increased in the lung. Xiong et al (43) revealed increased levels of chemokines such as monocyte chemotactic protein 1 (MCP-1), interferon-inducible protein-10, macrophage inflammatory protein-1α in the BALF obtained from COVID-19 patients. This cytokine storm leads to the systemic intravascular coagulation, multiple organ dysfunction syndrome (MODS), and fatal outcome (9). Indeed, Cao et al (44) integrated data obtained from more than 46,000 COVID-19 cases, and reported that the prevalence of ARDS was 28.8%, that of MODS was 8.5%, and the fatality rate was 6.8%. Therefore, the regulation of the overproduced cytokine is a focus of treatments targeting suppression of IL-1 family and IL-6 currently in trials (26). The multiple inflammatory mediators also can produce microcirculatory injury and thrombus formation. In the postmortem evaluation of COVID-19 pulmonary tissues, the arterial vessels demonstrated neutrophilic and mononuclear cellular infiltration, and apoptosis of endothelial cells and mononuclear cells based on caspase 3 immunostaining (13).

Mehta et al (45) reported that severe COVID-19 resembles hemophagocytic lymphohistiocytosis (HLH) most frequently triggered by viral infection, a clinical scenario with uncontrolled cytokine production and typically presentation of fever, splenomegaly, cytopenia of two or more lineages, increased ferritin, low fibrinogen level, and MODS, including ARDS (46, 47). Chest radiographic findings in HLH include bilateral

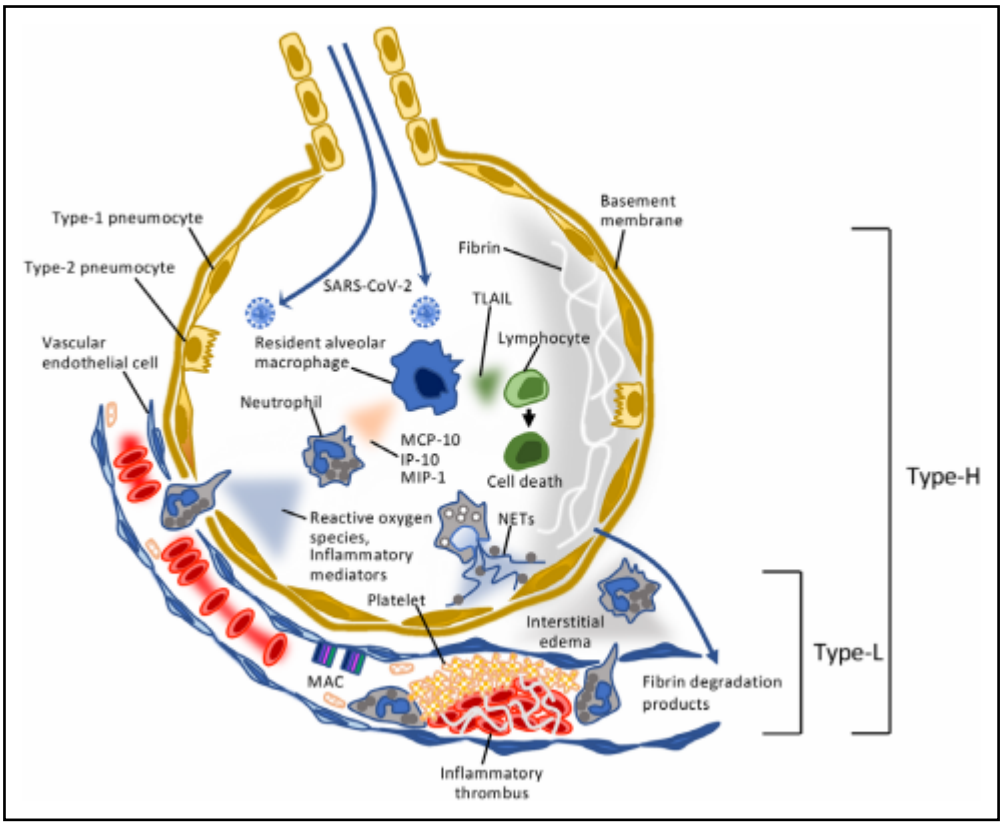

Figure 2. Lung injury in coronavirus disease 2019 (COVID-19). COVID-19 infection causes acute lung injury induced by activation of residential macrophages, lymphocyte apoptosis, and neutrophils. The macrophages produce cytokines and chemokines including monocyte chemotactic protein 1 (MCP-1), interferon-inducible protein (IP)-10, macrophage inflammatory protein (MIP)-1, and releases these mediators into the alveolar space. Increased tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL) stimulates the lymphocyte apoptosis. COVID-19 also induces vascular endothelial damage through activating the complement system that leads to increased permeability and inflammatory thrombus formation. The fibrinolytic system is activated releasing fibrin degradation fragments (d-dimers) in the circulation. When the changes in the blood vessel are dominant and the damage in the alveolar space is relatively mild, that situation is considered as type-L, and when the damage advances to the alveolar space, it turns to type-H. MAC = membrane attack complex, NETs = neutrophil extracellular traps, SARS-CoV-2 = severe acute respiratory syndrome coronavirus 2.

ground-glass opacities and consolidation that are similar to COVID-19. In laboratory testing, hyperferritinemia and high LDH levels are common, but low fibrinogen levels and cytopenias of more than two cell lineages by hemophagocytosis are not reported in COVID-19. Taken together, it may be reasonable to think that the pathophysiology of COVID-19 overlaps with low-grade HLH, and the differences and similarities of HLH and COVID-19 should be examined in future studies.

VENOUS THROMBOEMBOLISM AND PULMONARY EMBOLISM

Immobilization, inflammation, activated coagulation, and suppressed fibrinolysis increase the risk of VTE and PE. Increasing reports have indicated an increased risk of VTE and PE in COVID-19 (1, 48). Cui et al (49) examined thrombosis in non-symptomatic lower limbs by ultrasonography in COVID-19 pneumonia patients treated in ICU and reported that the prevalence was 25% (20/81). In another study in SARS-CoV-1 infected patients, it was reported that 20.5% of patients had DVT, and 11.4% had PE (50). Klok et al (15) studied 184 ICU patients and confirmed VTE in 27% and arterial thrombotic events in 3.7% patients. It should be kept in mind that the prevalence of VTE and PE is underestimated since the access to contrast-enhanced CT may be limited in critically ill patients for practical reasons. d-dimer levels can also not accurately differentiate between the presence of thrombosis and high levels due to the critical illness state. Therefore, all critically ill patients should receive VTE prophylaxis, preferably using low-molecular-weight (LMW) heparin regardless of their d-dimer level. In case of sudden deterioration, increased oxygenation requirements, right heart failure, and/or shock, a very high suspicion for PE should be maintained (51).

COAGULATION DISORDERS OF SARS-COV-2 INFECTION IN PREGNANCY

The effect of SARS-CoV-2 infection on pregnancy is not clear and, Liu et al (52) reported pregnancy and childbirth did not aggravate the course of COVID-19 pneumonia in the small case study (15 cases). However, Dashraath et al (53) suggested that 2% of pregnant women will require mechanical ventilation, 9% will have fetal growth restriction, and 43% will deliver preterm. In addition, since there are changes in coagulation/fibrinolysis that occur naturally during pregnancy, with hyperfibrinogenemia, there are considerable concerns for the risk of pregnant patients for thrombotic complications and coagulopathy. ISTH released an interim guideline for the management of COVID-19–associated coagulopathy and DIC in pregnant women (54), and this guidance recommends admission of any patients with markedly raised d-dimer, prolonged PT, platelet county less than 100×10^9/L, or fibrinogen less than 2 g/L, even in absence of other concerns, with the consideration for the use of prophylactic LMW heparin in all patients who require hospital admission in the absence of contraindications.

COAGULATION DISORDER IN CANCER PATIENTS

Patients with cancer are more susceptible to SARS-CoV-2 infection due to immunosuppression, poor nutrition,

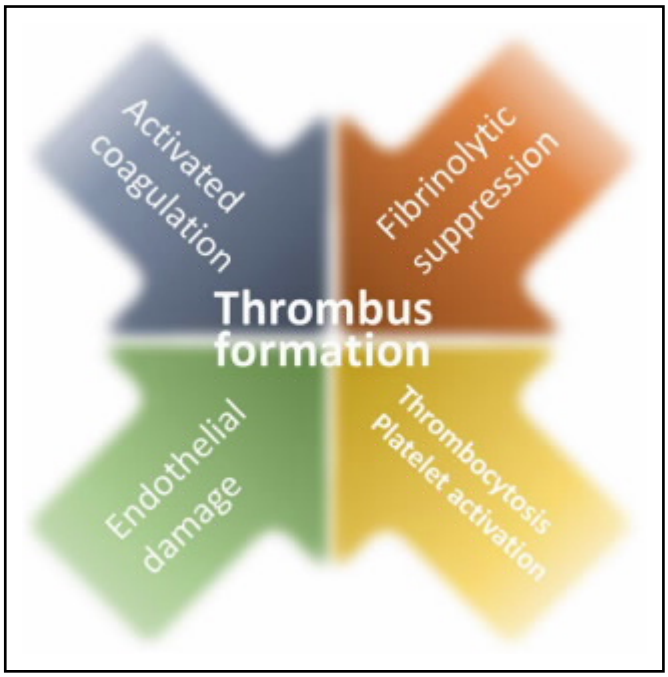

Figure 3. Thrombus formation in coronavirus disease 2019 (COVID-19). There are four major factors that accelerate thrombosis formation. First, severe acute respiratory syndrome coronavirus 2 infection-induced cytokine storm activates coagulation. Proinflammatory cytokines such as interleukin (IL)-1β and IL-6 stimulate the expression of tissue factor on immune cells and initiates extrinsic coagulation cascade activation. Second, the fibrinolytic system is suppressed by the decreased activity of urokinase-type plasminogen activator and increased release of plasminogen activator inhibitor-1. Third, platelets are activated by various proinflammatory cytokines and the damaged endothelium readily bind platelets. Fourth, endothelial damage induced by inflammation further accelerates the thrombotic reaction.

comorbidities, and immobilization (55). COVID-19 affected cancer patients require specific attention as they are prone to thromboembolic complications, and thromboprophylaxis is mandatory. However, evidence on the clinical course of COVID-19 in cancer patients is scarce so far, and more studies are warranted.

TREATMENT WITH ANTICOAGULANTS

Heparin for VTE Prevention

ISTH interim guidance recommends the use of prophylactic LMW heparin in severe COVID-19 patients (51). The effect of heparin, mainly LMW heparin, is reported by Tang et al (56) showing a reduced mortality in cases with coagulopathy and treated with heparin compared with the patients who did have coagulopathy and were not treated with heparin (40.0% vs 64.2%, respectively, $p = 0.029$). In the same study, increasing levels of d-dimer were related to increasing mortality in non-heparin treated patients. Heparin exhibits anti-inflammatory effects by neutralizing DAMPs to protect the endothelial cells by reducing the toxicity of histones on endothelial tight junctions, and decrease lung edema and vascular leakage (57, 58). Regarding the type and dose of heparins, we summarize the current recommendation in **Table 1**. Caution is required for the application of the treatment dose of heparins. The overall effectiveness is still under debate (59).

TABLE 1. Dosing Recommendations for Unfractionated and Low-Molecular-Weight Heparins

Drug	Prophylaxis	Treatment
Dalteparin (subcutaneously)	5,000 IU once daily	200 U/kg daily
Enoxaparin (subcutaneously)	40 mg once daily	1 mg/kg bid
Nadroparin (subcutaneously)	2,850 IU once daily	171 IU/kg once daily
Tinzaparin (subcutaneously)	4,500 IU once daily	175 IU/kg once daily
Unfractionated heparin	5,000 units twice/three times a day (subcutaneously)	IV titrated to target laboratory values

IU = international units.

Anticoagulant Therapies for Inflammatory Thrombus Prevention

In addition to VTE prevention, anticoagulant therapy may also have anti-inflammatory effects. Glas et al (34) proposed the administration of anticoagulants such as antithrombin and activated protein C for the treatment of classical ARDS. Others have suggested therapies to reverse pulmonary microthrombi in ARDS with tissue plasminogen activator; however, supporting evidence in humans is currently unavailable (60, 61).

Antiplatelet Therapies

Although platelets may be involved in the local and systemic thrombotic response in COVID-19 coagulopathy, adding a platelet inhibitor to unfractionated heparin or LMW heparin at therapeutic doses would increase the potential for risk for bleeding. This is a known phenomenon in acute coronary syndromes where anticoagulant therapy along with antiplatelet therapy may decrease arterial thrombosis, but it is associated with increased bleeding risk that also increases adverse events and most P2Y12 inhibitors have long half-lives without the availability of any reversal agent (62). Further, platelet function testing is cumbersome, and research studies on platelet activation biomarkers are still premature. The microvascular thrombosis, DVT, and pulmonary artery thrombosis appear to be due to abnormally elevated coagulation factor levels and the absence of the usual protective effects of the vascular endothelium. The role of platelet activation in this process is less well defined and not clearly implicated.

SUMMARY

SARS-CoV-2/COVID-19 frequently induces hypercoagulability with inflammation driving increased levels of procoagulant clotting factors and disruption of the normal

homeostasis of vascular endothelial cells resulting in microangiopathy, local thrombus formation, and a systemic coagulation defect leading to large vessel thrombosis and major thromboembolic complications including PE in critically ill hospitalized patients. In patients with infection-induced coagulopathies, a critical component of management is treating the underlying disease. In COVID-19, because we currently do not have a standard antiviral therapy, we believe some of the unique microvascular and macrovascular hypercoagulability clinician are observing represent thromboinflammatory responses to the continuing infection. As a result, sequential monitoring of coagulation tests every 2–3 days is recommended. Surveillance for development of VTE is important with heightened suspicion in patients with sudden decompensation not attributable to other factors. All hospitalized patients should receive VTE prophylaxis; higher than conventional doses of LMW heparin are currently being investigated in clinical trials, although many centers have adopted escalated or intermediate doses for VTE prophylaxis. Whether anticoagulation alone is sufficient to prevent these thrombotic events, especially those driven by endothelial dysfunction, is unknown. Additional strategies and studies to address all factors that result in microvascular and macrovascular thrombosis are needed.

Dr. Levy received funding from research, data safety, or advisory committees for CSL Behring, Instrumentation Labs, Janssen, Merck, and Octapharma. Dr. Connors' institution received funding from CSL Behring; received funding from Abbott (consulting), Bristol-Myers Squibb (consulting), and Portola (scientific advisory board). The remaining authors have disclosed that they do not have any potential conflicts of interest.

EDITORIAL

A Randomized Trial of Convalescent Plasma for COVID-19—Potentially Hopeful Signals

Arturo Casadevall, MD, PhD; Michael J. Joyner, MD; Liise-Anne Pirofski, MD

Convalescent plasma for the treatment of infectious diseases has been used since the early 20th century and was associated with reduced mortality during the 1918 influenza,[1] 2003 SARS,[2] and 2009 influenza H1N1[3] pandemics. However, most published studies of these diseases were case series and retrospective comparisons of treated and nontreated individuals. Consistent with this, several uncontrolled case series of convalescent plasma use in patients with coronavirus disease (2019) COVID-19 have suggested a possible benefit.[4-6] Given encouraging historical precedents and the absence of proven SARS-CoV-2 (severe acute respiratory disease coronavirus 2) antiviral therapies, convalescent plasma therapy has been proposed as a treatment option for COVID-19.[7] The availability of clinical information generated from randomized clinical trials is therefore of substantial importance given that the world remains in the grip of the COVID-19 epidemic and convalescent plasma is currently in use in many countries, including the US.

Related article

In their article in *JAMA*, Li et al[8] present findings from the first randomized clinical trial of convalescent plasma therapy for patients with COVID-19 conducted in China. In contrast to most other reports of convalescent plasma use in past epidemics, this study is noteworthy in that it used a randomized trial design and well-characterized plasma units with a high titer of antibody to SARS-CoV-2. It was an important accomplishment to conduct a carefully controlled trial during a pandemic with an entirely new highly contagious disease that stressed health systems in an unprecedented way.

However, the authors report that because the COVID-19 outbreak in China was being contained while the trial was ongoing and new cases were unavailable for enrollment, the trial was terminated before it reached its targeted original sample size of 200 patients; only 103 were enrolled (for whom randomization was stratified by disease severity). Consequently, the study was underpowered and many comparisons between the convalescent plasma group and the control group were not statistically significant.

In the primary analysis, based on 52 patients who were randomized to receive convalescent plasma in addition to standard treatment and 51 patients who were randomized to receive standard treatment alone (control), the primary outcome of time to clinical improvement within 28 days (defined as being discharged alive or having a reduction of 2 points on a 6-point disease severity scale) was 2.15 days shorter (95% CI, −5.28 to 0.99 days) in the intervention group compared with the control group, and clinical improvement at 28 days occurred in 27 patients (51.9%) in the intervention group vs 22 patients (43.1%) in the control group (difference, 8.8%; 95% CI, −10.4% to 28%; hazard ratio, 1.40 [95% CI, 0.79-2.49]; $P = .26$).

In analyses stratified by disease severity, among patients with severe disease (23 in the convalescent plasma group and 22 in the control group), time to clinical improvement within 28 days was 4.94 days shorter (95% CI, −9.33 to −0.54 days) in the intervention group compared with the control group, and clinical improvement at 28 days occurred in 21 patients (91.3%) in the intervention group vs 15 patients (68.2%) in the control group (hazard ratio, 2.15 [95% CI, 1.07-4.32]; $P = .03$). Among the subgroup of patients with life-threatening disease (29 in the convalescent plasma group and 29 in the control group), there were no significant differences in the primary outcome or rates of clinical improvement at 28 days: 6 patients (20.7%) in the convalescent plasma group vs 7 patients (24.1%) in the control group (HR, 0.88 [95% CI, 0.30-2.63]; $P = .83$) (P for interaction = .17).

In the entire study population, the findings for several of the secondary end points appeared to signal a more favorable outcome for patients who received convalescent plasma, although there were no statistically significant differences between the convalescent plasma group vs the control group in any of the major secondary outcomes, including 28-day mortality (15.7% vs 24.0%, respectively; $P = .30$) or rate of discharge at 28 days (51% vs 36%; $P = .13$).

Convalescent plasma use in the study by Li et al[8] was associated with some clinical improvement in severely ill patients, but not in critically ill patients. Greater efficacy in less ill individuals is expected because antibody therapies generally work best when administered earlier in disease.[9] Historically, antibody therapy was effective in reducing the mortality of pneumococcal pneumonia when instituted in the first 3 days of symptom onset.[10] Consequently, it is not surprising that patients with COVID-19 who had tachypnea and hypoxia might benefit more from convalescent plasma than those who required mechanical ventilation. However, any indication of possible benefit in the severely ill group is noteworthy because these individuals had advanced disease, which is not considered optimal for antibody therapy. Lack of efficacy among patients who were receiving mechanical ventilation, some with multiorgan failure, highlights that the pathologic process in these individuals is likely irreversible.

The convalescent plasma used in the study by Li et al had high titers of IgG to SARS-CoV-2, which correlated with neutralizing activity. While neutralizing activity is considered to be the main determinant of convalescent plasma efficacy,

Downloaded From: https://jamanetwork.com/ by a Mayo Clinic Library User on 06/03/2020

other antibody functions may also mediate protection. Correlates of antibody efficacy should be investigated in future studies. As reported in case series from Wuhan,[4,5] plasma-treated patients had large reductions in their serum viral loads and most were virus negative 3 days after infusion. This observation establishes that convalescent plasma has antiviral activity, which is important because it indicates that antibody administration mediates a clear biological effect. The precedent of antiviral drug use against HIV and hepatitis C shows that reductions in viral load translate into clinical improvement, and earlier therapy is more effective than later therapy when organ damage is already present. In this regard, antibody-mediated viral elimination removes damaging antigens, which may translate into reduced tissue damage and inflammation. Hence, the antiviral effect of COVID-19 convalescent plasma suggests that its use earlier in the course of disease could have potentially important therapeutic activity, especially in less severely ill individuals.

Significant concerns have been raised about the use of convalescent plasma in COVID-19.[11] These include transfusion-related lung injury and transfusion-related circulatory overload. In addition, there have been theoretical concerns that the administration of antibodies might aggravate disease through antibody-mediated enhancement of proinflammatory effects.[11] The study by Li et al[8] reported only 2 adverse events among the 52 individuals who received convalescent plasma, each of whom responded to corticosteroid administration. The occurrence of one episode within 2 hours of plasma administration characterized by chills and rash suggests a transfusion reaction. However, the second episode occurred within 6 hours and its association with plasma infusion is less certain. Overall, the paucity of adverse effects is reassuring and reduces concerns about adverse effects from antibody administration.

Although the observed differences in mortality rates and hospital discharge rates between the convalescent plasma group and the control group did not reach statistical significance, these data provide valuable information for the magnitude of effects that may be expected in convalescent plasma studies. For example, the observed overall mortality difference of 24% vs 15.7% provides actionable information for the design of future trials to help ensure they are adequately powered. This difference in mortality is smaller than mortality reductions associated with convalescent plasma reported in prior studies involving 1918 influenza,[1] SARS,[2] and 2009 influenza H1N1,[3] which ranged from 50% to 70%. Hence, assuming the results of the study by Li et al[8] are generalizable, the findings may be helpful in estimating effect sizes for future studies of convalescent plasma use in hospitalized patients with COVID-19.

In the study by Li et al, the median age of the patients with severe disease was 70 years, and the median time between symptom onset and randomization was 30 days. Promising results with convalescent plasma treatment in patients with SARS[2] and influenza H1N1[3] were obtained among younger patients, and in the case of SARS, earlier in the disease. The importance of a possible treatment benefit in older persons, in whom mortality from COVID-19 is markedly higher than in younger persons,[12] cannot be overstated. In addition, the apparent improvement in the clinical status of the subgroup of less severely ill patients a month after the onset of symptoms suggests that the beneficial effects of antibodies in COVID-19 may be measurable as an improvement in inflammatory markers and viral elimination before clinical improvement is observed. The prolonged course of COVID-19 in patients who recover also should be considered in the design of future studies.

However, the study by Li et al has several important limitations, which are acknowledged by the investigators. The early termination of the trial most likely resulted in an underpowered study, thereby precluding any definitive conclusions about the role and potential efficacy of convalescent plasma for patients with COVID-19. In addition, the open-label design, the possibility of an element of subjectivity for the primary outcome, lack of a protocolized approach to standard therapy, and variability among study centers also must be considered when interpreting the study findings. Despite these limitations, by virtue of its randomized design, this study takes prior case studies[5,6] one step further by helping to separate the effects of convalescent plasma from concurrently administered agents, such as corticosteroids and antiviral agents.[13]

The signal of potential benefit of convalescent plasma in the subgroup of patients with severe COVID-19 disease (ie, those without life-threatening COVID-19 disease) is similar to findings from a recent preliminary report of a clinical trial of remdesivir for COVID-19.[14] Like remdesivir, convalescent plasma administration was associated with clinical improvement without a statistically significant effect on mortality, with the important caveat that remdesivir was evaluated in a larger study (n = 1063 randomized patients), whereas the study by Li et al[8] was terminated prematurely and underpowered. For both studies, the importance of clinical improvement as a primary end point became apparent as the trials progressed.[14]

The availability of both convalescent plasma and remdesivir means that physicians now have at least 2 therapeutic options for COVID-19, which raises the question of combination therapy. Despite only a few studies of the efficacy of combination therapy with antiviral drugs and specific antibodies, there is evidence that these agents may work well in combination.[9] Given that the mechanisms of action of antiviral drugs and neutralizing antibodies are distinct, they could be synergistic. Future trials should consider the efficacy of combination antiviral and antibody therapies.

In summary, the first randomized clinical trial of convalescent plasma in COVID-19, reported by Li et al in *JAMA*, showed no statistically significant benefit in clinical improvement at 28 days or mortality among all randomized patients, but does provide an important signal of possible benefit in the subgroup of severely ill patients and suggests that high titer antibody against SARS-CoV-2 may have antiviral efficacy. These results, while preliminary and subject to important study limitations, should stimulate more clinical trials to establish the optimal conditions for antibody therapies against COVID-19 and suggest that future studies

© 2020 American Medical Association. All rights reserved.

Downloaded From: https://jamanetwork.com/ by a Mayo Clinic Library User on 06/03/2020

should focus on determining efficacy in less severely ill patients. If the efficacy of convalescent plasma is established by future studies, the ratio of donor to patients is favorable because individuals who recover from COVID-19 can donate 2 or 3 units of plasma, which could be used to treat more than 1 person with COVID-19 disease. Therapeutic success against such a complex and challenging disease as COVID-19 is likely to require more than 1 modality, and the results from Li et al [8] provide optimism for the future of antibody therapy in this disease.

IMPORTANCE Convalescent plasma is a potential therapeutic option for patients with coronavirus disease 2019 (COVID-19), but further data from randomized clinical trials are needed.

OBJECTIVE To evaluate the efficacy and adverse effects of convalescent plasma therapy for patients with COVID-19.

DESIGN, SETTING, AND PARTICIPANTS Open-label, multicenter, randomized clinical trial performed in 7 medical centers in Wuhan, China, from February 14, 2020, to April 1, 2020, with final follow-up April 28, 2020. The trial included 103 participants with laboratory-confirmed COVID-19 that was severe (respiratory distress and/or hypoxemia) or life-threatening (shock, organ failure, or requiring mechanical ventilation). The trial was terminated early after 103 of a planned 200 patients were enrolled.

INTERVENTION Convalescent plasma in addition to standard treatment (n = 52) vs standard treatment alone (control) (n = 51), stratified by disease severity.

MAIN OUTCOMES AND MEASURES Primary outcome was time to clinical improvement within 28 days, defined as patient discharged alive or reduction of 2 points on a 6-point disease severity scale (ranging from 1 [discharge] to 6 [death]). Secondary outcomes included 28-day mortality, time to discharge, and the rate of viral polymerase chain reaction (PCR) results turned from positive at baseline to negative at up to 72 hours.

RESULTS Of 103 patients who were randomized (median age, 70 years; 60 [58.3%] male), 101 (98.1%) completed the trial. Clinical improvement occurred within 28 days in 51.9% (27/52) of the convalescent plasma group vs 43.1% (22/51) in the control group (difference, 8.8% [95% CI, −10.4% to 28.0%]; hazard ratio [HR], 1.40 [95% CI, 0.79-2.49]; P = .26). Among those with severe disease, the primary outcome occurred in 91.3% (21/23) of the convalescent plasma group vs 68.2% (15/22) of the control group (HR, 2.15 [95% CI, 1.07-4.32]; P = .03); among those with life-threatening disease the primary outcome occurred in 20.7% (6/29) of the convalescent plasma group vs 24.1% (7/29) of the control group (HR, 0.88 [95% CI, 0.30-2.63]; P = .83) (P for interaction = .17). There was no significant difference in 28-day mortality (15.7% vs 24.0%; OR, 0.65 [95% CI, 0.29-1.46]; P = .30) or time from randomization to discharge (51.0% vs 36.0% discharged by day 28; HR, 1.61 [95% CI, 0.88-2.93]; P = .12). Convalescent plasma treatment was associated with a negative conversion rate of viral PCR at 72 hours in 87.2% of the convalescent plasma group vs 37.5% of the control group (OR, 11.39 [95% CI, 3.91-33.18]; P < .001). Two patients in the convalescent plasma group experienced adverse events within hours after transfusion that improved with supportive care.

CONCLUSION AND RELEVANCE Among patients with severe or life-threatening COVID-19, convalescent plasma therapy added to standard treatment, compared with standard treatment alone, did not result in a statistically significant improvement in time to clinical improvement within 28 days. Interpretation is limited by early termination of the trial, which may have been underpowered to detect a clinically important difference.

Since December 2019, coronavirus disease 2019 (COVID-19), caused by SARS-CoV-2 (severe acute respiratory syndrome coronavirus 2), has spread rapidly around the world, with high rates of transmission and substantial mortality. COVID-19 symptoms can range from mild, self-limited respiratory disease to severe progressive pneumonia, multiple organ failure, and even death. [1,2] To date, there is no effective treatment or vaccine to contain the disease.

Convalescent plasma therapy has been used to treat patients with infections using plasma collected from recovered patients. [3] This approach has been evaluated in the treatment of SARS,[4,5] Middle East respiratory syndrome (MERS), [6] and Ebola, [7] but not well studied and with no definitive results. Recently, case series from China reported improved outcomes after COVID-19 convalescent plasma transfusion. [8,9] The US Food and Drug Administration (FDA) recently approved the emergency use of convalescent plasma for patients with severe or life-threatening COVID-19. [10] Although the use of convalescent plasma shows promise, the evidence supporting its use in the treatment of COVID-19 remains limited, and thus its use remains investigational.

In addition, due to the limited understanding of the mechanism and precise therapeutic components of convalescent plasma, there is no standardization or evidence-based rationale for donor selection, quality control of convalescent plasma, or recipient transfusion indications for convalescent plasma. This may help to explain the varied therapeutic effects of convalescent plasma seen in a variety of infectious diseases. To address these issues, the World Health Organization issued a guideline on the use of convalescent plasma in a pandemic, advocating for standardization in donor selection and convalescent plasma quality control to maximize therapeutic potency. [11]

The objective of this randomized clinical trial was to evaluate the efficacy and adverse effects of convalescent plasma added to standard treatment, compared with standard treatment alone, for patients with severe or life-threatening COVID-19 using a standardized approach in donor selection and convalescent plasma quality control.

Key Points

Question What is the effect of convalescent plasma therapy added to standard treatment, compared with standard treatment alone, on clinical outcomes in patients with severe or life-threatening coronavirus disease 2019 (COVID-19)?

Finding In this randomized clinical trial that included 103 patients and was terminated early, the hazard ratio for time to clinical improvement within 28 days in the convalescent plasma group vs the standard treatment group was 1.40 and was not statistically significant.

Meaning Among patients with severe or life-threatening COVID-19, convalescent plasma therapy added to standard treatment did not significantly improve the time to clinical improvement within 28 days, although the trial was terminated early and may have been underpowered to detect a clinically important difference.

Methods

This study was a collaborative effort by the Institute of Blood Transfusion of the Chinese Academy of Medical Sciences; Union Hospital of Tongji Medical College of Huazhong University of Science and Technology; the Guanggu District Maternal and Child Health Hospital of Hubei Province; Tongji Hospital of Tongji Medical College of Huazhong University of Science and Technology; General Hospital of the Central Theater Command of the People's Liberation Army; Wuhan Red Cross Hospital; Wuhan Asia Heart Hospital; and Wuhan Pulmonary Hospital.

This study was approved by the ethics committee of the Institute of Blood Transfusion of the Chinese Academy of Medical Sciences and the ethics committees of the participating hospitals. Written informed consent was obtained from all study participants or their legal representatives. The trial protocol and statistical analysis plan are available in Supplement 1 and Supplement 2 .

Participants

Patients were recruited from 7 medical centers. The study recruitment was from February 14, 2020, to April 1, 2020. Follow-up was completed on April 28, 2020.

Inclusion Criteria

Inclusion criteria were the following: (1) signed informed consent; (2) aged at least 18 years; (3) COVID-19 diagnosis based on polymerase chain reaction (PCR) testing; (4) positive PCR result within 72 hours prior to randomization; (5) pneumonia confirmed by chest imaging; (6) clinical symptoms meeting the definitions of severe or life-threatening COVID-19; (7) acceptance of random group assignment; (8) hospital admission; (9) willingness to participate in all necessary research studies and be able to complete the study follow-up; and (10) no participation in other clinical trials, such as antiviral trials, during the study period.

Severe COVID-19 was defined as respiratory distress (≥30 breaths/min; in resting state, oxygen saturation of 93% or less on room air; or arterial partial pressure of oxygen (PaO_2)/fraction of inspired oxygen (FIO_2) of 300 or less. Life-threatening COVID-19 was defined as respiratory failure requiring mechanical ventilation; shock; or other organ failure (apart from lung) requiring intensive care unit (ICU) monitoring.

Exclusion Criteria

Exclusion criteria were the following: (1) pregnancy or lactation; (2) immunoglobulin allergy; (3) IgA deficiency; (4) preexisting comorbidity that could increase the risk of thrombosis; (5) life expectancy less than 24 hours; (6) disseminated intravascular coagulation; (7) severe septic shock; (8) PaO_2/FIO2 of less than 100; (9) severe congestive heart failure; (10) detection of high titer of S protein–RBD-specific (receptor binding domain) IgG antibody (≥1:640); (11) other contraindications as determined by the patient's physicians; and (12) participation in any antiviral clinical trials for COVID-19 within 30 days prior to enrollment.

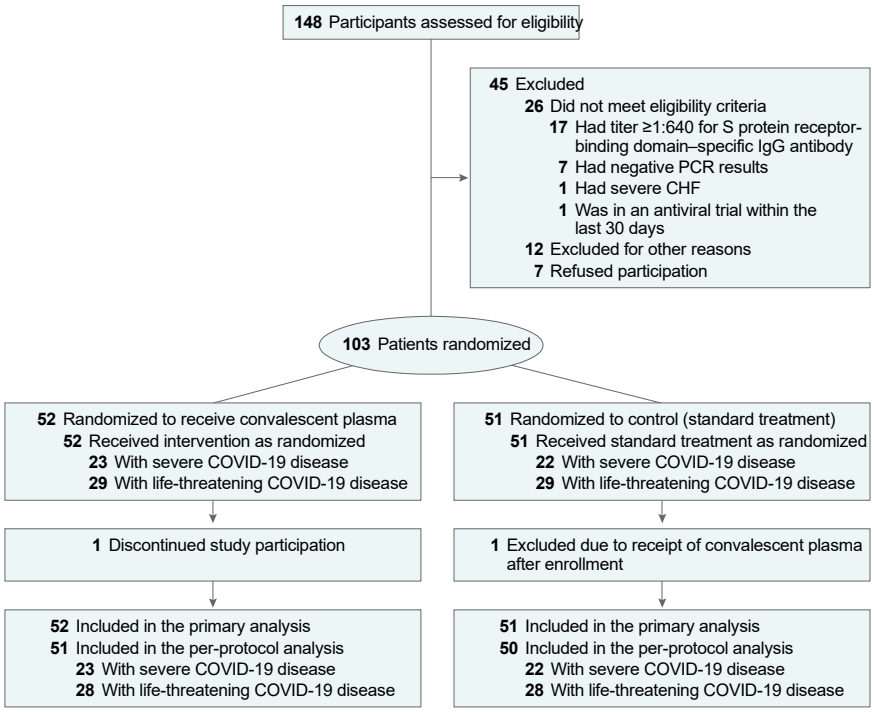
Figure 1. Patient Enrollment and Treatment Assignment



PCR indicates polymerase chain reaction; CHF, congestive heart failure; COVID-19, coronavirus disease 2019.

Randomization

Potential study participants were screened for eligibility 72 hours prior to study randomization. Patients were randomly assigned via computer-generated random numbering (1:1) to receive standard treatment coupled with convalescent plasma transfusion or standard treatment alone (control group) (Figure 1). The randomization was stratified based on the severity of COVID-19 (severe or life-threatening) and a randomization schedule was generated using block randomization with block size of 4 for each type of COVID-19 by SAS software. Patients and clinicians were not masked to treatment assignment.

Procurement of Convalescent Plasma

In brief, patients with a laboratory-confirmed COVID-19 diagnosis, who had fully recovered and been discharged from the hospital for more than 2 weeks, were recruited. Convalescent plasma–specific donor screening and selection were based on the following criteria: age of 18 through 55 years, suitable for blood donation, initially diagnosed with COVID-19 but with 2 negative PCR test results from nasopharyngeal swabs (at least 24 hours apart) prior to hospital discharge, discharged for more than 2 weeks from the hospital, and no persisting COVID-19 symptoms. Convalescent plasma collection was performed based on routine plasma collection procedures via plasmapheresis. The plasma products were prepared as fresh-f rozen plasma. COVID-19 convalescent plasma was collected and processed at the Wuhan Blood Center.

S-RBD–specific IgG antibody titer was measured for convalescent plasma products and reported as the following: less than 1:160, 1:160, 1:320, 1:640, 1: 1280, or greater than 1:1280. There was a positive correlation between the SARS-CoV-2 viral neutralization titer and the S-RBD–specific IgG titer (r = 0.622, P = .03). A serum neutralization titer of 1:80 is approximately equivalent to a titer of 1:1280 for S-RBD–specific IgG. To ensure the therapeutic potency of the convalescent plasma, only the plasma units with an S-RBD–specific IgG titer of at least 1:640 were used for this study.

Additional details regarding plasma preparation standards can be found in the eMethods in Supplement 3 , and the preparation requirements of convalescent plasma used were similar to the recently updated FDA recommendations. [10]

Convalescent Plasma Transfusion

The transfusion dose of COVID-19 convalescent plasma was approximately 4 to 13 mL/kg of recipient body weight. ABO type of the convalescent plasma transfused was compatible with the patient's ABO type. In addition, the convalescent plasma was crossmatched with the patient's red blood cells to ensure compatibility. Convalescent plasma transfusion was administered at approximately 10 mL for the first 15 minutes, which was then increased to approximately 100 mL per hour with close monitoring. Adjustments in the infusion rates were allowed based on the patient's risk for volume overload and tolerance, at the discretion of the treating physicians. No premedication was given before convalescent plasma transfusion.

Standard Treatment

Standard treatment consisted of symptomatic control and supportive care for COVID-19, mostly based on the evolving Chinese national COVID-19 treatment guidelines and hospital

Downloaded From: https://jamanetwork.com/ by a Mayo Clinic Library User on 06/03/2020

practice.[12] Possible treatments included antiviral medications, antibacterial medications, steroids, human immunoglobulin, Chinese herbal medicines, and other medications.

OutcomeMeasures

The primary end point was time to clinical improvement within a 28-day period. Clinical improvement was defined as patient discharge or a reduction of 2 points on a 6-point disease severity scale.[13] The scale was defined as follows: 6 points, death; 5 points, hospitalization plus extracorporeal membrane oxygenation (ECMO) or invasive mechanical ventilation; 4 points, hospitalization plus noninvasive ventilation or high-flow supplemental oxygen; 3 points, hospitalization plus supplemental oxygen (not high-flow or noninvasive ventilation); 2 points, hospitalization with no supplemental oxygen; 1 point, hospital discharge.

Patient discharge criteria included body temperature returned to normal for longer than 3 days, respiratory symptoms significantly improved without the need for oxygen support, and 2 consecutive negative PCR test results from nasopharyngeal swabs at least 24 hours apart.

Secondary clinical outcomes were as follows: (1) 28-day mortality, including analysis of time from randomization to death; (2) duration of hospitalization, including analyses of time from randomization to discharge, time from admission to discharge, and 28-day discharge rates; and (3) conversion of nasopharyngeal swab viral PCR results from positive at baseline to negative at follow-up assessed at 24, 48, and 72 hours. Once nasopharyngeal swab viral PCR testing yielded negative results 2 times consecutively, no further testing was performed.

A post hoc analysis was added to compare rates of improvement at days 7, 14, and 28.

This clinical trial was an open-label, randomized clinical study. To avoid assessment bias, the evaluation of clinical outcomes was performed by an investigator who was blind to the study group allocation.

StatisticalAnalysis

The original sample size was determined to be 100 for each group, which would provide 80% power, with a 2-sided significance level of $\alpha = .05$, to detect an 8-day change for the convalescent plasma group in time to clinical improvement, assuming that this would be 20 days in the control group and 60% of the patients would reach clinical improvement.

Unless otherwise stated, analyses were performed based on the full analysis set, which is defined as the set of all randomized patients who received at least one treatment specified in the trial. Statistical analysis was performed on randomly assigned treatment groups. Continuous variables were summarized by presenting the median and interquartile range (IQR) for the total number of patients who contributed values. Categorical variables were summarized by presenting the frequency and proportion of patients in each category. Time-to-event data were analyzed using the Kaplan-Meier method, and the median time to event and corresponding 95% CI were calculated. For the cases in which more than 50% of patients were censored and therefore the median time to event was indeterminate, the restricted mean survival time would be used for post hoc analysis.

For the primary end point of time to clinical improvement, death, withdrawal, and crossover between groups before day 28 were considered to be right-censored at day 28, and otherwise would be considered to be right-censored at the last observation date. Hazard ratios (HRs) with 95% CIs were calculated using Cox proportional hazards models. Three Cox proportional hazards models were fitted in this study. We referred to the model that included only the treatment group as the unadjusted model. The model that included disease severity (severe or life-threatening) and treatment group is referred to as model 1, and the model that further considered the interaction between disease severity and treatment group is referred to as model 2. Study sites were considered as a random effect in these models. Proportionality hazard assumption was assessed for treatment group and disease severity by extending the Cox models to include the corresponding time-dependent covariates.[14] If the coefficient of the time-dependent covariate was statistically significant, the proportionality hazard assumption would be considered to be violated.

A per-protocol analysis was performed for the primary end point as a sensitivity analysis. The per-protocol set was defined as the set of all randomized patients who received at least one treatment specified in the trial and who had no significant protocol violations that affected the efficacy evaluation.

Treatment effects for secondary end points were assessed using odds ratios and HRs with 95% CIs for the discrete variables and time-to-event data, respectively. For the analyses of time from randomization to discharge, time from randomization to death, and length of stay, the definition of censoring was consistent with the primary end point. Missing data for secondary outcomes and adverse events were not imputed. Only observed values were used for data analysis and presentation.

Subgroup analyses of efficacy were performed according to disease severity. Interactions between treatment group and disease severity group were tested using model 2.

Statistical analyses were performed with SAS software, version 9.4. Statistical significance was defined using a 2-sided significance level of $\alpha = .05$. Because of the potential for type I error due to multiple comparisons, findings for analyses of secondary end points should be interpreted as exploratory.

EarlyStudyTermination

Due to the containment of the COVID-19 epidemic in Wuhan, China, the numbers of patients with COVID-19 decreased in late March 2020. No new cases were reported in Wuhan for 7 consecutive days after March 24 (data from the National Health Commission of the People's Republic of China).[15] The last patient enrolled in this study was on March 27, 2020, and for the next 3 days, we were not able to recruit more patients and did not have any recruitment targets. After discussion with the expert committee of the Institute of Blood Transfusion, the study was terminated by the sponsor (Chinese Academy of Medical Sciences) and the leading primary investigator on April 1, 2020, with a total of 103 patients enrolled.

>1.5 mg/dL	4/50 (8.0)	2/49 (4.1)

Abbreviations: ALT, alanine aminotransferase; APTT, activated partial thromboplastin time; AST, aspartate aminotransferase; COVID-19, coronavirus disease 2019; CRP, C-reactive protein; IQR, interquartile range.

SI conversion factors: To convert D-dimer to nmol/L, multiply values by 5.476; to convert urea nitrogen to mmol/L, multiply values by 0.357; to convert creatinine to μmol/L, multiply values by 88.4.

[a] The values shown were based on total number of patients who contributed values.

[b] History of allergy to certain allergens, including food, medicine, etc.

[c] Details of coexisting diseases were collected from medical records.

[d] The vital signs and laboratory values are the last available values within 72 hours prior to randomization. The laboratory values selected were associated with the clinical status and factors that may affect convalescent plasma therapy. The values used for categorization of laboratory values are local divisions of low, normal, and high values.

There was no interim or preliminary data review prior to making this decision.

Results

Study Population

A total of 103 patients were enrolled in this randomized clinical trial. They were assigned to either the convalescent plasma group or the control group in a 1:1 ratio and were categorized as follows: 23 patients in the convalescent plasma group and 22 patients in the control group had severe COVID-19, and 29 patients in the convalescent plasma group and 29 patients in the control group had life-threatening COVID-19. Of these, 1 patient with life-threatening disease in the convalescent plasma treatment group withdrew from the study and 1 patient with life-threatening disease in the control group received convalescent plasma transfusion after randomization (protocol violation). Thus, 103 patients were included in the full analysis set and 101 patients were included in the per-protocol set (Figure 1).

The median age was 70 years (IQR, 62-78 years) among all patients, 71 years (IQR, 66-82 years) for patients with severe COVID-19, and 69 years (IQR, 61-76 years) for patients with life-threatening COVID-19. Of the patients included in the study, 60 (58.3%) were men, and the percentages of men with severe and life-threatening COVID-19 were 53.3% and 62.1%, respectively. A total of 89.2% of the patients had a normal body temperature at the time of participation, and the median body temperature was 36.5 °C (IQR, 36.2-36.7 °C) (Table 1 and eTable 1 and eTable 2 in Supplement 3).

The median interval between the onset of symptoms and randomization was 30 days (IQR, 20-39 days) overall, 33 days (IQR, 22-43 days) for patients with severe disease, and 26 days (IQR, 20-36 days) for patients with life-threatening disease. There were 5 patients with severe disease and 3 patients with life-threatening disease who had an interval between the onset of symptoms and randomization that was fewer than 14 days (Table 2).

Overall and within disease severity strata, the convalescent plasma and control groups were similar in terms of demographic characteristics, baseline laboratory results, and distribution on the 6-point disease severity scale at baseline, with the exception of systolic blood pressure in the patients with severe COVID-19 and sex in the patients with life-threatening COVID-19 (eTable 1 and eTable 2 in Supplement 3). Additional details regarding patients' clinical status at the time of randomization and additional medications received are provided in Table 2 and eTable 3, eTable 4, and eTable 7 in Supplement 3 . For patients in the convalescent plasma group, median plasma infusion volume was 200 mL (IQR, 200-300 mL), and 96% received a single dose of plasma infusion.

Primary Clinical Outcome

For all patients combined, there was no significant difference in the primary outcome of time to clinical improvement within 28 days: 51.9% (27/52) in the convalescent plasma group vs 43.1% (22/51) in the control group (difference, 8.8% [95% CI, −10.4% to 28.0%]; HR, 1.40 [95% CI, 0.79-2.49]; $P = .26$). Results for the per-protocol population were not materially different (eTable 5 in Supplement 3). Among those with severe disease, the primary outcome occurred in 91.3% (21/23) vs 68.2% (15/22) (HR, 2.15 [95% CI, 1.07-4.32]; $P = .03$). Among those with life-threatening disease, the primary outcome occurred in 20.7% (6/29) vs 24.1% (7/29) (HR, 0.88 [95% CI, 0.30-2.63]; $P = .83$) (P for interaction = .17) (Table 3 , Figure 2 , and eTable 6 in Supplement 3). For all proportional hazards models, the proportionality assumptions were met.

Secondary Clinical Outcomes

There was no significant difference in the secondary outcome of 28-day mortality (15.7% in the convalescent plasma group vs 24.0% in the control group; OR, 0.65 [95% CI, 0.29-1.46]; $P = .30$). There was also no significant difference in the time from randomization to death between the convalescent group and the control group (HR, 0.74 [95% CI, 0.30-1.82]; $P = .52$) (Table 3). Among patients with severe disease, no patients died in the convalescent plasma group, while 2 patients (9.1%) died in the control group. Among patients with life-threatening disease, 8 patients (28.6%) died in the convalescent plasma group, while 10 patients (35.7%) died in the control group.

There was also no significant difference in the secondary outcome of time from randomization to discharge (51.0% in the convalescent plasma group vs 36.0% in the control group were discharged by day 28; HR, 1.61 [95% CI, 0.88-2.93]; $P = .12$). The 28-day discharge rate of the convalescent plasma group reached 51%, among which the discharge rate of those with severe disease in the convalescent plasma group reached 91.3%.

At 24, 48, and 72 hours, the rates of negative SARS-CoV-2 viral PCR in the convalescent plasma group were all significantly higher than that of the control group (44.7% vs 15.0%, $P = .003$ at 24 hours; 68.1% vs 32.5%, $P = .001$ at 48 hours; 87.2% vs 37.5%, $P < .001$ at 72 hours) (Table 3 and eFigure 1 in Supplement 3). Among patients with severe disease, the rate of negative viral PCR at 72 hours was significantly higher in the convalescent plasma group compared with the control group, but there was no significant difference at 24 hours and 48 hours. Among patients with life-threatening disease, there was a statistically significant difference in favor of the convalescent plasma group at 24, 48, and 72 hours.

Post hoc Analysis

The clinical improvement rates overall and by disease severity subgroups at various time points during the study are presented in Table 3.

Adverse Events

Two participants reported transfusion-related adverse events following convalescent plasma transfusion. One patient in the severe COVID-19 group developed chills and rashes within 2 hours of transfusion but recovered fully after treatment with dexamethasone and promethazine. This was determined to be a definite nonsevere allergic transfusion reaction and also a probable nonsevere febrile nonhemolytic transfusion reaction. The other patient, who was in the life-threatening COVID-19 group, presented with shortness of breath, cyanosis, and severe dyspnea within 6 hours of transfusion. The patient was given dexamethasone, aminophylline, and other supportive care immediately and gradually improved after 2 hours. This was determined to be possible severe transfusion-associated dyspnea.

Table 2. Patients' Clinical Status at Randomization and Medications Received[a]

All patients	Convalescent plasma group (n = 52)	Control group (n = 51)
Time between symptom onset and randomization, median (IQR), d	27 (22-39) [n = 49]	30 (19-38) [n = 48]
≤14 d, No. (%)	3/49 (6.1)	5/48 (10.4)
>14 d, No. (%)	46/49 (93.9)	43/48 (89.6)
Interval between symptom onset and admission, median (IQR), d	12 (5-20) [n = 49]	10 (6-16) [n = 48]
6-Point scale at study day 1, No. (%)		
2- Hospitalization, no supplemental oxygen	1/51 (2.0)	1/50 (2.0)
3- Hospitalization, requiring supplemental oxygen (not high-flow or noninvasive ventilation)	15/51 (29.4)	15/50 (30.0)
4- Hospitalization, requiring noninvasive ventilation and/or high-flow supplemental oxygen	21/51 (41.2)	23/50 (46.0)
5- Hospitalization, requiring extracorporeal membrane oxygenation and/or invasive mechanical ventilation	14/51 (27.5)	11/50 (22.0)
Medications used after randomization		
Antiviral	41/46 (89.1)	44/49 (89.8)
Antibacterial	38/46 (82.6)	39/49 (79.6)
Chinese herbal medicine	26/46 (56.5)	30/49 (61.2)
Steroids	21/46 (45.7)	16/49 (32.7)
Antifungal	15/46 (32.6)	13/49 (26.5)
Human immunoglobulin	13/46 (28.3)	11/49 (22.5)
Interferon	12/46 (26.1)	7/49 (14.3)

[a] The values shown were based on total number of patients who contributed values. Details of medications used were provided in eTable 7 in Supplement 3.

Discussion

In this randomized clinical trial of patients with severe or life-threatening COVID-19, there was no significant difference in the time to clinical improvement between patients who received convalescent plasma transfusion therapy combined with standard treatment vs those who received standard treatment alone. There was also no significant difference in secondary outcomes of 28-day mortality or time from randomization to discharge. Convalescent plasma treatment was

At 72 h	22/26 (84.6)	8/23 (34.8)	49.8% (25.9% to 73.7%)	OR, 10.31 (2.63-40.50)	<.001

Abbreviations: HR, hazard ratio; IQR, interquartile range; OR, odds ratio.

[a] The values shown were based on total number of patients who contributed values. The primary clinical outcome was analyzed by primary analysis set. Times to outcomes in the secondary clinical outcomes were analyzed by primary analysis set. Indeterminate events could not be calculated due to the low percentage of outcome events.

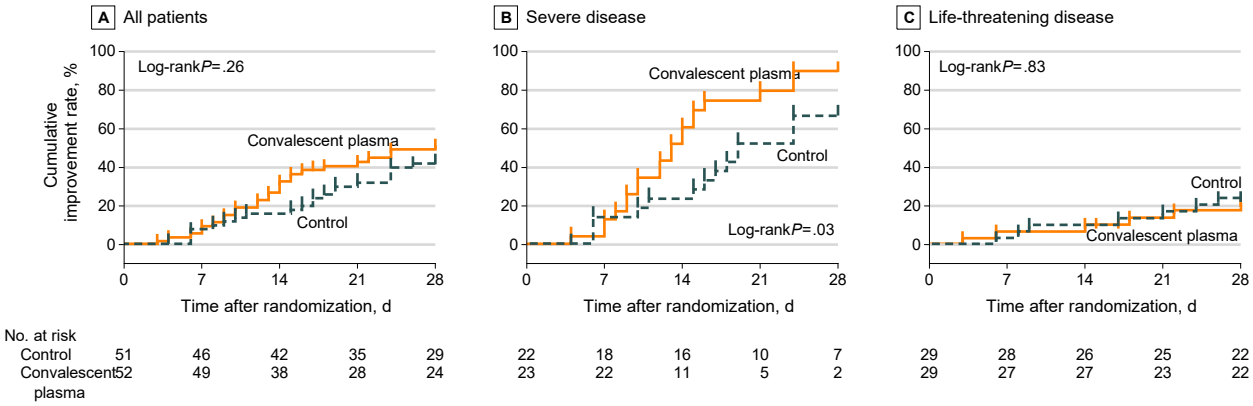
[b] The absolute differences of time to clinical improvement, times to discharge, and times from randomization to death were calculated based on restricted mean survival time.

[c] *P* value was calculated by Cox regression, χ^2 test, or Fisher exact test.

[d] Medians and quartiles of time to clinical improvement, times to discharge, and times from randomization to death could not be determined because too few patients had reached improvement or discharge by the end of the study. By the end of the study, for all, severe, and life-threatening patients, respectively, 27 (51.9%), 21 (91.3%), and 6 (20.7%) were clinically improved in the convalescent plasma group; 22 (43.1%), 15 (68.2%), and 7 (24.1%) were clinically improved in the control group; 26 (51.0%), 21 (91.3%), and 5 (17.9%) were discharged in the convalescent plasma group; 18 (36.0%), 15 (68.2%), and 3 (10.7%) were discharged in the control group; 8 (15.7%), 0, and 8 (28.6%) died in the convalescent plasma group; and 12 (24.0%), 2 (9.1%), and 10 (35.7%) died in the control group.

[e] These analyses were developed post hoc to better illustrate disease progression.

Figure 2. Time to Clinical Improvement in Patients With COVID-19



The cumulative improvement rate is the percentage of patients who experienced a 2-point improvement or were discharged alive from the hospital. Ticks on the curves indicate censored events. All patients who did not reach clinical improvement were observed for the full 28-day period or until death. COVID-19 indicates coronavirus disease 2019.

The median (IQR) follow-up times for the convalescent plasma group and control group, respectively, were 15 (10-28) days and 24 (13-28) days overall; 13 (10-16) and 18.5 (11-26) days among those with severe COVID-19; and 28 (12-28) and 26 (15-28) days among those with life-threatening COVID-19.

associated with higher rates of negative SARS-CoV-2 viral PCR results from nasopharyngeal swabs at 24, 48, and 72 hours, demonstrating that the convalescent plasma treatment was associated with antiviral activity in patients with COVID-19.

Plasma transfusions can result in transfusion-related adverse events including febrile and allergic transfusion reactions, transfusion-associated dyspnea, hypotensive transfusion reaction, to hemolytic transfusion reactions, septic transfusion reaction, transfusion-related acute lung injury, and transfusion-associated circulatory overload. In this study, most patients tolerated convalescent plasma transfusions well. There were 2 cases of reported transfusion-associated adverse events. One case was determined to be a definite nonsevere allergic transfusion reaction and also a probable nonsevere febrile

Downloaded From: https://jamanetwork.com/ by a Mayo Clinic Library User on 06/03/2020

nonhemolytic transfusion reaction, and the other case was determined to be possible severe transfusion-associated dyspnea. The rate is somewhat higher than the general rate of reactions associated with plasma transfusion, possibly due to the small sample size and active surveillance. [16]

In the subgroup analysis by disease severity, there was a signal of possible clinical benefit for convalescent plasma among patients with severe COVID-19. However, bec ause the test for interaction by disease severity was not statistically significant, the findings for the severe and life-threatening subgroups should not be interpreted as different. Given the early study termination, it is possible that the study was underpowered to detect a statistically significant interaction, and a larger trial of convalescent plasma focusing on patients with severe COVID-19 may be warranted.

Patients with COVID-19 who were recruited in this study were heterogeneous with regard to the duration and severity of the illness. The possible antiviral activity with convalescent plasma treatment in patients aged 60 to 80 years and after 14 days of disease onset is notable. To our knowledge, no other antiviral treatments have demonstrated therapeutic effects in this age group or this late in the course of the disease. However, the con valescent plasma treatment was given at least 14 days after the onset of symptoms in most cases, and it is not known whether earlier convalescent plasma treatment could have resulted in better clinical outcomes. Further studies are needed to optimize patient selection and timing of convalescent plasma treatment.

While the use of convalescent plasma has been investigated and used many times in the past, [3,17] its use has not been well studied. It is notable that for most studies of the use of convalescent plasma, [4,5,18] there was lack of standardization and procedure control with regard to the donor selection process and the nature or level of antibodies in convalescent plasma units. This may explain the varied therapeutic effects seen across a variety of diseases or even across patients with the same disease. The guidance on convalescent plasma issued by the World Health Organization [11] highlighted the importance of standardized processes and laboratory testing–based quality control of convalescent plasma units, the selection of clinical indications, as well as program deployment to recruit adequate numbers of donors and maintain sufficient inventory.

One of the potential strengths of this study was the controlled process for donor selection and convalescent plasma quality control. A predefined process was used to enroll donors for convalescent plasma collection. Only units with a high titer of S-RBD–specific IgG antibody were used for convalescent plasma treatment in this study.

Limitations

This study has several limitations. First, the sample size was small and the study was terminated early. It is possible that the study was underpowered to detect a clinically important benefit of convalescent plasma therapy. Second, the median time between the onset of symptoms and randomization was 30 days, and it is unclear whether earlier treatment would have resulted in greater benefit. Third, this was an open-label study and the primary outcome was based to some degree on physicians' clinical management decisions. Fourth, the use of standard therapy was allowed in both groups and was not protocolized, which could have potentially influenced outcomes. Fifth, the relatively short 28-day time frame of the study follow-up may have precluded the observation of clinical improvement in patients with severe diseases, especially life-threatening COVID-19, as they may take longer time to respond and recover. Sixth, plasma was not used for the control group, which would have been a more ideal control group, making blinded design possible. Seventh, the study findings should be interpreted cautiously given that practices may vary from country to country, and hospital to hospital, such as the types of standard treatment, supportive care, and thresholds for intubation and hospital admission. The outcomes of this study may be related to a combination of many factors, such as the quality of the convalescent plasma products in terms of potency, the selection of the patients (severe and life-threatening COVID-19), and the timing of convalescent plasma transfusion.

Conclusion

Among patients with severe or life-threatening COVID-19, convalescent plasma therapy added to standard treatment, compared with standard treatment alone, did not significantly improve the time to clinical improvement within 28 days. Interpretation is limited by early termination of the trial, which may have been underpowered to detect a clinically important difference.

A Randomized Trial of Convalescent Plasma for COVID-19—Potentially Hopeful Signals

Arturo Casadevall, MD, PhD; Michael J. Joyner, MD; Liise-Anne Pirofski, MD

Convalescent plasma for the treatment of infectious diseases has been used since the early 20th century and was associated with reduced mortality during the 1918 influenza,[1] 2003 SARS,[2] and 2009 influenza H1N1[3] pandemics. However, most published studies of these diseases were case series and retrospective comparisons of treated and nontreated individuals. Consistent with this, several uncontrolled case series of convalescent plasma use in patients with coronavirus disease (2019) COVID-19 have suggested a possible benefit.[4-6] Given encouraging historical precedents and the absence of proven SARS-CoV-2 (severe acute respiratory disease coronavirus 2) antiviral therapies, convalescent plasma therapy has been proposed as a treatment option for COVID-19.[7] The availability of clinical information generated from randomized clinical trials is therefore of substantial importance given that the world remains in the grip of the COVID-19 epidemic and convalescent plasma is currently in use in many countries, including the US.

Related article

In their article in *JAMA*, Li et al[8] present findings from the first randomized clinical trial of convalescent plasma therapy for patients with COVID-19 conducted in China. In contrast to most other reports of convalescent plasma use in past epidemics, this study is noteworthy in that it used a randomized trial design and well-characterized plasma units with a high titer of antibody to SARS-CoV-2. It was an important accomplishment to conduct a carefully controlled trial during a pandemic with an entirely new highly contagious disease that stressed health systems in an unprecedented way.

However, the authors report that because the COVID-19 outbreak in China was being contained while the trial was ongoing and new cases were unavailable for enrollment, the trial was terminated before it reached its targeted original sample size of 200 patients; only 103 were enrolled (for whom randomization was stratified by disease severity). Consequently, the study was underpowered and many comparisons between the convalescent plasma group and the control group were not statistically significant.

In the primary analysis, based on 52 patients who were randomized to receive convalescent plasma in addition to standard treatment and 51 patients who were randomized to receive standard treatment alone (control), the primary outcome of time to clinical improvement within 28 days (defined as being discharged alive or having a reduction of 2 points on a 6-point disease severity scale) was 2.15 days shorter (95% CI, −5.28 to 0.99 days) in the intervention group compared with the control group, and clinical improvement at 28 days occurred in 27 patients (51.9%) in the intervention group vs 22 patients (43.1%) in the control group (difference, 8.8%; 95% CI, −10.4% to 28%; hazard ratio, 1.40 [95% CI, 0.79-2.49]; $P = .26$).

In analyses stratified by disease severity, among patients with severe disease (23 in the convalescent plasma group and 22 in the control group), time to clinical improvement within 28 days was 4.94 days shorter (95% CI, −9.33 to −0.54 days) in the intervention group compared with the control group, and clinical improvement at 28 days occurred in 21 patients (91.3%) in the intervention group vs 15 patients (68.2%) in the control group (hazard ratio, 2.15 [95% CI, 1.07-4.32]; $P = .03$). Among the subgroup of patients with life-threatening disease (29 in the convalescent plasma group and 29 in the control group), there were no significant differences in the primary outcome or rates of clinical improvement at 28 days: 6 patients (20.7%) in the convalescent plasma group vs 7 patients (24.1%) in the control group (HR, 0.88 [95% CI, 0.30-2.63]; $P = .83$) (P for interaction = .17).

In the entire study population, the findings for several of the secondary end points appeared to signal a more favorable outcome for patients who received convalescent plasma, although there were no statistically significant differences between the convalescent plasma group vs the control group in any of the major secondary outcomes, including 28-day mortality (15.7% vs 24.0%, respectively; $P = .30$) or rate of discharge at 28 days (51% vs 36%; $P = .13$).

Convalescent plasma use in the study by Li et al[8] was associated with some clinical improvement in severely ill patients, but not in critically ill patients. Greater efficacy in less ill individuals is expected because antibody therapies generally work best when administered earlier in disease.[9] Historically, antibody therapy was effective in reducing the mortality of pneumococcal pneumonia when instituted in the first 3 days of symptom onset.[10] Consequently, it is not surprising that patients with COVID-19 who had tachypnea and hypoxia might benefit more from convalescent plasma than those who required mechanical ventilation. However, any indication of possible benefit in the severely ill group is noteworthy because these individuals had advanced disease, which is not considered optimal for antibody therapy. Lack of efficacy among patients who were receiving mechanical ventilation, some with multiorgan failure, highlights that the pathologic process in these individuals is likely irreversible.

The convalescent plasma used in the study by Li et al had high titers of IgG to SARS-CoV-2, which correlated with neutralizing activity. While neutralizing activity is considered to be the main determinant of convalescent plasma efficacy,

Downloaded From: https://jamanetwork.com/ by a Mayo Clinic Library User on 06/03/2020

other antibody functions may also mediate protection. Correlates of antibody efficacy should be investigated in future studies. As reported in case series from Wuhan,[4,5] plasma-treated patients had large reductions in their serum viral loads and most were virus negative 3 days after infusion. This observation establishes that convalescent plasma has antiviral activity, which is important because it indicates that antibody administration mediates a clear biological effect. The precedent of antiviral drug use against HIV and hepatitis C shows that reductions in viral load translate into clinical improvement, and earlier therapy is more effective than later therapy when organ damage is already present. In this regard, antibody-mediated viral elimination removes damaging antigens, which may translate into reduced tissue damage and inflammation. Hence, the antiviral effect of COVID-19 convalescent plasma suggests that its use earlier in the course of disease could have potentially important therapeutic activity, especially in less severely ill individuals.

Significant concerns have been raised about the use of convalescent plasma in COVID-19.[11] These include transfusion-related lung injury and transfusion-related circulatory overload. In addition, there have been theoretical concerns that the administration of antibodies might aggravate disease through antibody-mediated enhancement of proinflammatory effects.[11] The study by Li et al[8] reported only 2 adverse events among the 52 individuals who received convalescent plasma, each of whom responded to corticosteroid administration. The occurrence of one episode within 2 hours of plasma administration characterized by chills and rash suggests a transfusion reaction. However, the second episode occurred within 6 hours and its association with plasma infusion is less certain. Overall, the paucity of adverse effects is reassuring and reduces concerns about adverse effects from antibody administration.

Although the observed differences in mortality rates and hospital discharge rates between the convalescent plasma group and the control group did not reach statistical significance, these data provide valuable information for the magnitude of effects that may be expected in convalescent plasma studies. For example, the observed overall mortality difference of 24% vs 15.7% provides actionable information for the design of future trials to help ensure they are adequately powered. This difference in mortality is smaller than mortality reductions associated with convalescent plasma reported in prior studies involving 1918 influenza,[1] SARS,[2] and 2009 influenza H1N1,[3] which ranged from 50% to 70%. Hence, assuming the results of the study by Li et al[8] are generalizable, the findings may be helpful in estimating effect sizes for future studies of convalescent plasma use in hospitalized patients with COVID-19.

In the study by Li et al, the median age of the patients with severe disease was 70 years, and the median time between symptom onset and randomization was 30 days. Promising results with convalescent plasma treatment in patients with SARS[2] and influenza H1N1[3] were obtained among younger patients, and in the case of SARS, earlier in the disease. The importance of a possible treatment benefit in older persons, in whom mortality from COVID-19 is markedly higher than in younger persons,[12] cannot be overstated. In addition, the apparent improvement in the clinical status of the subgroup of less severely ill patients a month after the onset of symptoms suggests that the beneficial effects of antibodies in COVID-19 may be measurable as an improvement in inflammatory markers and viral elimination before clinical improvement is observed. The prolonged course of COVID-19 in patients who recover also should be considered in the design of future studies.

However, the study by Li et al has several important limitations, which are acknowledged by the investigators. The early termination of the trial most likely resulted in an underpowered study, thereby precluding any definitive conclusions about the role and potential efficacy of convalescent plasma for patients with COVID-19. In addition, the open-label design, the possibility of an element of subjectivity for the primary outcome, lack of a protocolized approach to standard therapy, and variability among study centers also must be considered when interpreting the study findings. Despite these limitations, by virtue of its randomized design, this study takes prior case studies[5,6] one step further by helping to separate the effects of convalescent plasma from concurrently administered agents, such as corticosteroids and antiviral agents.[13]

The signal of potential benefit of convalescent plasma in the subgroup of patients with severe COVID-19 disease (ie, those without life-threatening COVID-19 disease) is similar to findings from a recent preliminary report of a clinical trial of remdesivir for COVID-19.[14] Like remdesivir, convalescent plasma administration was associated with clinical improvement without a statistically significant effect on mortality, with the important caveat that remdesivir was evaluated in a larger study (n = 1063 randomized patients), whereas the study by Li et al[8] was terminated prematurely and underpowered. For both studies, the importance of clinical improvement as a primary end point became apparent as the trials progressed.[14]

The availability of both convalescent plasma and remdesivir means that physicians now have at least 2 therapeutic options for COVID-19, which raises the question of combination therapy. Despite only a few studies of the efficacy of combination therapy with antiviral drugs and specific antibodies, there is evidence that these agents may work well in combination.[9] Given that the mechanisms of action of antiviral drugs and neutralizing antibodies are distinct, they could be synergistic. Future trials should consider the efficacy of combination antiviral and antibody therapies.

In summary, the first randomized clinical trial of convalescent plasma in COVID-19, reported by Li et al in *JAMA*, showed no statistically significant benefit in clinical improvement at 28 days or mortality among all randomized patients, but does provide an important signal of possible benefit in the subgroup of severely ill patients and suggests that high titer antibody against SARS-CoV-2 may have antiviral efficacy. These results, while preliminary and subject to important study limitations, should stimulate more clinical trials to establish the optimal conditions for antibody therapies against COVID-19 and suggest that future studies

© 2020 American Medical Association. All rights reserved.

Downloaded From: https://jamanetwork.com/ by a Mayo Clinic Library User on 06/03/2020

should focus on determining efficacy in less severely ill patients. If the efficacy of convalescent plasma is established by future studies, the ratio of donor to patients is favorable because individuals who recover from COVID-19 can donate 2 or 3 units of plasma, which could be used to treat more than 1 person with COVID-19 disease. Therapeutic success against such a complex and challenging disease as COVID-19 is likely to require more than 1 modality, and the results from Li et al [8] provide optimism for the future of antibody therapy in this disease.

IMPORTANCE Convalescent plasma is a potential therapeutic option for patients with coronavirus disease 2019 (COVID-19), but further data from randomized clinical trials are needed.

OBJECTIVE To evaluate the efficacy and adverse effects of convalescent plasma therapy for patients with COVID-19.

DESIGN, SETTING, AND PARTICIPANTS Open-label, multicenter, randomized clinical trial performed in 7 medical centers in Wuhan, China, from February 14, 2020, to April 1, 2020, with final follow-up April 28, 2020. The trial included 103 participants with laboratory-confirmed COVID-19 that was severe (respiratory distress and/or hypoxemia) or life-threatening (shock, organ failure, or requiring mechanical ventilation). The trial was terminated early after 103 of a planned 200 patients were enrolled.

INTERVENTION Convalescent plasma in addition to standard treatment (n = 52) vs standard treatment alone (control) (n = 51), stratified by disease severity.

MAIN OUTCOMES AND MEASURES Primary outcome was time to clinical improvement within 28 days, defined as patient discharged alive or reduction of 2 points on a 6-point disease severity scale (ranging from 1 [discharge] to 6 [death]). Secondary outcomes included 28-day mortality, time to discharge, and the rate of viral polymerase chain reaction (PCR) results turned from positive at baseline to negative at up to 72 hours.

RESULTS Of 103 patients who were randomized (median age, 70 years; 60 [58.3%] male), 101 (98.1%) completed the trial. Clinical improvement occurred within 28 days in 51.9% (27/52) of the convalescent plasma group vs 43.1% (22/51) in the control group (difference, 8.8% [95% CI, −10.4% to 28.0%]; hazard ratio [HR], 1.40 [95% CI, 0.79-2.49]; P = .26). Among those with severe disease, the primary outcome occurred in 91.3% (21/23) of the convalescent plasma group vs 68.2% (15/22) of the control group (HR, 2.15 [95% CI, 1.07-4.32]; P = .03); among those with life-threatening disease the primary outcome occurred in 20.7% (6/29) of the convalescent plasma group vs 24.1% (7/29) of the control group (HR, 0.88 [95% CI, 0.30-2.63]; P = .83) (P for interaction = .17). There was no significant difference in 28-day mortality (15.7% vs 24.0%; OR, 0.65 [95% CI, 0.29-1.46]; P = .30) or time from randomization to discharge (51.0% vs 36.0% discharged by day 28; HR, 1.61 [95% CI, 0.88-2.93]; P = .12). Convalescent plasma treatment was associated with a negative conversion rate of viral PCR at 72 hours in 87.2% of the convalescent plasma group vs 37.5% of the control group (OR, 11.39 [95% CI, 3.91-33.18]; P < .001). Two patients in the convalescent plasma group experienced adverse events within hours after transfusion that improved with supportive care.

CONCLUSION AND RELEVANCE Among patients with severe or life-threatening COVID-19, convalescent plasma therapy added to standard treatment, compared with standard treatment alone, did not result in a statistically significant improvement in time to clinical improvement within 28 days. Interpretation is limited by early termination of the trial, which may have been underpowered to detect a clinically important difference.

Since December 2019, coronavirus disease 2019 (COVID-19), caused by SARS-CoV-2 (severe acute respiratory syndrome coronavirus 2), has spread rapidly around the world, with high rates of transmission and substantial mortality. COVID-19 symptoms can range from mild, self-limited respiratory disease to severe progressive pneumonia, multiple organ failure, and even death. [1,2] To date, there is no effective treatment or vaccine to contain the disease.

Convalescent plasma therapy has been used to treat patients with infections using plasma collected from recovered patients. [3] This approach has been evaluated in the treatment of SARS,[4,5] Middle East respiratory syndrome (MERS), [6] and Ebola, [7] but not well studied and with no definitive results. Recently, case series from China reported improved outcomes after COVID-19 convalescent plasma transfusion. [8,9] The US Food and Drug Administration (FDA) recently approved the emergency use of convalescent plasma for patients with severe or life-threatening COVID-19. [10] Although the use of convalescent plasma shows promise, the evidence supporting its use in the treatment of COVID-19 remains limited, and thus its use remains investigational.

In addition, due to the limited understanding of the mechanism and precise therapeutic components of convalescent plasma, there is no standardization or evidence-based rationale for donor selection, quality control of convalescent plasma, or recipient transfusion indications for convalescent plasma. This may help to explain the varied therapeutic effects of convalescent plasma seen in a variety of infectious diseases. To address these issues, the World Health Organization issued a guideline on the use of convalescent plasma in a pandemic, advocating for standardization in donor selection and convalescent plasma quality control to maximize therapeutic potency. [11]

The objective of this randomized clinical trial was to evaluate the efficacy and adverse effects of convalescent plasma added to standard treatment, compared with standard treatment alone, for patients with severe or life-threatening COVID-19 using a standardized approach in donor selection and convalescent plasma quality control.

Key Points

Question What is the effect of convalescent plasma therapy added to standard treatment, compared with standard treatment alone, on clinical outcomes in patients with severe or life-threatening coronavirus disease 2019 (COVID-19)?

Finding In this randomized clinical trial that included 103 patients and was terminated early, the hazard ratio for time to clinical improvement within 28 days in the convalescent plasma group vs the standard treatment group was 1.40 and was not statistically significant.

Meaning Among patients with severe or life-threatening COVID-19, convalescent plasma therapy added to standard treatment did not significantly improve the time to clinical improvement within 28 days, although the trial was terminated early and may have been underpowered to detect a clinically important difference.

Methods

This study was a collaborative effort by the Institute of Blood Transfusion of the Chinese Academy of Medical Sciences; Union Hospital of Tongji Medical College of Huazhong University of Science and Technology; the Guanggu District Maternal and Child Health Hospital of Hubei Province; Tongji Hospital of Tongji Medical College of Huazhong University of Science and Technology; General Hospital of the Central Theater Command of the People's Liberation Army; Wuhan Red Cross Hospital; Wuhan Asia Heart Hospital; and Wuhan Pulmonary Hospital.

This study was approved by the ethics committee of the Institute of Blood Transfusion of the Chinese Academy of Medical Sciences and the ethics committees of the participating hospitals. Written informed consent was obtained from all study participants or their legal representatives. The trial protocol and statistical analysis plan are available in Supplement 1 and Supplement 2 .

Participants

Patients were recruited from 7 medical centers. The study recruitment was from February 14, 2020, to April 1, 2020. Follow-up was completed on April 28, 2020.

Inclusion Criteria

Inclusion criteria were the following: (1) signed informed consent; (2) aged at least 18 years; (3) COVID-19 diagnosis based on polymerase chain reaction (PCR) testing; (4) positive PCR result within 72 hours prior to randomization; (5) pneumonia confirmed by chest imaging; (6) clinical symptoms meeting the definitions of severe or life-threatening COVID-19; (7) acceptance of random group assignment; (8) hospital admission; (9) willingness to participate in all necessary research studies and be able to complete the study follow-up; and (10) no participation in other clinical trials, such as antiviral trials, during the study period.

Severe COVID-19 was defined as respiratory distress (≥30 breaths/min; in resting state, oxygen saturation of 93% or less on room air; or arterial partial pressure of oxygen (PaO_2)/fraction of inspired oxygen (FIO_2) of 300 or less. Life-threatening COVID-19 was defined as respiratory failure requiring mechanical ventilation; shock; or other organ failure (apart from lung) requiring intensive care unit (ICU) monitoring.

Exclusion Criteria

Exclusion criteria were the following: (1) pregnancy or lactation; (2) immunoglobulin allergy; (3) IgA deficiency; (4) preexisting comorbidity that could increase the risk of thrombosis; (5) life expectancy less than 24 hours; (6) disseminated intravascular coagulation; (7) severe septic shock; (8) PaO_2/FIO2 of less than 100; (9) severe congestive heart failure; (10) detection of high titer of S protein–RBD-specific (receptor binding domain) IgG antibody (≥1:640); (11) other contraindications as determined by the patient's physicians; and (12) participation in any antiviral clinical trials for COVID-19 within 30 days prior to enrollment.

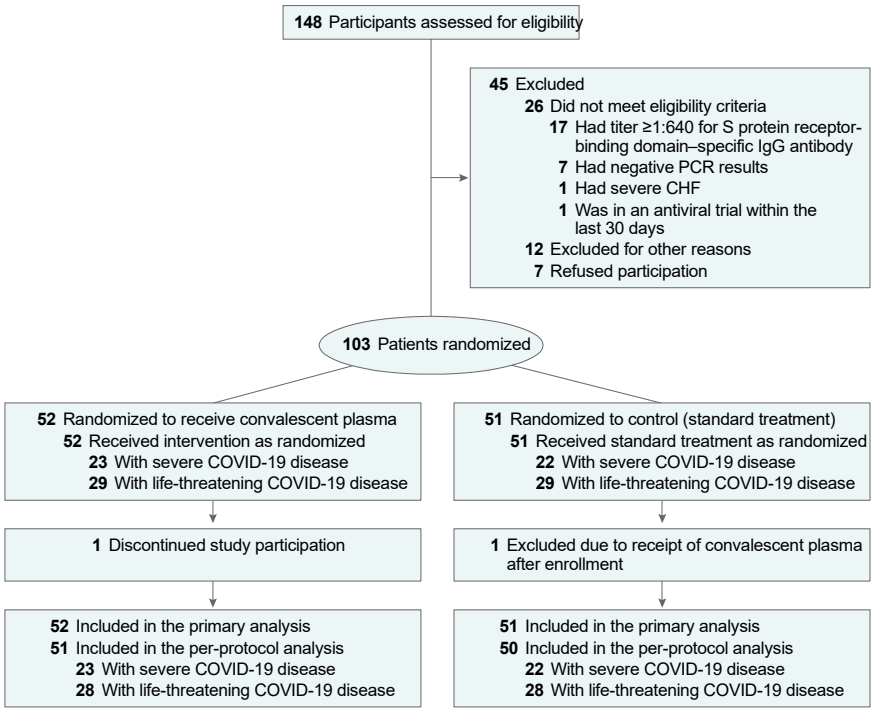
Figure 1. Patient Enrollment and Treatment Assignment



PCR indicates polymerase chain reaction; CHF, congestive heart failure; COVID-19, coronavirus disease 2019.

Randomization

Potential study participants were screened for eligibility 72 hours prior to study randomization. Patients were randomly assigned via computer-generated random numbering (1:1) to receive standard treatment coupled with convalescent plasma transfusion or standard treatment alone (control group) (Figure 1). The randomization was stratified based on the severity of COVID-19 (severe or life-threatening) and a randomization schedule was generated using block randomization with block size of 4 for each type of COVID-19 by SAS software. Patients and clinicians were not masked to treatment assignment.

Procurement of Convalescent Plasma

In brief, patients with a laboratory-confirmed COVID-19 diagnosis, who had fully recovered and been discharged from the hospital for more than 2 weeks, were recruited. Convalescent plasma–specific donor screening and selection were based on the following criteria: age of 18 through 55 years, suitable for blood donation, initially diagnosed with COVID-19 but with 2 negative PCR test results from nasopharyngeal swabs (at least 24 hours apart) prior to hospital discharge, discharged for more than 2 weeks from the hospital, and no persisting COVID-19 symptoms. Convalescent plasma collection was performed based on routine plasma collection procedures via plasmapheresis. The plasma products were prepared as fresh-f rozen plasma. COVID-19 convalescent plasma was collected and processed at the Wuhan Blood Center.

S-RBD–specific IgG antibody titer was measured for convalescent plasma products and reported as the following: less than 1:160, 1:160, 1:320, 1:640, 1: 1280, or greater than 1:1280. There was a positive correlation between the SARS-CoV-2 viral neutralization titer and the S-RBD–specific IgG titer (r = 0.622, P = .03). A serum neutralization titer of 1:80 is approximately equivalent to a titer of 1:1280 for S-RBD–specific IgG. To ensure the therapeutic potency of the convalescent plasma, only the plasma units with an S-RBD–specific IgG titer of at least 1:640 were used for this study.

Additional details regarding plasma preparation standards can be found in the eMethods in Supplement 3 , and the preparation requirements of convalescent plasma used were similar to the recently updated FDA recommendations. [10]

Convalescent Plasma Transfusion

The transfusion dose of COVID-19 convalescent plasma was approximately 4 to 13 mL/kg of recipient body weight. ABO type of the convalescent plasma transfused was compatible with the patient's ABO type. In addition, the convalescent plasma was crossmatched with the patient's red blood cells to ensure compatibility. Convalescent plasma transfusion was administered at approximately 10 mL for the first 15 minutes, which was then increased to approximately 100 mL per hour with close monitoring. Adjustments in the infusion rates were allowed based on the patient's risk for volume overload and tolerance, at the discretion of the treating physicians. No premedication was given before convalescent plasma transfusion.

Standard Treatment

Standard treatment consisted of symptomatic control and supportive care for COVID-19, mostly based on the evolving Chinese national COVID-19 treatment guidelines and hospital

Downloaded From: https://jamanetwork.com/ by a Mayo Clinic Library User on 06/03/2020

practice.[12] Possible treatments included antiviral medications, antibacterial medications, steroids, human immunoglobulin, Chinese herbal medicines, and other medications.

OutcomeMeasures

The primary end point was time to clinical improvement within a 28-day period. Clinical improvement was defined as patient discharge or a reduction of 2 points on a 6-point disease severity scale.[13] The scale was defined as follows: 6 points, death; 5 points, hospitalization plus extracorporeal membrane oxygenation (ECMO) or invasive mechanical ventilation; 4 points, hospitalization plus noninvasive ventilation or high-flow supplemental oxygen; 3 points, hospitalization plus supplemental oxygen (not high-flow or noninvasive ventilation); 2 points, hospitalization with no supplemental oxygen; 1 point, hospital discharge.

Patient discharge criteria included body temperature returned to normal for longer than 3 days, respiratory symptoms significantly improved without the need for oxygen support, and 2 consecutive negative PCR test results from nasopharyngeal swabs at least 24 hours apart.

Secondary clinical outcomes were as follows: (1) 28-day mortality, including analysis of time from randomization to death; (2) duration of hospitalization, including analyses of time from randomization to discharge, time from admission to discharge, and 28-day discharge rates; and (3) conversion of nasopharyngeal swab viral PCR results from positive at baseline to negative at follow-up assessed at 24, 48, and 72 hours. Once nasopharyngeal swab viral PCR testing yielded negative results 2 times consecutively, no further testing was performed.

A post hoc analysis was added to compare rates of improvement at days 7, 14, and 28.

This clinical trial was an open-label, randomized clinical study. To avoid assessment bias, the evaluation of clinical outcomes was performed by an investigator who was blind to the study group allocation.

StatisticalAnalysis

The original sample size was determined to be 100 for each group, which would provide 80% power, with a 2-sided significance level of $\alpha = .05$, to detect an 8-day change for the convalescent plasma group in time to clinical improvement, assuming that this would be 20 days in the control group and 60% of the patients would reach clinical improvement.

Unless otherwise stated, analyses were performed based on the full analysis set, which is defined as the set of all randomized patients who received at least one treatment specified in the trial. Statistical analysis was performed on randomly assigned treatment groups. Continuous variables were summarized by presenting the median and interquartile range (IQR) for the total number of patients who contributed values. Categorical variables were summarized by presenting the frequency and proportion of patients in each category. Time-to-event data were analyzed using the Kaplan-Meier method, and the median time to event and corresponding 95% CI were calculated. For the cases in which more than 50% of patients were censored and therefore the median time to event was indeterminate, the restricted mean survival time would be used for post hoc analysis.

For the primary end point of time to clinical improvement, death, withdrawal, and crossover between groups before day 28 were considered to be right-censored at day 28, and otherwise would be considered to be right-censored at the last observation date. Hazard ratios (HRs) with 95% CIs were calculated using Cox proportional hazards models. Three Cox proportional hazards models were fitted in this study. We referred to the model that included only the treatment group as the unadjusted model. The model that included disease severity (severe or life-threatening) and treatment group is referred to as model 1, and the model that further considered the interaction between disease severity and treatment group is referred to as model 2. Study sites were considered as a random effect in these models. Proportionality hazard assumption was assessed for treatment group and disease severity by extending the Cox models to include the corresponding time-dependent covariates.[14] If the coefficient of the time-dependent covariate was statistically significant, the proportionality hazard assumption would be considered to be violated.

A per-protocol analysis was performed for the primary end point as a sensitivity analysis. The per-protocol set was defined as the set of all randomized patients who received at least one treatment specified in the trial and who had no significant protocol violations that affected the efficacy evaluation.

Treatment effects for secondary end points were assessed using odds ratios and HRs with 95% CIs for the discrete variables and time-to-event data, respectively. For the analyses of time from randomization to discharge, time from randomization to death, and length of stay, the definition of censoring was consistent with the primary end point. Missing data for secondary outcomes and adverse events were not imputed. Only observed values were used for data analysis and presentation.

Subgroup analyses of efficacy were performed according to disease severity. Interactions between treatment group and disease severity group were tested using model 2.

Statistical analyses were performed with SAS software, version 9.4. Statistical significance was defined using a 2-sided significance level of $\alpha = .05$. Because of the potential for type I error due to multiple comparisons, findings for analyses of secondary end points should be interpreted as exploratory.

EarlyStudyTermination

Due to the containment of the COVID-19 epidemic in Wuhan, China, the numbers of patients with COVID-19 decreased in late March 2020. No new cases were reported in Wuhan for 7 consecutive days after March 24 (data from the National Health Commission of the People's Republic of China).[15] The last patient enrolled in this study was on March 27, 2020, and for the next 3 days, we were not able to recruit more patients and did not have any recruitment targets. After discussion with the expert committee of the Institute of Blood Transfusion, the study was terminated by the sponsor (Chinese Academy of Medical Sciences) and the leading primary investigator on April 1, 2020, with a total of 103 patients enrolled.

Abbreviations: ALT, alanine aminotransferase; APTT, activated partial thromboplastin time; AST, aspartate aminotransferase; COVID-19, coronavirus disease 2019; CRP, C-reactive protein; IQR, interquartile range.

SI conversion factors: To convert D-dimer to nmol/L, multiply values by 5.476; to convert urea nitrogen to mmol/L, multiply values by 0.357; to convert creatinine to μmol/L, multiply values by 88.4.

[a] The values shown were based on total number of patients who contributed values.

[b] History of allergy to certain allergens, including food, medicine, etc.

[c] Details of coexisting diseases were collected from medical records.

[d] The vital signs and laboratory values are the last available values within 72 hours prior to randomization. The laboratory values selected were associated with the clinical status and factors that may affect convalescent plasma therapy. The values used for categorization of laboratory values are local divisions of low, normal, and high values.

There was no interim or preliminary data review prior to making this decision.

Results

Study Population

A total of 103 patients were enrolled in this randomized clinical trial. They were assigned to either the convalescent plasma group or the control group in a 1:1 ratio and were categorized as follows: 23 patients in the convalescent plasma group and 22 patients in the control group had severe COVID-19, and 29 patients in the convalescent plasma group and 29 patients in the control group had life-threatening COVID-19. Of these, 1 patient with life-threatening disease in the convalescent plasma treatment group withdrew from the study and 1 patient with life-threatening disease in the control group received convalescent plasma transfusion after randomization (protocol violation). Thus, 103 patients were included in the full analysis set and 101 patients were included in the per-protocol set (Figure 1).

The median age was 70 years (IQR, 62-78 years) among all patients, 71 years (IQR, 66-82 years) for patients with severe COVID-19, and 69 years (IQR, 61-76 years) for patients with life-threatening COVID-19. Of the patients included in the study, 60 (58.3%) were men, and the percentages of men with severe and life-threatening COVID-19 were 53.3% and 62.1%, respectively. A total of 89.2% of the patients had a normal body temperature at the time of participation, and the median body temperature was 36.5 °C (IQR, 36.2-36.7 °C) (Table 1 and eTable 1 and eTable 2 in Supplement 3).

The median interval between the onset of symptoms and randomization was 30 days (IQR, 20-39 days) overall, 33 days (IQR, 22-43 days) for patients with severe disease, and 26 days (IQR, 20-36 days) for patients with life-threatening disease. There were 5 patients with severe disease and 3 patients with life-threatening disease who had an interval between the onset of symptoms and randomization that was fewer than 14 days (Table 2).

Overall and within disease severity strata, the convalescent plasma and control groups were similar in terms of demographic characteristics, baseline laboratory results, and distribution on the 6-point disease severity scale at baseline, with the exception of systolic blood pressure in the patients with severe COVID-19 and sex in the patients with life-threatening COVID-19 (eTable 1 and eTable 2 in Supplement 3). Additional details regarding patients' clinical status at the time of randomization and additional medications received are provided in Table 2 and eTable 3, eTable 4, and eTable 7 in Supplement 3 . For patients in the convalescent plasma group, median plasma infusion volume was 200 mL (IQR, 200-300 mL), and 96% received a single dose of plasma infusion.

Primary Clinical Outcome

For all patients combined, there was no significant difference in the primary outcome of time to clinical improvement within 28 days: 51.9% (27/52) in the convalescent plasma group vs 43.1% (22/51) in the control group (difference, 8.8% [95% CI, −10.4% to 28.0%]; HR, 1.40 [95% CI, 0.79-2.49]; $P = .26$). Results for the per-protocol population were not materially different (eTable 5 in Supplement 3). Among those with severe disease, the primary outcome occurred in 91.3% (21/23) vs 68.2% (15/22) (HR, 2.15 [95% CI, 1.07-4.32]; $P = .03$). Among those with life-threatening disease, the primary outcome occurred in 20.7% (6/29) vs 24.1% (7/29) (HR, 0.88 [95% CI, 0.30-2.63]; $P = .83$) (P for interaction = .17) (Table 3 , Figure 2 , and eTable 6 in Supplement 3). For all proportional hazards models, the proportionality assumptions were met.

Secondary Clinical Outcomes

There was no significant difference in the secondary outcome of 28-day mortality (15.7% in the convalescent plasma group vs 24.0% in the control group; OR, 0.65 [95% CI, 0.29-1.46]; $P = .30$). There was also no significant difference in the time from randomization to death between the convalescent group and the control group (HR, 0.74 [95% CI, 0.30-1.82]; $P = .52$) (Table 3). Among patients with severe disease, no patients died in the convalescent plasma group, while 2 patients (9.1%) died in the control group. Among patients with life-threatening disease, 8 patients (28.6%) died in the convalescent plasma group, while 10 patients (35.7%) died in the control group.

There was also no significant difference in the secondary outcome of time from randomization to discharge (51.0% in the convalescent plasma group vs 36.0% in the control group were discharged by day 28; HR, 1.61 [95% CI, 0.88-2.93]; $P = .12$). The 28-day discharge rate of the convalescent plasma group reached 51%, among which the discharge rate of those with severe disease in the convalescent plasma group reached 91.3%.

At 24, 48, and 72 hours, the rates of negative SARS-CoV-2 viral PCR in the convalescent plasma group were all significantly higher than that of the control group (44.7% vs 15.0%, $P = .003$ at 24 hours; 68.1% vs 32.5%, $P = .001$ at 48 hours; 87.2% vs 37.5%, $P < .001$ at 72 hours) (Table 3 and eFigure 1 in Supplement 3). Among patients with severe disease, the rate of negative viral PCR at 72 hours was significantly higher in the convalescent plasma group compared with the control group, but there was no significant difference at 24 hours and 48 hours. Among patients with life-threatening disease, there was a statistically significant difference in favor of the convalescent plasma group at 24, 48, and 72 hours.

Post hoc Analysis

The clinical improvement rates overall and by disease severity subgroups at various time points during the study are presented in Table 3.

Adverse Events

Two participants reported transfusion-related adverse events following convalescent plasma transfusion. One patient in the severe COVID-19 group developed chills and rashes within 2 hours of transfusion but recovered fully after treatment with dexamethasone and promethazine. This was determined to be a definite nonsevere allergic transfusion reaction and also a probable nonsevere febrile nonhemolytic transfusion reaction. The other patient, who was in the life-threatening COVID-19 group, presented with shortness of breath, cyanosis, and severe dyspnea within 6 hours of transfusion. The patient was given dexamethasone, aminophylline, and other supportive care immediately and gradually improved after 2 hours. This was determined to be possible severe transfusion-associated dyspnea.

Table 2. Patients' Clinical Status at Randomization and Medications Received[a]

All patients	Convalescent plasma group (n = 52)	Control group (n = 51)

>14 d, No. (%)	46/49 (93.9)	43/48 (89.6)
Interval between symptom onset and admission, median (IQR), d	12 (5-20) [n = 49]	10 (6-16) [n = 48]
6-Point scale at study day 1, No. (%)		
2- Hospitalization, no supplemental oxygen	1/51 (2.0)	1/50 (2.0)
3- Hospitalization, requiring supplemental oxygen (not high-flow or noninvasive ventilation)	15/51 (29.4)	15/50 (30.0)
4- Hospitalization, requiring noninvasive ventilation and/or high-flow supplemental oxygen	21/51 (41.2)	23/50 (46.0)
5- Hospitalization, requiring extracorporeal membrane oxygenation and/or invasive mechanical ventilation	14/51 (27.5)	11/50 (22.0)
Medications used after randomization		
Antiviral	41/46 (89.1)	44/49 (89.8)
Antibacterial	38/46 (82.6)	39/49 (79.6)
Chinese herbal medicine	26/46 (56.5)	30/49 (61.2)
Steroids	21/46 (45.7)	16/49 (32.7)
Antifungal	15/46 (32.6)	13/49 (26.5)
Human immunoglobulin	13/46 (28.3)	11/49 (22.5)
Interferon	12/46 (26.1)	7/49 (14.3)

[a] The values shown were based on total number of patients who contributed values. Details of medications used were provided in eTable 7 in Supplement 3.

Discussion

In this randomized clinical trial of patients with severe or life-threatening COVID-19, there was no significant difference in the time to clinical improvement between patients who received convalescent plasma transfusion therapy combined with standard treatment vs those who received standard treatment alone. There was also no significant difference in secondary outcomes of 28-day mortality or time from randomization to discharge. Convalescent plasma treatment was

Abbreviations: HR, hazard ratio; IQR, interquartile range; OR, odds ratio.

[a] The values shown were based on total number of patients who contributed values. The primary clinical outcome was analyzed by primary analysis set. Times to outcomes in the secondary clinical outcomes were analyzed by primary analysis set. Indeterminate events could not be calculated due to the low percentage of outcome events.

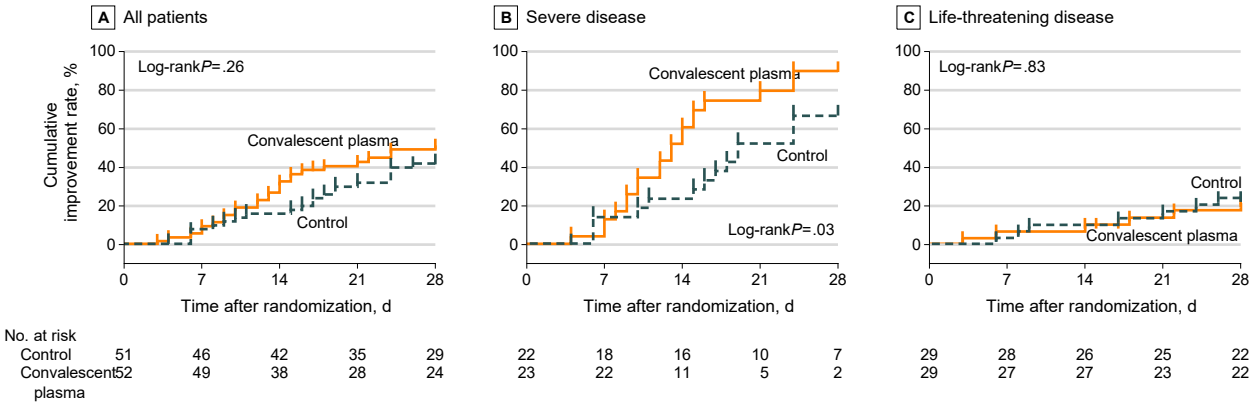
[b] The absolute differences of time to clinical improvement, times to discharge, and times from randomization to death were calculated based on restricted mean survival time.

[c] *P* value was calculated by Cox regression, χ^2 test, or Fisher exact test.

[d] Medians and quartiles of time to clinical improvement, times to discharge, and times from randomization to death could not be determined because too few patients had reached improvement or discharge by the end of the study. By the end of the study, for all, severe, and life-threatening patients, respectively, 27 (51.9%), 21 (91.3%), and 6 (20.7%) were clinically improved in the convalescent plasma group; 22 (43.1%), 15 (68.2%), and 7 (24.1%) were clinically improved in the control group; 26 (51.0%), 21 (91.3%), and 5 (17.9%) were discharged in the convalescent plasma group; 18 (36.0%), 15 (68.2%), and 3 (10.7%) were discharged in the control group; 8 (15.7%), 0, and 8 (28.6%) died in the convalescent plasma group; and 12 (24.0%), 2 (9.1%), and 10 (35.7%) died in the control group.

[e] These analyses were developed post hoc to better illustrate disease progression.

Figure 2. Time to Clinical Improvement in Patients With COVID-19



The cumulative improvement rate is the percentage of patients who experienced a 2-point improvement or were discharged alive from the hospital. Ticks on the curves indicate censored events. All patients who did not reach clinical improvement were observed for the full 28-day period or until death. COVID-19 indicates coronavirus disease 2019.

The median (IQR) follow-up times for the convalescent plasma group and control group, respectively, were 15 (10-28) days and 24 (13-28) days overall; 13 (10-16) and 18.5 (11-26) days among those with severe COVID-19; and 28 (12-28) and 26 (15-28) days among those with life-threatening COVID-19.

associated with higher rates of negative SARS-CoV-2 viral PCR results from nasopharyngeal swabs at 24, 48, and 72 hours, demonstrating that the convalescent plasma treatment was associated with antiviral activity in patients with COVID-19.

Plasma transfusions can result in transfusion-related adverse events including febrile and allergic transfusion reactions, transfusion-associated dyspnea, hypotensive transfusion reaction, to hemolytic transfusion reactions, septic transfusion reaction, transfusion-related acute lung injury, and transfusion-associated circulatory overload. In this study, most patients tolerated convalescent plasma transfusions well. There were 2 cases of reported transfusion-associated adverse events. One case was determined to be a definite nonsevere allergic transfusion reaction and also a probable nonsevere febrile

Downloaded From: https://jamanetwork.com/ by a Mayo Clinic Library User on 06/03/2020

nonhemolytic transfusion reaction, and the other case was determined to be possible severe transfusion-associated dyspnea. The rate is somewhat higher than the general rate of reactions associated with plasma transfusion, possibly due to the small sample size and active surveillance. [16]

In the subgroup analysis by disease severity, there was a signal of possible clinical benefit for convalescent plasma among patients with severe COVID-19. However, bec ause the test for interaction by disease severity was not statistically significant, the findings for the severe and life-threatening subgroups should not be interpreted as different. Given the early study termination, it is possible that the study was underpowered to detect a statistically significant interaction, and a larger trial of convalescent plasma focusing on patients with severe COVID-19 may be warranted.

Patients with COVID-19 who were recruited in this study were heterogeneous with regard to the duration and severity of the illness. The possible antiviral activity with convalescent plasma treatment in patients aged 60 to 80 years and after 14 days of disease onset is notable. To our knowledge, no other antiviral treatments have demonstrated therapeutic effects in this age group or this late in the course of the disease. However, the con valescent plasma treatment was given at least 14 days after the onset of symptoms in most cases, and it is not known whether earlier convalescent plasma treatment could have resulted in better clinical outcomes. Further studies are needed to optimize patient selection and timing of convalescent plasma treatment.

While the use of convalescent plasma has been investigated and used many times in the past, [3,17] its use has not been well studied. It is notable that for most studies of the use of convalescent plasma, [4,5,18] there was lack of standardization and procedure control with regard to the donor selection process and the nature or level of antibodies in convalescent plasma units. This may explain the varied therapeutic effects seen across a variety of diseases or even across patients with the same disease. The guidance on convalescent plasma issued by the World Health Organization [11] highlighted the importance of standardized processes and laboratory testing–based quality control of convalescent plasma units, the selection of clinical indications, as well as program deployment to recruit adequate numbers of donors and maintain sufficient inventory.

One of the potential strengths of this study was the controlled process for donor selection and convalescent plasma quality control. A predefined process was used to enroll donors for convalescent plasma collection. Only units with a high titer of S-RBD–specific IgG antibody were used for convalescent plasma treatment in this study.

Limitations

This study has several limitations. First, the sample size was small and the study was terminated early. It is possible that the study was underpowered to detect a clinically important benefit of convalescent plasma therapy. Second, the median time between the onset of symptoms and randomization was 30 days, and it is unclear whether earlier treatment would have resulted in greater benefit. Third, this was an open-label study and the primary outcome was based to some degree on physicians' clinical management decisions. Fourth, the use of standard therapy was allowed in both groups and was not protocolized, which could have potentially influenced outcomes. Fifth, the relatively short 28-day time frame of the study follow-up may have precluded the observation of clinical improvement in patients with severe diseases, especially life-threatening COVID-19, as they may take longer time to respond and recover. Sixth, plasma was not used for the control group, which would have been a more ideal control group, making blinded design possible. Seventh, the study findings should be interpreted cautiously given that practices may vary from country to country, and hospital to hospital, such as the types of standard treatment, supportive care, and thresholds for intubation and hospital admission. The outcomes of this study may be related to a combination of many factors, such as the quality of the convalescent plasma products in terms of potency, the selection of the patients (severe and life-threatening COVID-19), and the timing of convalescent plasma transfusion.

Conclusion

Among patients with severe or life-threatening COVID-19, convalescent plasma therapy added to standard treatment, compared with standard treatment alone, did not significantly improve the time to clinical improvement within 28 days. Interpretation is limited by early termination of the trial, which may have been underpowered to detect a clinically important difference.

Host Genomics Research and Data Collection Efforts Related to COVID-19

Joint Meeting
of the
Roundtable on Genomics and Precision Health
and the
Standing Committee on Emerging Infectious Diseases and 21st Century Health Threats

A VIRTUAL MEETING
July 1, 2020
1:00 PM – 2:45 PM ET
Zoom Link: https://nasem.zoom.us/j/95540901323

Aims for the meeting:

- To understand the scientific challenges that the field of genomics is facing
  - What has been the effect of the pandemic on genomics research and data collection and sharing? What is the role of the genomics community during the pandemic? What research is underway? What research still needs to be done?
  - What gaps and challenges in the field is this crisis highlighting? What unique contributions of the field are not being leveraged effectively?
- To explore innovative approaches to overcoming those challenges
  - What new approaches are you using to solve a problem? Could these be applied to the field of genomics? Are there lessons from genomics that are being used in light of the pandemic? What are the opportunities for connecting efforts and data sets (e.g. across institutions, genotype and phenotype data)?
- To discuss opportunities for the Genomics Roundtable and for the Standing Committee on Emerging Infectious Diseases and 21st Century Health Threats to facilitate progress
  - Are there opportunities for the Roundtable and Standing Committee to act that align with strategic priorities?
  - Are the Roundtable and Standing Committee uniquely positioned to address specific challenges?

AGENDA:

1:00 p.m. ET Welcoming Remarks

GEOFFREY GINSBURG, *Roundtable Co-Chair*
Director, Duke Center for Applied Genomics & Precision Medicine
Professor, Medicine, Pathology, and Biomedical Engineering
Duke University Medical Center

MICHELLE PENNY, *Roundtable Co-Chair*
Vice President and Head of Genomics
Goldfinch Bio

HARVEY FINEBERG, *Standing Committee Chair*
President
Gordon and Betty Moore Foundation

1:15 p.m. **An Introduction to the Host Genetics of COVID-19**

MAXIMILIAN MUENKE
CEO
American College of Medical Genetics and Genomics (ACMG)

Understanding Host Genetics and Genomics Related to COVID-19 and Opportunities for Forming Data Sharing COVID-19 Communities

1:25 p.m. SHARON TERRY
Founder and CEO
Genetic Alliance

1:35 p.m. JOYCE TUNG
Vice President, Research
23andMe

1:45 p.m. GEOFFREY GINSBURG, *Roundtable Co-Chair*
Director, Duke Center for Applied Genomics & Precision Medicine
Professor, Medicine, Pathology, and Biomedical Engineering
Duke University Medical Center

1:55 p.m. **Discussion with Roundtable and Standing Committee Members**

2:30 p.m. **Next Steps**

Questions:

- What challenges or gaps were exposed today?
- Is there an area that should be incorporated into the Roundtable's strategic planning or the Standing Committee's work?

GEOFFREY GINSBURG, *Roundtable Co-Chair*
Director, Duke Center for Applied Genomics & Precision Medicine
Professor, Medicine, Pathology, and Biomedical Engineering

Vice President and Head of Genomics
Goldfinch Bio

HARVEY FINEBERG, *Standing Committee Chair*
President
Gordon and Betty Moore Foundation

2:45 p.m. Adjourn

ROUNDTABLE AND STANDING COMMITTEE INFORMATION

The National Academies of
SCIENCES • ENGINEERING • MEDICINE

Roundtable on GENOMICS and PRECISION HEALTH

The sequencing of the human genome is rapidly opening new doors to research and progress in biology, medicine, and health care. At the same time, these developments have produced a diversity of new issues to be addressed.

The National Academies of Sciences, Engineering, and Medicine has convened a Roundtable on Genomics and Precision Health (previously the Roundtable on Translating Genomic-Based Research for Health) that brings together leaders from academia, industry, government, foundations and associations, and representatives of patient and consumer interests who have a mutual concern and interest in addressing the issues surrounding the translation of genome-based research for use in maintaining and improving health. The mission of the Roundtable is to advance the field of genomics and improve the translation of research findings to health care, education, and policy. The Roundtable will discuss the translation process, identify challenges at various points in the process, and discuss approaches to address those challenges.

The field of genomics and its translation involves many disciplines, and takes place within different economic, social, and cultural contexts, necessitating a need for increased communication and understanding across these fields. As a convening mechanism for interested parties from diverse perspectives to meet and discuss complex issues of mutual concern in a neutral setting, the Roundtable: fosters dialogue across sectors and institutions; illuminates issues, but does not necessarily resolve them; and fosters collaboration among stakeholders.

To achieve its objectives, the Roundtable conducts structured discussions, workshops, and symposia. Workshop summaries will be published and collaborative efforts among members are encouraged (e.g., journal articles). Specific issues and agenda topics are determined by the Roundtable membership, and span a broad range of issues relevant to the translation process.

Issues may include the integration and coordination of genomic information into health care and public health including encompassing standards for genetic screening and testing, improving information technology for use in clinical decision making, ensuring access while protecting privacy, and using genomic information to reduce health disparities. The patient and family perspective on the use of genomic information for translation includes social and behavioral issues for target populations. There are evolving requirements for the health professional community, and the need to be able to understand and responsibly apply genomics to medicine and public health.

Of increasing importance is the need to identify the economic implications of using genome-based research for health. Such issues include incentives, cost-effectiveness, and sustainability.

Issues related to the developing science base are also important in the translation process. Such issues could include studies of gene-environment interactions, as well as the implications of genomics for complex disorders such as addiction, mental illness, and chronic diseases.

Roundtable sponsors include federal agencies, pharmaceutical companies, medical and scientific associations, foundations, and patient/public representatives. For more information about the Roundtable on Genomics and Precision Health, please visit our website at nationalacademies.org/GenomicsRT or contact Sarah Beachy at 202-334-2217, or by e-mail at sbeachy@nas.edu.

The National Academy of Sciences, National Academy of Engineering, and National Academy of Medicine work together as the National Academies of Sciences, Engineering, and Medicine ("the Academies") to provide independent, objective analysis and advice to the nation and conduct other activities to solve complex problems and inform public policy decisions. The Academies also encourage education and research, recognize outstanding contributions to knowledge, and increase public understanding in matters of science, engineering, and medicine.

Health and Medicine Division

Standing Committee on Emerging Infectious Diseases and 21st Century Health Threats

In response to a request from the Office of Science and Technology Policy (OSTP) and the Office of the Assistant Secretary for Preparedness and Response (ASPR), the National Academies of Sciences, Engineering, and Medicine will convene a standing committee of experts to help inform the federal government on critical science and policy issues related to emerging infectious diseases and other 21st century health threats. The standing committee will include members with expertise in emerging infectious diseases, public health, public health preparedness and response, biological sciences, clinical care and crisis standards of care, risk communication, epidemiology, and regulatory issues, as well as veterinary science, One Health, ethics, and community engagement. The standing committee will provide a venue for the exchange of ideas among federal government agencies, the private sector, and the academic community, as well as other relevant stakeholders.

The standing committee will:

- Stand ready to respond on short notice to requests from the federal government to assess and consider the science and policy implications of an emerging infectious disease or significant public health threat;
- Provide a venue to enable science and policy discussions relevant to the federal government on emerging issues, research, and activities through in-depth knowledge of the sponsor's programs, goals, and objectives;
- Identify opportunities to integrate science into national preparedness and response decision making;
- Explore lessons learned and best practices from previous preparedness and response efforts, and identify opportunities to disseminate that information to a variety of stakeholders;
- Serve as a focal point for national policy discussions by experts and other leaders in the field;
- Consider, identify, and discuss strategies for addressing misinformation; and
- Respond to the federal government's needs for continuing dialog related to strategic planning and program development to address emerging infectious diseases, biosecurity, and public health and medical preparedness.

At the request of the sponsors, the standing committee will be involved in the planning, development, and oversight of related ad hoc activities undertaken by separately appointed committees operating under its auspices.

The standing committee will serve as a focal point for the discussion of scientific, technical, and policy issues relevant to emerging infectious diseases and public health preparedness and response that warrant detailed examination. Topics for discussion with the standing committee may include:

- Technical assistance and/or assessment of response to emerging infectious diseases;
- Availability of and access to information, samples, and other materials to determine the origin and evolution of emerging infectious diseases;
- International coordination and engagement;
- Technical assessment of ecological and evolutionary drivers of disease emergence;
- Approaches to proactive public messaging and strategies to address misinformation;
- Other science and policy issues relevant to emerging infectious diseases and 21st century health threats.

The committee will carry out its charge at its in-person and virtual meetings by gathering evidence from experts, deliberating, and, when necessary, by preparing short reports.

COMMITTEE SPONSORS

White House Office of Science and Technology Policy and HHS Office of Assistant Secretary for Preparedness and Response

COMMITTEE ROSTER

Harvey Fineberg, M.D., Ph.D. ***(Chair)***
President
Gordon and Betty Moore Foundation

Kristian Andersen, Ph.D.
Associate Professor and Director of Infectious Disease Genomics, Scripps Research Translational Institute
The Scripps Research Institute

Ralph Steven Baric, Ph.D.
William R. Kenan, Jr. Distinguished Professor
The University of North Carolina at Chapel Hill

Mary Bassett, M.D., M.P.H.
Director of the François-Xavier Bagnoud Center for Health and Human Rights
Harvard School of Public Health

Trevor Bedford, Ph.D.
Associate Faculty Member, Vaccine and Infectious Disease Division, Public Health Sciences Division, and Human Biology Division
Fred Hutchinson Cancer Research Center

Georges Benjamin, M.D.
Executive Director
American Public Health Association

Donald Berwick, M.D., M.P.P., F.R.C.P, KBE
Lecturer of Health Care Policy

SPEAKER AND CHAIR BIOGRAPHIES

Harvey V. Fineberg, M.D., Ph.D. ***(Standing Committee Chair)***
Dr. Fineberg is the president of the Gordon and Betty Moore Foundation, which fosters path-breaking scientific discovery, environmental conservation, improvements in patient care and preservation of the special character of the San Francisco Bay Area. He previously held the Presidential Chair for 2014-2015 as visiting professor at the University of California, San Francisco. Prior to that, he served as president of the Institute of Medicine from 2002 to 2014 and as provost of Harvard University from 1997 to 2001, following 13 years as dean of the Harvard School of Public Health. He has devoted most of his academic career to the fields of health policy and medical decision-making. His past research has focused on the process of policy development and implementation, assessment of medical technology, evaluation and use of vaccines, and dissemination of medical innovations. Fineberg chairs the board of the Carnegie Endowment for International Peace and serves on the boards of the William and Flora Hewlett Foundation and the China Medical Board. He helped found and served as president of the Society for Medical Decision Making and also served as consultant to the World Health Organization. Fineberg is co-author of the books Clinical Decision Analysis, Innovators in Physician Education and The Epidemic That Never Was, an analysis of the controversial federal immunization program against swine flu in 1976. He has co-edited several books on such diverse topics as AIDS prevention, vaccine safety, understanding risk in society and global health. He has also authored numerous articles published in professional journals. Fineberg is the recipient of several honorary degrees—the Frank A. Calderone Prize in Public Health, the Henry G. Friesen International Prize in Health Research and the Harvard Medal, awarded by the alumni association of the university from which he earned his bachelor's and doctoral degrees.

Geoffrey Ginsburg, M.D., Ph.D. (Roundtable *Co-Chair*)
Dr. Ginsburg is the founding director for the Center for Applied Genomics & Precision Medicine at the Duke University Medical Center and for MEDx, a partnership between the Schools of Medicine and Engineering to spark and translate innovation. His research addresses the challenges for translating genomic and digital information into medical practice and the integration of precision medicine into healthcare. In 2017 he received Duke's Translational Research Mentorship Award and is a finalist in the NIH/BARDA Antimicrobial Resistance Prize.

He is a member of the Advisory Council to the Director of NIH and is co-chair of the National Academies Roundtable on Genomics and Precision Health and is founder and president of the Global Genomic Medicine

Collaborative, a not for profit organization aimed creating international partnerships to advance the implementation of precision medicine. He has recently served as a member of the Board of External Experts for the NHLBI, the advisory council for the National Center for Accelerating Translational Science, the chair of the review for Genome Canada's Large Scale Applied Research Competition in Genomics and Precision Medicine, and the World Economic Forum's Global Agenda Council on the Future of the Health Sector. He is a founder of Predigen Inc and MeTree&You Inc. He was previously Vice President of Molecular Medicine at Millennium Pharmaceuticals, Inc and a faculty member at Harvard Medical School.

Maximilian Muenke, M.D., FACMG
Dr. Muenke joined the American College of Medical Genomics (ACMG) as CEO in 2019. Recognized as a highly acclaimed physician-scientist and dedicated clinical and research mentor, Dr. Muenke has more than three decades of experience to the ACMG, including 10 years on the faculty of the University of Pennsylvania School of Medicine. Since 2000, Dr. Muenke has served as Senior Investigator, Head of the Human Development Section, and Chief of the Medical Genetics Branch at the National Human Genome Research Institute (NHGRI) of the National Institutes of Health (NIH). The focus of his laboratory's research was on the delineation and identification of the underlying causes of craniofacial and related anomalies in humans including holoprosencephaly as well as Muenke syndrome, a relatively common craniosynostosis syndrome. Dr. Muenke is passionate about training the next generation of leaders in the field of genetics and genomic medicine. He has directed medical genetics training since 1994, first at the University of Pennsylvania and then at the NIH, where he was the Director of the NIH Medical Genetics and Genomic Medicine Residency and Fellowship Training Programs.

Michelle Penny, Ph.D. ***(Roundtable Co-Chair)***
Dr. Penny is a Vice President and Head of Genomics at Golfich Bio. Prior to that, she was the Head of Translational Genome Sciences at Biogen. She received her Ph.D. in Genetics from the University of Birmingham, UK in 1993. After a postdoctoral fellowship in the Virology Division at the National Institute of Medical Research, Mill Hill, London, she joined Imperial College London, Department of Medical and Community Genetics where she was a postdoctoral research scientist until taking a lectureship in Human Molecular Genetics in 1998. Her academic research career focused on the study of complex polygenic diseases particularly autoimmune disease and susceptibility to infection. In 2002, Dr. Penny joined the Clinical Pharmacogenomics group at Pfizer in Sandwich, UK, and moved to New London, CT in 2006 to take on the role of Oncology Molecular Medicine Lead until 2009 when she moved to Indianapolis to lead the Pharmacogenomics work at Eli Lilly and Company.

Sharon Terry, M.A.
Sharon Terry is President and CEO of Genetic Alliance, a large network engaging individuals, families and communities to transform health. Genetic Alliance works to provide programs, products and tools for ordinary people to take charge of their health.

As 'just a Mom' with a master's degree in Theology, she cofounded PXE International, a research advocacy organization for the genetic condition pseudoxanthoma elasticum (PXE), in response to the diagnosis of PXE in her two children in 1994. With her husband, she co-discovered the ABCC6 gene, patented it to ensure ethical stewardship in 2000, and assigned their rights to the foundation. She subsequently developed a diagnostic test and conducts clinical trials. She is the author of 140 peer-reviewed papers, of which 30 are clinical PXE studies.

In her focus at the forefront of consumer participation in genetics research, services and policy, she serves in a leadership role on many of the major international and national organizations, including the Precision Medicine Initiative Cohort Advisory Panel, Accelerating Medicines Partnership, Institute of Medicine (IOM) Science and Policy Board, the IOM Roundtable on Translating Genomic-Based Research for Health, the PubMed Central National Advisory Committee, the PhenX scientific advisory board, the Global Alliance for Genomics and Health, the International Rare Disease Research Consortium Executive Committee and as Founding President of EspeRare Foundation of Geneva, Switzerland. Terry is co-founder of the Genetic Alliance Registry and Biobank. She is on the editorial boards of several journals. She led the coalition that was instrumental in the passage of the Genetic Information Nondiscrimination Act. She received an honorary doctorate from Iona College for her

community engagement work in 2006; the Research!America Distinguished Organization Advocacy Award in 2009; and the Clinical Research Forum and Foundation's Annual Award for Leadership in Public Advocacy in 2011. She was named one of FDA's "30 Heroes for the Thirtieth Anniversary of the Orphan Drug Act" in 2013. She is co-inventor of the Platform for Engaging Everyone Responsibly (PEER). PEER received $500,000 from the Robert Wood Johnson Foundation in 2014. PEER undergirds the Community Engaged Network for All (CENA), a PCORnet member funded in 2013 for Phase I and in 2015 for Phase II. She is Co-PI of the PCORnet Coordinating Center and Chair of the PCORnet Engagment Committee.

Joyce Tung, Ph.D.
Joyce joined 23andMe in 2007 and manages the 23andMe research team, which is responsible for consumer health and ancestry research and development, academic and industry collaborations, computational analyses for therapeutics, and new research methods and tools development. While a postdoctoral fellow at Stanford University, Joyce studied the genetics of mouse and human pigmentation. She graduated from Stanford with honors and distinction with a B.S. in Biological Sciences and a minor in computer science, and earned her Ph.D. in Genetics from the University of California, San Francisco where she was a National Science Foundation graduate research fellow.

Genomewide Association Study of Severe Covid-19 with Respiratory Failure

BACKGROUND

There is considerable variation in disease behavior among patients infected with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the virus that causes coronavirus disease 2019 (Covid-19). Genomewide association analysis may allow for the identification of potential genetic factors involved in the development of Covid-19.

A Host Transcriptional Signature for Presymptomatic Detection of Infection in Humans Exposed to Influenza H1N1 or H3N2

BACKGROUND

There is great potential for host-based gene expression analysis to impact the early diagnosis of infectious diseases. In particular, the influenza pandemic of 2009 highlighted the challenges and limitations of traditional pathogen-based testing for suspected upper respiratory viral infection.

A crowdsourced analysis to identify ab initio molecular signatures predictive of susceptibility to viral infection

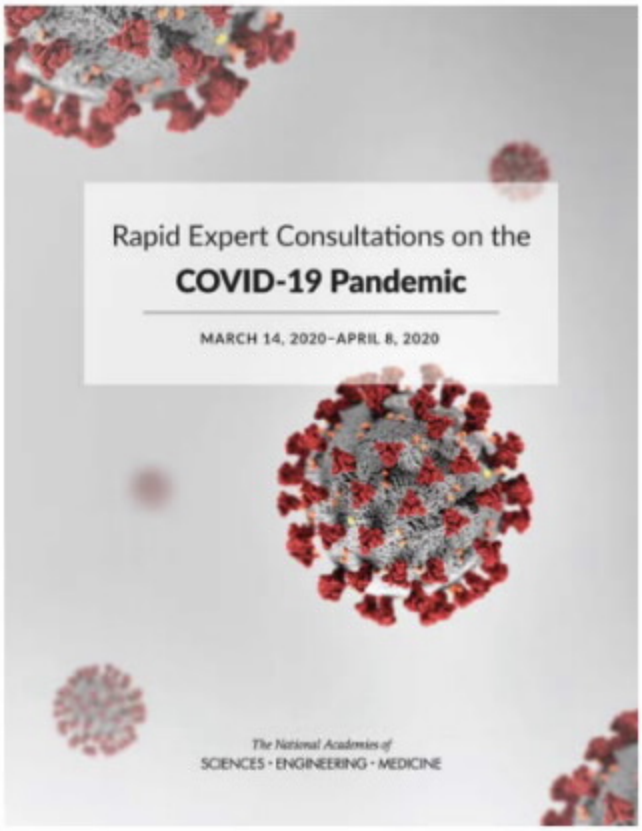
BACKGROUND

The response to respiratory viruses varies substantially between individuals, and there are currently no known molecular predictors from the early stages of infection. Here we conduct a community-based analysis to determine whether pre- or early post-exposure molecular factors could predict physiologic responses to viral exposure.

A Host-Based RT-PCR Gene Expression Signature to Identify Acute Respiratory Viral Infection

Improved ways to diagnose acute respiratory viral infections could decrease inappropriate antibacterial use and serve as a vital triage mechanism in the event of a potential viral pandemic. Measurement of the host response to infection is an alternative to pathogen-based

diagnostic testing and may improve diagnostic accuracy. We have developed a host-based assay with a reverse transcription polymerase chain reaction (RT-PCR) TaqMan low-density array (TLDA) platform for classifying respiratory viral infection.



Rapid Expert Consultations on the COVID-19 Pandemic

In response to a request from the Office of Science and Technology Policy and the Office of the Assistant Secretary for Preparedness and Response, the National Academies of Sciences, Engineering, and Medicine convened a standing committee of experts to help inform the federal government on critical science and policy issues related to emerging infectious diseases and other 21st century health threats. This set of Rapid Expert Consultations are the first of their kind and represent the best evidence available to the Committee at the time each publication was released.

Research in context

Evidence before this study

An increasing body of research has demonstrated that host gene expression patterns in peripheral blood offer a high degree of accuracy for diagnosis of acute infections at the time of clinical presentation.

Added value of this study

For the first time we demonstrate in a real-world setting that a blood-based gene expression test can accurately predict impending viral infection even before typical symptoms are present.

Implications of all the available evidence

These data show that biomarkers of viral infection are present and detectable even before clinical disease develops, opening the door to novel approaches to early treatment and outbreak management.

Abstract

Background

Early and accurate identification of persons with viral infections can be of critical importance for clinical management and public health interventions. Measuring host responses through gene signature-based biomarkers offer promise for improved diagnosis of respiratory viral infections, but little is known how early in disease such measures may be effective.

Methods

We performed a modified index-cluster study in 1465 university dormitory residents over five years. Each year, we monitored for symptomatic Index Cases (IC) and identified clusters of their Close Contacts (CC) who would be at presumed increased risk of developing symptomatic respiratory tract infection (RTI) while under observation. We then monitored each CC for 5 days for development of RTI and measured transcriptomic responses at each timepoint via a blood-based 36-gene RT-PCR assay.

Findings

Of 264 ICs with RTI symptoms, 150 (56%) had a confirmed viral etiology detected. Of their 555 CCs, 106 (19%) developed symptomatic RTI with a proven viral etiology during the observation window. The transcriptomic assay accurately predicts infection at the time of peak symptoms despite heterogeneity of hosts and nine different viral etiologies (auROC 0·96). Furthermore, these genomic biomarkers are capable of identifying early disease one, two and three days prior to peak illness when minimal to no symptoms are present (auROC 0·87, 0·86, and 0·77, respectively), and when nearly two-thirds of subjects (62%) are not yet producing detectable viral shedding.

Interpretation

Transcriptional biomarkers accurately predict and diagnose infection across diverse viral etiologies and stages of disease, and may prove useful for guiding administration of early effective therapy, quarantine decisions, and other clinical and public health interventions in the setting of endemic and pandemic infectious disease.

Funding: US Defense Advanced Research Projects Agency

Introduction

Acute viral infections are among the most common causes of acute physician visits in the United States[1]. In a given year, influenza alone affects 5-20% of the population in the US, causes over 400,000 hospitalizations, and as many as 56,000 deaths.[2,3] Outbreaks of viral infection continue to plague modern society, including heavy resource-requiring outbreaks of measles in the developed world, global pandemics like the novel H1N1 outbreak of 2009, or the deadly epidemics of SARS and MERS-CoV.[4-6] However, molecular tools that can contribute to outbreak investigation or directing early clinical management are often lacking. Traditional pathogen-focused diagnostic modalities for viral infection (culture, serology, antigen detection, PCR) offer considerable utility but can also be slow, costly, limited in terms of breadth of pathogen detection, require an *a priori* knowledge of the pathogen to be tested, may not detect emerging strains (as with the 2009 influenza pandemic[7]), or are incapable of distinguishing between active infection and colonization, all of which can minimize the impact of their use. Therefore, there is increasing interest in host-derived biomarkers to aid in the determination of the presence and/or type of infection in at-risk hosts - from single-analyte biomarkers like procalcitonin to composite, multiplex biomarker panels such as those included in a growing number of gene expression-based studies.[8-21] However, the published works on diagnostics for naturally-acquired infection focus on identifying symptomatic subjects at the time of clinical presentation for medical care[19], which is often late in the time course of many viral diseases. Identification of infectious etiologies in earlier, even pre-symptomatic phases of illness, offers the ability to optimize and deliver timely and thus more effective therapy, refine prophylaxis decisions, and guide public health interventions such as isolation and quarantine.[13,22] However, identifying subjects who have been exposed to infectious virus but are not yet exhibiting symptoms of clinical illness is logistically challenging, resulting in a dearth of literature to address these problems.

We have previously shown that during experimental influenza infection of healthy volunteers the host genomic response is robust and detectable well before typical symptoms become apparent.[16,22,23] Other

investigators have confirmed that transcriptomic markers can be indicative of early viral infection in experimental human challenge models as well as animal models of disease.[24-27] However, the mechanism of challenge infection is contrived rather than natural, typically consists of highly egg-adapted viral strains, and the severity of clinical illness does not fully replicate that seen in naturally-acquired infection, all of which can limit the broad applicability of findings from this approach.[16,22,28-31] To date there has been no significant description of the host response to infection during the pre-symptomatic phase of naturally-occurring disease. Here we have utilized a unique index-cluster study design with a focus on serial sampling of 'real world', healthy close contacts of infected individuals to enrich for cases of naturally-occurring infection during these early, post-exposure, but pre-symptomatic time points. This unique design has permitted real-world validation of a transcriptomic signature in peripheral blood that is capable of accurately identifying exposed but apparently healthy individuals who will go on to develop symptomatic viral infection.

Methods

Surveillance Cohort

Over five academic years, we enrolled 1465 Duke University undergraduate students (age 18-24, most of whom live in dormitories on campus) in a modified index-cluster study design (Figure 1). At the time of enrollment, we collected baseline biospecimens and standardized questionnaires to ascertain demographic, behavioral, and other medical characteristics. After enrollment, participating students completed a daily, web-based survey to describe the presence and severity of eight symptoms of RTI (scored 0-4) on a daily basis (see eMethods for details). We monitored the surveys daily for a 6-point increase in a subject's cumulative daily symptom score which would trigger a sample and data collection event for a potential Index Case. Suspected ICs were then assessed for confirmation of illness and biospecimen collection. Using these sentinel cases of RTI suggestive of viral etiology we then identified and monitored a prospective observational cohort of asymptomatic but potentially exposed Close Contacts (people living in the same dormitory or identified by the IC as a Close Contact), who were then monitored and sampled for up to 5 days (the Observation Window).

Sample and data collection

Confirmed IC's provided blood and nasal swab samples at the time of illness identification. Viral etiology was assessed using a commercial multiplex PCR assay (QIAGEN ResPlex II v2·0, Luminex RVP, or Biofire FilmArray RP). Healthy CCs living in proximity to an IC provided blood and respiratory samples for up to five consecutive days and were monitored for symptomatic conversion and viral shedding.

Real-time PCR

Peripheral blood was collected in PAXgene™ Blood RNA tubes (PreAnalytiX), and total RNA extracted using the PAXgene™ Blood miRNA Kit (QIAGEN). cDNA synthesis was performed using SuperScript VILO™ Master Mix (Invitrogen) according to manufacturer's instructions. Real-time PCR was performed using custom TLDA 384-well microfluidic cards with TaqMan Gene Expression Master Mix, and run on a ViiA7 Real-Time PCR System (Applied Biosystems).

Statistical Analysis

For RT-PCR data the Cq values were transformed into normalized relative quantities using reference genes - those with the most stable combined coefficient of variation across all samples - FPGS and TRAP1 were used for the first batch, and DECR1 and TRAP1 were used for the second batch, and data was normalized as previously described.[8,9] We utilized a regularized (2-norm) logistic regression model to discriminate cases from controls (see eMethods for complete details). The data was split into training and testing sets 25 times using repeated random subsampling and each of the 25 models was trained using all timepoints. We evaluated the model's performance separately at each individual timepoint. All model analyses were implemented in Python and Tensorflow.[32]

Results

Brief Description of Study

Healthy first year students at Duke University (n=1465) were enrolled into a surveillance cohort at the beginning of each academic year. After enrollment, we electronically monitored self-reported daily symptoms throughout the duration of the academic year via an online portal. When one or more subjects indicated a change in respiratory symptoms, the sample collection protocol was initiated for individuals (Index Cases, ICs) that met the clinical case definition for acute, community-acquired RTI (see Methods), as well as for a subset of other currently healthy study participants who were in close proximity to the Index Case (Close Contacts, CCs). CCs were monitored for symptoms and serially sampled for serum, whole blood PAXgene RNA, and respiratory samples for 5 days from identification of their Index Case, regardless of symptomatology (Figure 1). This design permitted enrichment for, and collection of, samples from CCs during the timeframe between exposure (which occurred at an unknown time) and subsequent development of symptomatic disease (which occurred under observation).

Prevalence, Transmission, and Clinical Outcomes of Viral Respiratory Tract Infection

We identified 264 clinical ICs, of whom 150 had a confirmed respiratory viral etiology by multiplex PCR testing of NP samples, and 555 CCs, 19% (106) of whom developed symptomatic RTI with concomitant confirmatory viral PCR. Only 57% of the CCs were infected with the same virus as their associated IC. Nine different viral pathogens were detected, and there was marked variation in viral etiologies detected from year to year (Table 1). Infection resulted in many common symptoms of upper respiratory tract infection with clinical variation amongst viral etiologies (Figure 2). For example, symptoms were almost twice as severe in individuals with influenza infection compared to all other viruses (mean symptom score of 20 for influenza vs 13 for all others ($p=0.005$)), although all subjects in the study remained well enough to be managed in the outpatient setting.

Since the exact time of exposure/transmission during naturally-acquired infection is unknown, for analysis CC days were aligned to the time of maximal illness (day of highest symptom score) for each subject (Time "T") in order to attempt to place subjects on broadly similar time scales in terms of the host response to infection. The average total symptom score for all CCs at Time T was 14·8, although this varied by viral etiology (Figures 1,2). For each individual CC, the day before their day of maximal symptoms was termed T-minus 1 ("T-1"), 48 hours prior to symptom max was "T-2" and 72 hours prior to symptom max was time "T-3". At times prior to maximal illness the average total symptom score for CCs was 7·0 (T-1), 4·1 (T-2), and 1·7 (T-3). In our studies a daily symptom score of 6 represents mild clinical illness and was the threshold for defining a 'symptomatic' day. Thus, at days T-2 and earlier, most subjects exhibited subclinical or absent illness (65% asymptomatic at Time T-3, 32% at T-2).

An RT-PCR signature identifies symptomatic subjects with naturally-acquired viral RTI

We previously developed a host response-derived transcriptomic signature of symptomatic viral infection using microarray data[30]. However, microarray and bulk RNA sequencing platforms are impractical for rapid clinical testing. We therefore migrated our prior 'pan-viral' signature to an RT-PCR platform with potential for more direct translation to point-of-care testing [8,9]. Using sparsity-imposing techniques (see eMethods), we selected 36 pre-designed TaqMan probes representing genes comprising the acute respiratory viral signature (and normalization controls) to be used on a TaqMan Low Density Array (TLDA) platform[8]. We then utilized a regularized (2-norm) logistic regression model to determine coefficients for each gene in the signature[33], such that the output of the model is a probability that a given subject will go on to have a symptomatic, viral PCR-positive event during the observation window. The performance of the RT-PCR signature for classification of symptomatic individuals was evaluated using a repeated random subsampling validation strategy on relevant participants across all study years. Overall, the RT-PCR-based host gene expression assay distinguished symptomatic, virus-infected subjects from asymptomatic, viral PCR-negative controls with 92% accuracy (Figure 3). However, accuracy varied depending on viral etiology, ranging from 99% accuracy in influenza infection (where symptoms are

typically more severe) to 92% with Coronavirus and 81% accuracy with metapneumovirus infections (eFigure 1). Interestingly, analysis of individual gene components of the model demonstrates that many individual genes performed similar to the aggregate model across all iterations (eFigure 2-3). In fact, many individual gene targets alone had mean area under Receiver Operating Characteristic (auROC) of >0·90 at the time of maximal illness with the top performing genes at time T being IFIT3 (0·97), HERC5 (0·97), and RSAD2 (0·96)

The gene expression signature identifies naturally-acquired viral RTI during the pre-symptomatic phase.

In order to evaluate performance of the gene signature early in the course of natural infection, we selected CCs with positive microbiology and at least three days of sampling prior to the development of maximal symptoms. As noted previously, the RT-PCR gene signature correctly identified symptomatic subjects with 92% accuracy on the day of maximal symptoms. This decreased to 88% on day T-1 (24 hours before maximal symptoms), and 83% accuracy on day T-2 (48 hours before maximal symptoms) (Figure 3), although performance varies from virus to virus. Only one case of influenza infection had available pre-symptomatic samples at all times, and the signature correctly classified that individual at each timepoint (T-1, T-2, T-3, and T-4). For a fixed FPR of 0·2 (specificity 0·8), the model achieves greater sensitivity than either symptoms alone or viral PCR at all timepoints other than time T and for ICs (where symptom-based diagnosis by definition has a 100% sensitivity, eFigures 4-6). Critically, 62% of subjects who would develop proven viral RTI lacked detectable viral shedding at time T-3, and 44% were still negative for virus by routine clinical testing at day T-2, times where the gene signature outperforms the clinical standards of care - symptom evaluation and viral PCR.

Discussion

The unique design of this community study has allowed us to identify individuals (CCs) at increased risk for developing viral RTI while under observation. This approach has enabled us to demonstrate for the first time that host responses to naturally-acquired respiratory viral infection, as measured by gene expression in peripheral blood, are present well before the time of maximal illness and can be used to predict those at highest risk for developing active infection.

This study demonstrates that conserved genomic responses can be used to correctly classify individuals with a broad array of naturally-acquired respiratory viral infections well before the time when they would present for clinical evaluation, and even before detectable viral shedding begins for the majority of subjects (62%). The promise of this approach is manifested by the discriminative ability of the genomic signature from two and three days prior to maximal illness, when many individuals (65% at Time T-3, 32% at T-2) have no symptoms at all. Even the mild symptoms some subjects do have at early times are clinically vague and would be typical of seasonal allergies, mild COPD flares, or even symptoms due to sequelae of chronic smoking.[34] The potential utility of genomic analysis to classify viral infection among asymptomatic individuals or those with common, nonspecific upper respiratory symptoms is profound. That this holds true across 9 different respiratory viruses, each with its own incubation times and variable clinical progression and duration, also speaks to the potential power of this approach. Additionally, it is important to note that the signature utilized represents conserved underlying antiviral response pathways that are active, and thus discriminatory, across a wide range of illness and not just at early times. This is vital as any real-world use of such a biomarker assay would often be agnostic to where in the course of infection an individual exists at the moment of testing.

While this transcriptomic signature accurately classifies a wide spectrum of viral RTIs, it performs best in a subset of viruses including influenza and coronavirus, where it performs with a high degree of accuracy even during early and pre-symptomatic phases of disease. Influenza is one of the most important viral etiologies to identify early given its importance in pandemics where existing diagnostics may perform

poorly (especially for emerging strains as in 2009[35]), where questions of triage and quarantine are paramount, and where effective therapeutic options are readily available and most effective when given early in disease. Similarly, a number of novel highly virulent coronaviruses, including SARS-CoV and MERS-CoV, have recently arisen and driven global outbreaks, highlighting another area of need for such diagnostics.[5,36].It seems likely that our ability to accurately detect exposure to these types of emerging infections will only become more critical over time. Availability of tools that can aid in assessment of those with potential exposure, especially those that offer diagnostic utility prior to the time of detectable viral shedding, would be a valuable aid to existing epidemiologic and molecular approaches in outbreak settings.

A number of other studies have described interferon response-based transcriptomic signatures of acute respiratory infections which vary by target population, pathogens, modelling approaches, and numbers of genes required to discriminate disease states. [9,10,13-18,30] Some of this work has also been validated, combined, or expanded upon by secondary *ex vivo* analysis of publicly available data. [11,12,37] While the focused signature described here clearly represents a limited subset of all discriminating genes, some observations regarding simplified, IFN-driven signatures can be made. Our data confirm that that some genes from these prior works (such as IFI44L and IFI27[10,38]) both perform well as classifiers distinguishing between viral illness and the healthy state (median auROC = 0·92 and 0·87), being strongly upregulated in cases of viral infection. The data further suggest that a number of other single targets also perform this task well including RSAD2 (0·96), IFIT3 (0·97), and IFI44 (0·93). Based on our experience and the published literature, it seems that relatively simple classification tasks - where the biological responses are highly conserved, unique in character, and of great magnitude - may be reasonably addressed with pauci-analyte biomarker panels.[10,12,39-41] However, as complexity increases by adding more powerful interhost variability (such as immunosuppression), discriminating clinically similar groups with more varied underlying pathophysiology, or discriminating multiple clinical mimics at once,

more intricate biomarker panels will likely be required to maintain high fidelity in real-world settings.[9,14,42]

Our study has several limitations. This project was designed to validate the predictive power of a small set of genes which already had proven discriminatory capability during maximal illness, and thus was not designed to discover whether additional, untested gene sets may offer improved discriminatory performance at early times. Future work with RNASeq on whole blood, single cell sequencing, or other methods will be needed to more completely define early genomic changes in the naturally-infected host. Additionally, our patient cohort was comprised of otherwise young, healthy individuals with community-acquired viral RTI of mild to moderate severity. Therefore, application to patient populations from other age groups, those with immunologic comorbidities, or with more severe viral infections will need to be evaluated. Finally, we did not identify any confirmed infections due to bacterial or other pathogens. As a result, while these transcriptomic markers show great promise for differentiating early infection and pre-symptomatic viral exposure from noninfectious states (which it may mimic at early times), this study did not directly validate the ability of these markers to differentiate viral exposure from early forms of other types of infection[9,10,14,43]. As we move towards bringing transcriptomic biomarkers to the bedside, consideration of broad applicability and performance across a wide array of clinical settings will continue to be paramount.

We have for the first time defined the pre-symptomatic and temporal dynamics of transcriptomic biomarkers characterizing the host response to naturally-acquired viral infections in humans. Clinic-ready platforms capable of operationalizing PCR-based signatures of the size tested herein already exist, some of which are CLIA-approved with point-of-care functionality, offering a proximal pathway to clinical application of these findings. Thus, analysis of the evolution of gene expression-based biomarkers over time shows promise for driving development of diagnostics for early detection of viral exposure and infection which may prove useful for guiding administration of early effective therapy, quarantine

decisions, and other clinical and public health interventions in the setting of endemic and pandemic infectious disease.

Funding

Funding for this study was provided by the US Defense Advanced Research Projects Agency (DARPA), project # N66001-07-C-2024 and W911NF1410052. The statements and conclusions herein are those of the authors and do not reflect the position or policy of the United States Government.

Author contributions

MTM, ELT, GSG and CWW drafted the manuscript, which was critically revised by all remaining authors. MTM, BPN, TB, TV, GSG, and CWW helped conceive and implement the study. All authors helped acquire, analyze, or interpret data. Statistical analyses were performed by FJC, RH, SS, MN, and LP.

Figures

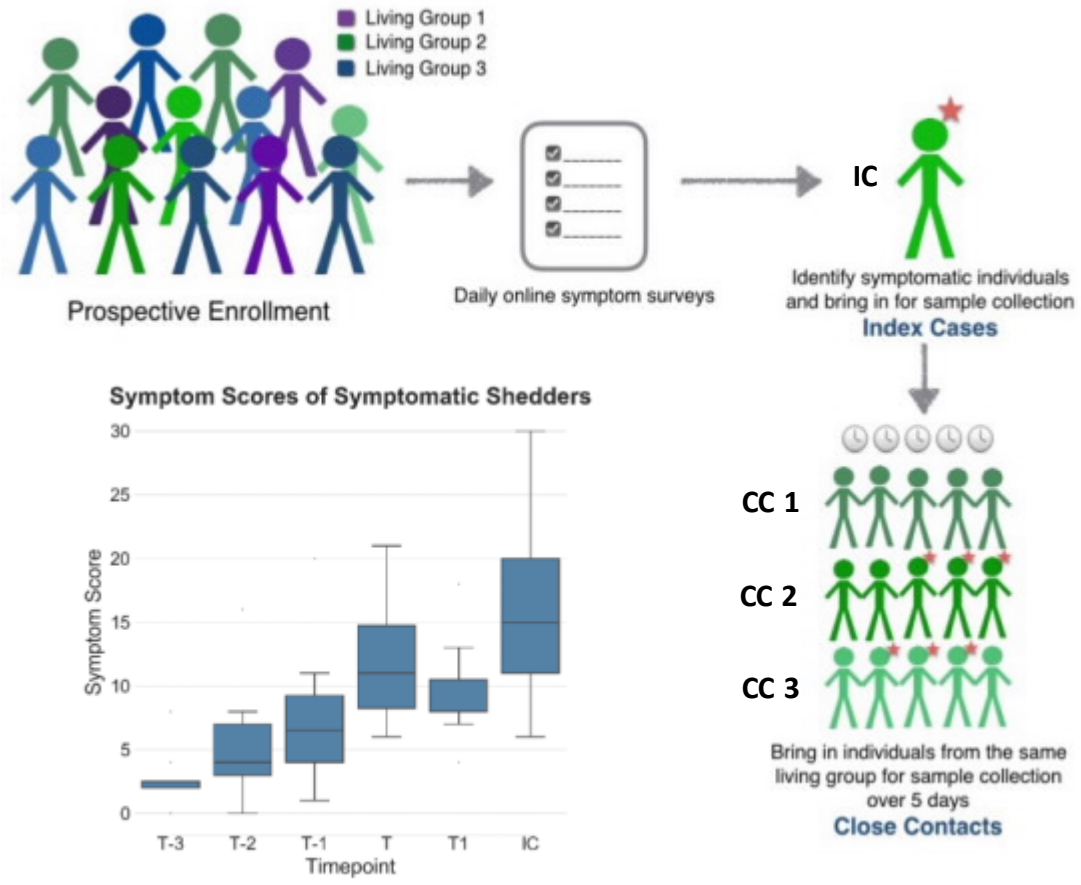

Figure 1: Study design. Students were enrolled at the beginning of the school year. Index Cases were identified when daily symptom surveys indicated potential respiratory illness. This flagged serial sampling of their Close Contacts, some of whom would also develop RTI during the 5-day observation window (red stars). This unique model permits blood sampling of some Close Contacts during early and presymptomatic phases of illness. Mean symptom scores of Close Contacts who developed PCR-proven RTI under observation are presented.

ECONOMIST
Laboratory mice

An animal model of covid-19 is now available

Another is on its way

Science & technology Jun 11th 2020 edition

Jun 11th 2020

Mice are, as it were, the guinea pigs of science. And these days they are often genetically engineered guinea pigs, to boot. The emergence of covid-19, for example, has created demand for laboratory animals that have human versions of a protein called the ace2 receptor. This molecule is the hook that sars-cov-2, the virus which causes covid-19, uses to attach itself to a cell before entering and turning that cell into a virus factory. The murine version of ace2 is, however, the wrong shape for the virus to link up with. That means unmodified mice cannot catch the infection. Hence the need for genetic engineering.

The first version of such a mouse has recently become available courtesy of the Jackson Laboratory, a not-for-profit biomedical research institution in Maine that specialises in breeding laboratory mice. By luck, the team that produced it had a head start. The original sars virus (now known as sars-cov-1), which came close to causing a pandemic in 2003, also uses ace2 as its point of entry. As a consequence Stanley Perlman and Paul McCray of the University of Iowa, who were researching sars, created a mouse with human ace2 receptors in 2007.

That project was eventually put on ice. But not before Dr Perlman had given some semen from his modified mice to the Jackson Lab. On hearing about the virus in early January researchers there, led by Cat Lutz, quickly thawed out this stored semen and started work. Five months later they have created enough of Dr Perlman’s mice to start making them widely available.

The Perlman mice are, however, not quite perfect for the job. Though their genome has had human ace2 added, the mouse variety has not been

subtracted. This means they make both versions of the protein. Also, the human version of the gene is in the wrong place in the cell nucleus. The ace2 gene's proper home is the x chromosome, one of the sex chromosomes. In Perlman mice it is elsewhere. That could change its activity.

Help may be on its way, though, from Wang Youchun at the National Institutes for Food and Drug Control in Beijing. As they describe in this week's *Cell Host & Microbe*, Dr Wang and his colleagues have excised the murine version of the ace2 gene completely from their own mice and substituted the human version in exactly the same place. They did this using crispr/Cas9 gene-editing technology, a technique unavailable to Dr Perlman back in 2007.

Spot-on

Dr Wang's initial tests of the new mouse suggest it generates ace2 receptor molecules in all of the parts of the body where researchers think the virus makes its initial attacks in human beings. They show, too, that sars-cov-2 replicates well in the animals' lungs and tracheas, and also in their digestive systems—another part of the human body that seems susceptible to sars-cov-2 infection. In the case of the digestive systems, however, the dose of virus needed to establish a gut infection is ten times that needed to start a respiratory-tract infection. Dr Wang suspects that this might be important. If alimentary-canal infection requires an equivalently large initial dose of viruses in people, as well, then that might make it easier to stop it happening in human intestines, by the practice of good food hygiene.

One further result of Dr Wang's investigation was the discovery that the virus also replicates in the brains of his mice. This suggests it may be making use of human nervous tissue for replication in a way that is not currently being detected, but is suspected by some researchers because one symptom of some people who have the illness is loss of the sense of smell.

Curiously, despite their propensity to infection by sars-cov-2, Dr Wang's mice, unlike Dr Perlman's, do not show obvious symptoms when infected. Given the apparently high rate of symptomless infection in human beings, that, too, may be a pertinent observation

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

In Brief

The COVID-19 pandemic has brought an urgent need for small animal models. Here, Sun et al. established an ACE2 humanized mouse by CRISPR/Cas9 knockin technology. These hACE2 mice are susceptible to SARS-CoV-2 infection upon intranasal inoculation, and the resulting pulmonary infection and pathological changes resemble those observed in COVID-19 patients.

Highlights

- Human ACE2 knockin mice were generated by using CRISPR/Cas9 technology
- SARS-CoV-2 leads to robust replication in lung, trachea, and brain
- SARS-CoV-2 causes interstitial pneumonia and elevated cytokine in aged hACE2 mice
- High dose of SARS-CoV-2 can establish infection via intragastric route in hACE2 mice

SUMMARY

Since December 2019, a novel coronavirus SARS-CoV-2 has emerged and rapidly spread throughout the world, resulting in a global public health emergency. The lack of vaccine and antivirals has brought an urgent need for an animal model. Human angiotensin-converting enzyme II (ACE2)has been identified as a functional receptor for SARS-CoV-2. In this study, we generated a mouse model expressing human ACE2 (hACE2)by using CRISPR/Cas9 knockin technology. In comparison with wild-type C57BL/6 mice, both young and aged hACE2 mice sustained high viral loads in lung, trachea, and brain upon intranasal infection. Although fatalities were not observed, interstitial pneumonia and elevated cytokines were seen in SARS-CoV-2 infected-aged hACE2 mice. Interestingly, intragastric inoculation of SARS-CoV-2 was seen to cause productive infection and lead to pulmonary pathological changes in hACE2 mice. Overall, this animal model described here provides a useful tool for studying SARS-CoV-2 transmission and pathogenesis and evaluating COVID-19 vaccines and therapeutics.

INTRODUCTION

Coronaviruses (CoVs) are a group of enveloped, positive-sensed, single-stranded RNA viruses within the subfamily *Coronavirinae* in the family *Coronaviridae* and the order *Nidovirales*. All coronaviruses can be divided into four genera: *alphacoronaviruses*, *betacoronaviruses*, *gammacoronaviruses*, and *deltacoronaviruses*. During the past decades, two highly transmissible and pathogenic CoVs, Severe Acute Respiratory Syndrome coronavirus (SARS-CoV)and Middle East respiratory syndrome coronavirus (MERS-CoV), have emerged in humans and caused global concerns. SARS-CoV was first recorded in Guandong, China, in December 2002 and rapidly spread to five continents (Peiris et al., 2003). The SARS-CoV outbreak ultimately caused 8,437 infections and 813 deaths worldwide, according to the World Health Organization (WHO). MERS-CoV first emerged in the Arabian Peninsula in 2012 (Zaki et al., 2012) and has caused 1,728 confirmed cases including 624 deaths in Middle Eastern countries, the United Kingdom, and South Korea, according to WHO. Both SARS-CoV and MERS-CoV likely originated from wild animals and are prone to cause lethal pneumonia in humans (Cui et al., 2019). There is currently no vaccine or specific antiviral drugs to prevent or treat their infections and transmission in humans.

In December 2019, a cluster of pneumonia patients with links to Huanan seafood market, and with potential animal contact, was reported in Wuhan, Hubei Province, China (Li et al., 2020; Zhou et al., 2020b; Zhu et al., 2020). Subsequently, the disease rapidly spread throughout the world to become a pandemic. The etiologic agent of the disease was then identified as a novel coronavirus by several independent groups (Wu et al., 2020; Zhou, et al., 2020b) and has now been named as SARS-CoV-2 because of its close relationship to SARS-CoV. The disease was subsequently termed coronavirus disease 19 (COVID-19). The most common clinical manifestations of the patients are fever, cough, shortness of breath, and fatigue, and some patients

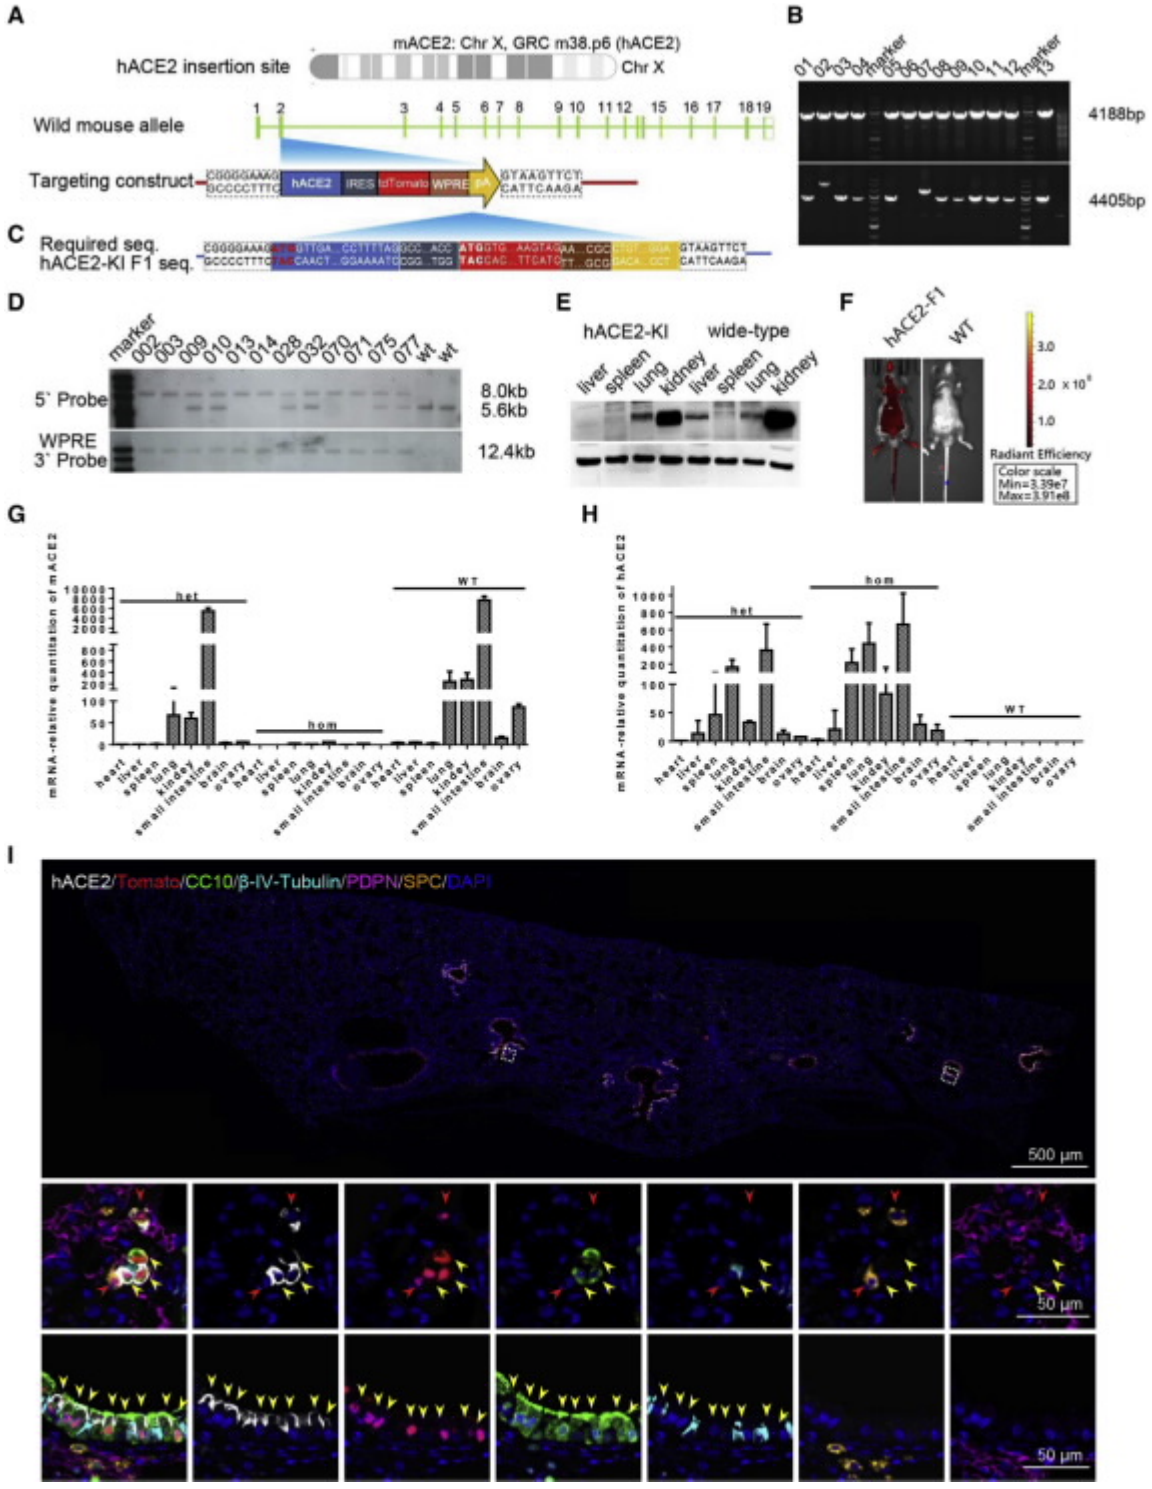

Figure 1. Construction and Characterization of hACE2 Humanized Mouse

(A) The hACE2 gene were inserted into exon2, the first coding exon, of mouse *ACE2* locating in chromosome X GRC m38.p6.

(B) The mice produced both 4,188 bp and 4,405 bp PCR amplicons that were identified as founder. Ten representative positive PCR results were shown.

(C) $F1^{+}$ mice were sequenced to confirm the right insertion. The head and tail bases of each part were aligned with expected one.

(D) Two endonucleases, *NcoI* and *StuI*, were used to digest DNA for identifying the right insertion and no random recombinant. The expected sizes of WT and gene-targeted bands were 5.6 kb and 8.0 kb, respectively. Heterozygous female mice had both bands, whereas homozygous male mice had only one 8.0 kb band. All the mice detected with WPRE probe had only one 12.4 kb band, indicating no random insertion.

(legend continued on next page)

Pleasecite this article in press as: Sun et al., A Mouse Model of SARS-CoV-2 Infection and Pathogenesis,Cell Host & Microbe (2020),https://doi.org/10.1016/j.chom.2020.05.020

have radiographic ground-glass lung changes and finally died from acute respiratory distress syndrome (ARDS)(Huang et al., 2020; Wang et al., 2020a).The WHO declared COVID-19 as a public health emergency of international concern on January 30, 2020.

Full genome-sequencing analysis has classified SARS-CoV-2 as a new member of the betacoronavirus genus, which includes SARS-CoV, MERS-CoV, and bat SARS-related coronaviruses (SARSr-CoV). SARS-CoV-2 has 82% nucleotide identity with SARS-CoV and 89% identify with a bat CoV, RaTG13, discovered in a cave of Yunnan, China, in 2013 (Lu et al., 2020; Zhou et al., 2020b). Like other CoVs, the genome RNA of SARS-CoV-2 encodes a non-structural replicase polyprotein and structural proteins, including spike (S), envelope (E), membrane (M), and nucleocapsid (N) proteins. The S protein of CoVs constitutes the spike on the virion surface and plays a vital role in viral binding, fusion, and entry as well as the induction of neutralizing antibody and T cell responses (Du et al., 2009). More importantly, several pioneering investigations have demonstrated that both SARS-CoV-2 and SARS-CoV utilize the same cellular receptor, human angiotensin-converting enzyme 2 (hACE2) to enter cells (Walls et al., 2020; Li et al., 2003; Zhou et al., 2020b). The crystal structure of the SARS-CoV-2 S protein receptor-binding domain (RBD) binding to hACE2 has been resolved, with an estimated 10- to 20-fold higher affinity toward hACE2 than SARS-CoV has (Lan et al., 2020; Shang et al., 2020). These findings pave the way for potent intervention strategies targeting RBD/hACE2 interactions. Exogenous hACE2 has been demonstrated to inhibit SARS-CoV-2 infection in cell cultures (Monteil et al., 2020; Ou et al., 2020), and several monoclonal antibodies targeting RBDs of SARS-CoV or SARS-CoV-2 are being tested with *in vitro* cultures (Walls et al., 2020). At present, no vaccine or antiviral drugs have been tested effectively in animal models.

Small animal models that reproduce the clinical course and pathology observed in COVID-19 patients are highly needed. In the present study, we generated a stable humanized ACE2 mice by using CRISPR/Cas9 knockin technology, replacing the endogenous mouse ACE2 (mACE2) with the human ACE2. Further characterization demonstrated that these humanized mice are highly susceptible to SARS-CoV-2 infection via intranasal inoculation, and the viral kinetics and pathological outcomes seen in the SARS-CoV-2-infected animals recapitulated the major finding from COVID-19 patients. Additionally, intragastric injection of SARS-CoV-2 could also establish infection and cause lung injury in the humanized ACE2 mice. This unique mouse model described here provides a useful tool for studying SARS-CoV-2 infection and transmission, as well as evaluating SARS-CoV-2 vaccines and therapeutics.

RESULTS

An hACE2 Humanized Mouse Was Established by Using CRISPR/Cas9

Previous studies have demonstrated that transgenic mice expressing human ACE2 became highly susceptible to SARS-CoV infection (McCray et al., 2007; Menachery et al., 2016; Netland et al., 2008; Tseng et al., 2007; Yang et al., 2007). Here, we aimed to establish a humanized ACE2 mouse by using CRISPR/Cas9 knockin technology. As shown in Figure 1A, the full cDNAs of hACE2 were inserted into Exon 2 (Figure 1A), the first coding exon, of the m*Ace2* gene located in GRC m38.p6 sites on chromosome X. This disrupted the m*Ace2* gene and terminated its expression. The *tdTomato* gene was inserted downstream of *hAce2* with an internal ribosome entry site (IRES),allowing co-expression of hACE2 and tdTomato. A woodchuck hepatitis virus posttranscriptional regulatory element (WPRE) and poly (A) sequence were added to enhance mRNA stability and translation efficiency. This targeting strategy allowed an intrinsic expression profile of *hACE2* under control of m*Ace2* promoter. Along with subgenomic RNA (sgRNA) and Cas9 mRNA, the targeting construct was injected into 370 zygotes of C57BL/6 mice. Successful insertion in 10 of 46 offspring (21.74%) was confirmed by PCR screen (Figure 1B); then three founders were backcrossed with C57BL/6 mice, and 37 $F1^{+}$ offspring were screened. The targeting results of 12 positive F1 mice were further confirmed by sequencing (Figure 1C) and Southern blotting (Figure 1D). As expected, no animals had random insertion as demonstrated by the WPRE internal probe (Figure 1D). Importantly, western blotting results showed that hACE2 expression was strong in lung and kidney but very weak in spleen and liver, which displayed a similar expression pattern of mACE2 protein in wild-type (WT) animals (Figure 1E). More importantly, the m*Ace2* gene was not detected by PCR in homozygous hACE2 mice and decreased largely in heterozygous mice (Figure 1F), whereas significant hACE2 expression was detected in lung, small intestine, spleen, and kidney from both hACE2 heterozygous and homozygous mice but not in the WT mice (Figure 1G). Profiting from the co-expression design, the rough global expression patterns of hACE2 were examined visually via bioluminescent imaging in the hACE2 mice (Figure 1H). Furthermore, immunofluorescence staining of the lung sections from the homozygous mice showed that hACE2, as well as tdTomato, were predominantly expressed in the $CC10^{+}$ Clara cells along the airway, as well as a small population of surfactant protein C positive (SPC^{+}) alveolar type II cells (Figure 1I). Thus, we established a homozygous mouse model that stably expresses hACE2 under the control of mACE2 promoter, which were termed hACE2-KI/NIFDC mice (abbreviated to hACE2 mice) accordingly.

(E) western blotting results of tissue distribution of hACE2 in humanized mice and WT mice. The primary antibody used here cross-reacted with both mACE2 and hACE2.

(F and G) The expression pattern of m*ACE2* (F) and h*ACE2* (G) in hACE2 heterozygous and homozygous and WT mice (n = 3) detected by real-time qPCR.

(H) Bioluminescence imaging (BLI) of homozygous mice and WT mice.

(I) Immunofluorescence staining analysis for the hAEC2-expressed cell types in lung of hACE2 mice. Paraffin lung sections were stained for hACE2 (white), tdTomato (red) CC10 (green), b-IV-Tubulin (cyan), PDPN (magenta), and SPC (gold). Two white frames were magnified below. Solid red and yellow arrows indicated the $ACE2^{+}$/tdTomato $^{+}$/SPC^{+} cells and $ACE2^{+}$/tdTomato $^{+}$/$CC10^{+}$ cells, respectively.

(D)Immunofluorescence staining analysis for the infected cells in lung. Cell markers for hACE2 (white), CC10 (red), b-IV-Tubulin (cyan), PDPN (magenta), and SPC (gold). White frame was magnified on the right. Solid yellow arrows indicate the SARS-CoV-2^+/hACE2^+/CC10^+ cells.

The hACE2 Mice Are Susceptible to Intranasal Infection of SARS-CoV-2

To further characterize the susceptibility of hACE2 mice to SARS-CoV-2 infection, groups of young (4.5-week-old) and aged (30-week-old) hACE2 mice were intranasally infected with 4 3 10^5 plaque-forming units (PFU) of SARS-CoV-2, and WT C57BL/6 mice that received the same dose of viral challenge were set as control (Figure 2A). All animals were monitored daily for clinical symptoms and body-weight changes and were sacrificed on day 6 post-infection (dpi). None of the inoculated animals displayed obvious clinical symptoms, and only the aged hACE2 mice lost 10% of their weight at 3 dpi and then recovered (Figure S1). As shown in Figure 2B, robust viral RNA replication was seen in lung, trachea, and brain tissues from both young and aged hACE2 mice, whereas no detectable viral RNA was seen in spleen, kidney, liver, intestine, and serum. Especially, infectious SARS-CoV-2 were successfully rescued from lung samples by using plaque assay. As expected, no viral RNAs were detected in any tested tissues or serum from the WT C57BL/6 mice (Figure 2). Interestingly, we also detected high levels of viral RNAs (2.9 3 10^5 copies/g) in feces of aged hACE2 mice. Further immunostaining of mouse lung section

Pleasecite this article in press as: Sun et al., A Mouse Model of SARS-CoV-2Infection and Pathogenesis,Cell Host & Microbe (2020),https://doi.org/10.1016/j.chom.2020.05.020

showed that robust viral S protein was detected along the airway in both young and aged hACE2 mice, and bare viral protein was detected in the SARS-CoV-2-inoculated WT mice (Figure 2C). To confirm the major target cells of SARS-CoV-2 in our model, we further stained the lung section from the infected hACE2 mice with different cell markers, including Clara cells (marked by Clara cell 10 kDa protein/CC10), ciliated cells (marked by b-IV-tubulin), alveolar type 1 cells (AT1, marked by podoplanin/PDPN), and alveolar type 2 cells (AT2, marked by surfactant protein C/SPC), as well as viral S protein and hACE2. As shown in Figure 2D, SARS-CoV-2 S protein predominantly colocalized with CC10 and hACE2, indicating that $CC10^+$ Clara cells are the major target cells of SARS-CoV-2 along the airway in our model. Additionally, immunostaining of brain sections from the infected hACE2 mice showed that robust viral S protein expression could also be detected in neuron, astrocyte, and microglial cells (Figure S2). Together, these results indicate that the hACE2 mice are highly susceptible to intranasal infection of SARS-CoV-2 in comparison with WT mice, with sustained robust viral RNA replication in lung Clara cells as well as in trachea and brain.

hACE2 Mice Developed Interstitial Pneumonia upon SARS-CoV-2 Infection

To check whether the SARS-CoV-2-infected hACE2 mice produced similar pathological features as those observed in COVID-19 patients, histopathological examination, immunohistochemistry (IHC), and immunofluorescence staining were performed in lung sections from SARS-CoV-2-infected animals. In comparison with SARS-CoV-2-infected WT mice, H&E staining showed that both young and aged hACE2 mice developed interstitial pneumonia characterized with inflammatory cell infiltration, alveolar septal thickening, and distinctive vascular system injury. More lesions of alveolar epithelial cells and focal hemorrhage were observed in the aged mice (Figure 3A). In comparison with WT mice, IHC staining analysis showed SARS-CoV-2 infection induced more neutrophil (Neu^+) and macrophage ($CD68^+$) inf ltration in the aged hACE2 mice (Figures 3B and 3C). Additionally, immunofluorescence co-staining showed SARS-CoV-2 directly infected $CD68^+$ macrophages in lung, resulting in significant apoptosis ($C\text{-}Casp3^+$) in the aged hACE2 mice (Figure 3D). Most importantly, Luminex cytokine analysis showed that SARS-CoV-2 infection led to elevated cytokine production including Eotaxin, G-CSF, IFN-g, IL-9, and MIP-1b in aged hACE2 mice, but it had a weaker response in young mice (Figure 3E; Table S1). Thus, the hACE2 mice not only sustained viral replication but also developed pulmonary pathology upon SARS-CoV-2 infection.

SARS-CoV-2 Established Productive Infection via Intragastric Route in hACE2 Mice

SARS-CoV-2 mainly transmits via droplets and close contact among humans. However, some patients with COVID-19 infection had gastrointestinal symptoms such as diarrhea, abdominal pain, and vomiting (Lin et al., 2020; Wang et al., 2020a), and viral RNAs have been detected in feces of COVID-19 patients (Cai et al., 2020; Xu et al., 2020), highlighting the possibility of fecal-oral transmission of SARS-CoV-2 (Yeo et al., 2020). Here, we sought to investigate whether SARS-CoV-2 could establish productive infection via intragastric route in hACE2 mice. After intragastric administration of SARS-CoV-2, all animals were subjected to daily monitoring and tissue processing on 5 dpi (Figure 4A). Although no clinical signs were seen in the three inoculated hACE2 mice, high levels of viral RNA were detected in trachea (2.9×10^6 copies/g) and lung (3.2×10^6 copies/g) of two animals (Figure 4B), which was comparable to that in animals infected via intranasal route. Importantly, the expression of SARS-CoV-2 S protein was also detected along the lung airway in the infected hACE2 mice (Figure 4C). In addition, interstitial inflammation was observed with alveolar septal thickening in the intagastric SARS-CoV-2-infected hACE2 mice (Figure 4D). Overall, our results demonstrated that intragastric administration of SARS-CoV-2 could also establish productive infection and lead to pulmonary pathological changes in hACE2 mice.

DISCUSSION

In the present study, we generated a stable humanized mouse strain in which hACE2 expression is under the control of IRES in fusion with the tdTomato reporter gene. Further characterization demonstrated that the expression of mACE2 was completely replaced by hACE2 in the homozygous mice with peak hACE2 expression in lung and small intestine (Figure 1). Previously, several hACE2 transgenic mice have been generated with different strategies and used for modeling SARS-CoV infection (McCray et al., 2007; Tseng et al., 2007). Generally, the pulmonary pathology caused by SARS-CoV in transgenic mice correlated with the level of hACE2 expression in lung. Thus, such transgenic mouse has been explored to mimic SARS-CoV-2 infection (Bao et al., 2020). When compared with such transgenic mouse model, our hACE2 mouse model has several advantages. First, the h*Ace2* gene was inserted at GRC m38.p6 sites on chromosome X to replace m*Ace2*, and there is no endogenous mACE2 expression in homozygous hACE2 mice. Because transgene insertion occurs randomly, the integrity of the landing genes would probably be affected. Second, the tissue distribution of hACE2 in our mouse model matches the clinical findings from COVID-19 patients, and high levels of hACE2 expression were detected in lung (Figure 1E). Interestingly, recent analysis based on single-cell sequencing results from human tissues showed that kidney, heart, esophagus, bladder, and ileum also represent tissues of high abundance (Qi et al., 2020; Zou et al., 2020), whereas liver, spleen, small intestine, ovary, and brain are the h*ACE2*-abundant tissues in our model (Figure 1H); this inconsistency between human and mice deserves further investigation. Third, the introduction of tdTomato gene allows real-time monitoring of hACE2 expression. All these ideal physiological features, stable inheritances, and phenotypes of hACE2 mice prompted us to test their application in reproducing SARS-CoV-2 infection.

(D) Immunofluorescence staining analysis for paraffin lung sections with markers for CD68 (green), cleaved-caspase 3 (C-Casp3, magenta), and SARS-CoV-2 S protein (red). White frame was magnified on the right. Solid yellow arrows indicated the $SARS\text{-}CoV\text{-}2^+/CD68^+/C\text{-}Casp3^+$ cells.
(E) Cytokine production in serum of SARS-CoV-2-infected mice.

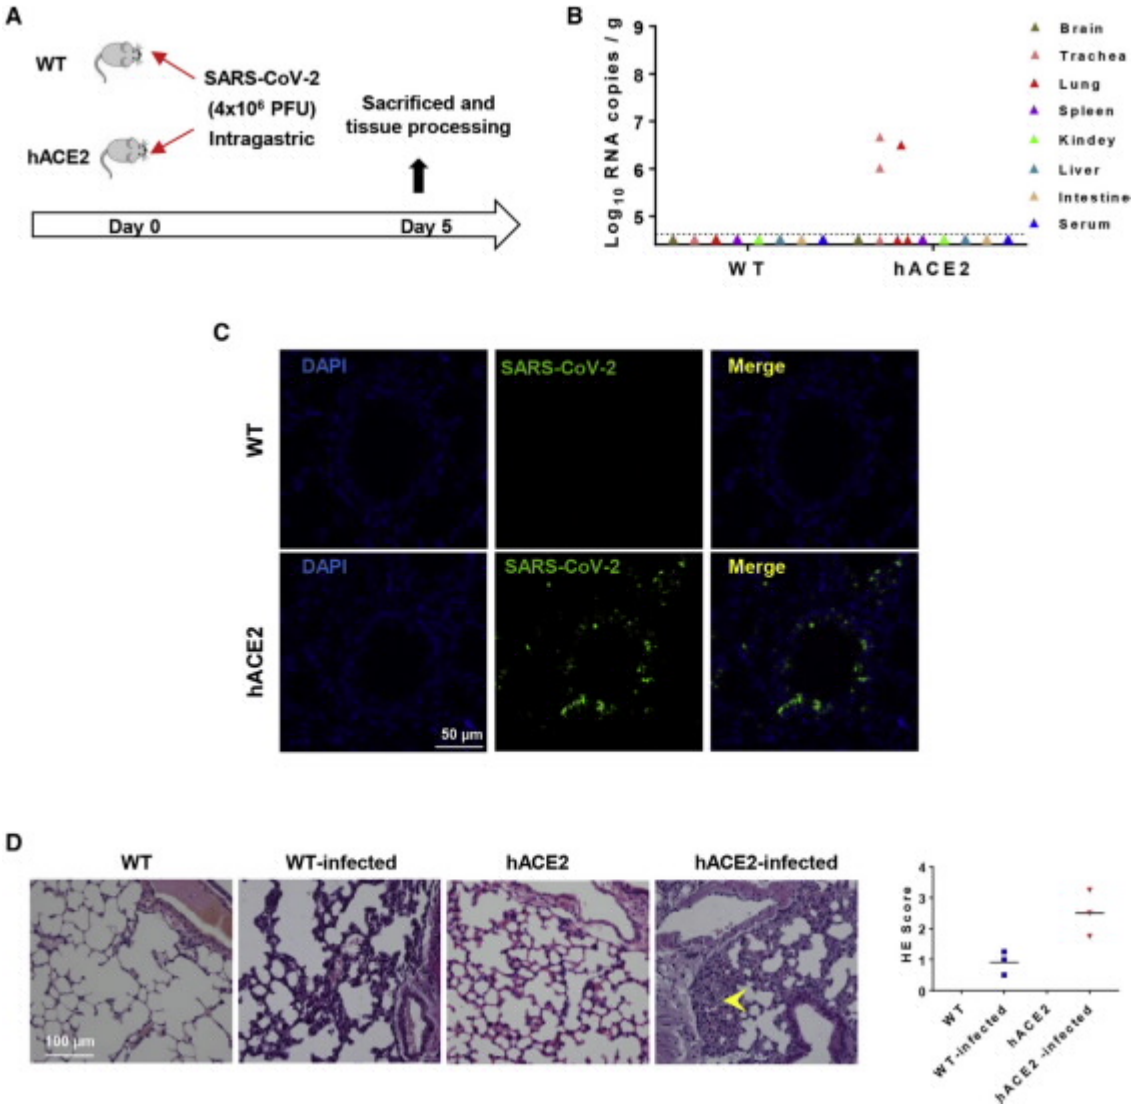

Figure 4. Intragastric Infection with SARS-CoV-2 in hACE2 Mice

(A) WT C57BL/6 mice and hACE2 mice (n = 3) at 4.5 weeks old were infected with 4 3 10^6 PFU of SARS-CoV-2 through intragastric administration, and all mice were sacrificed on 5 dpi for main tissues and serum collection.

(B) Tissue distribution of SARS-CoV-2 viral RNAs. Each tissue and serum were collected and viral RNA copies analysis by real-time qPCR.

(C) Immunofluorescence staining of mouse lung sections for SARS-CoV-2 S protein (green) and DAPI (blue).

(D) Histopathological analysis of mouse lung sections. Alveolar septal thickening was indicated with yellow arrow. Right panel, semiquantitative analysis of the H&E-stained lung sections.

Not surprisingly, our challenge experiment of SARS-CoV-2 clearly demonstrated that these hACE2 mice are highly susceptible to SARS-CoV-2 infection via intranasal inoculation, and 4 3 10^5 PFU of SARS-CoV-2 readily led to robust viral replication in respiratory tracts (lung and trachea) as well as in brain. The peaked viral RNA loads in lung reached 10^8 copies/g, which is much higher than that in hACE2 transgenic mice (Bao et al., 2020). The presence of viral RNAs in brain was somewhat unexpected, because few COVID-19 patients developed neurological systems (Chen et al., 2020). Previous findings from a SARS-CoV-infected transgenic model also confirmed viral tropism to brain (McCray et al., 2007), which is consistent with our findings. The underlying mechanism through which SARS-CoV or SARS-CoV-2 invade the brain and the correlation to disease severity remain to be determined. Further characterization demonstrated that $CC10^+$ Clara cells along the airway are the major target cells of SARS-CoV-2 (Figure 2D) in our model. Specific protease in Clara cells, like tryptase Clara, might contribute to the efficient cleavage of S protein to enhance viral entry into cells. Additionally, $CD68^+$ macrophages in pulmonary alveolus are also infected with SARS-CoV-2, resulting in severe cell apoptosis (Figure 3D). Interestingly, a significant population of cells that do not express hACE2 were also infected with SARS-CoV-2 (Figure 2D). How SARS-CoV-2 invades these cells also deserves further investigation. Overall, our result provides the

Pleasecite this article in press as: Sun et al., A Mouse Model of SARS-CoV-2 Infection and Pathogenesis, Cell Host & Microbe (2020), https://doi.org/10.1016/j.chom.2020.05.020

first line of evidence showing the specific major target cells of SARS-CoV-2 in mouse lung.

Most importantly, all hACE2 mice intranasally challenged with SARS-CoV-2 developed interstitial pneumonia characterized with inflammatory cell infiltration, alveolar septal thickening, and distinctive vascular system injury, which recapitulated the clinical features in most COVID-19 patients. Early epidemiological findings have suggested that advanced age resulted in increased mortality of COVID-19 patients (Chen et al., 2020; Yang et al., 2020; Zhou et al., 2020a), and our results from the hACE2 model reflect this finding well. The aged hACE2 mice (30 weeks old) lost weight upon SARS-CoV-2 infection, whereas young hACE2 mice (4.5 weeks old) as well as WT mice maintained their body weight increase during the observation period (Figure S1). Remarkably, although both young and aged mice sustained similar viral replication in lung, more severe pathological changes as well as increased cytokine response were seen in the aged hACE2 mice (Figure 3). These unique features in aged hACE2 mice resembling clinical findings (Wang et al., 2020b) highlight the potential application in different settings. It should be noted that no clinical symptoms or mortality was observed in our model, and other animal models that can recapitulate severe or lethal disease of COVID-19 should be warranted in the future.

There are several lines of evidence that support potential fecal-oral transmission of SARS-CoV-2. First, gastrointestinal symptoms were seen in many COVID-19 patients (Jin et al., 2020; Lin et al., 2020), and viral shedding in feces have been well reported. Second, ACE2 was found to be highly expressed in gastrointestinal epithelial cells, and *in vitro* studies also indicated SARS-CoV-2 can infect multiple cells from gastrointestinal tracts. Third, experience from SARS and MERS supported that human CoVs maintained their viability in environmental conditions essential for fecal-oral transmission (Chan et al., 2011; van Doremalen et al., 2013). Recent data from SARS-CoV-2 revealed similar stability to SARS-CoV, suggesting similar transmission routes are plausible (van Doremalen et al., 2020). Our results from hACE2 mouse model provide evidence supporting this hypothesis. Upon intranasal infection, viral RNA shading was also confirmed in feces from the hACE2 mice (data not shown). Due to facility limitation, we were not able to collect and quantitate feces samples from each individual animal. Importantly, SARS-CoV-2 given intragastrically caused productive infection in the respiratory tracts of hACE2 mice, as demonstrated by the presence of high level of viral RNAs and active viral protein expression (Figures 4B and 4C). Our preliminary results show, however, that intragastric infection of SARS-CoV is not as efficient as intranasal infection: the challenge dose of intragastric model is 10-fold higher than the intranasal model; however, pulmonary infection was only detected in one of three animals tested (Figure 4B); the viral RNA loads and protein expression were also lower than that in the intranasal model. Finally, whether intragastric infection of SARS-CoV-2 is actually occurring in clinical setting in humans remains to be confirmed. The underlying mechanism through which SARS-CoV-2 survives the gastrointestinal environment and finally invades the respiratory tracts in our mouse model warrants further investigation.

In summary, our results show that hACE2 mice are susceptible to intranasal and intragastric infection of SARS-CoV-2, and robust viral replication was seen in the pulmonary Clara cells and macrophages. Especially, the pathological changes observed in the aged hACE2 mice more closely resemble those observed in COVID-19 patients. Thus, the use of hACE2 mice described in our manuscript provides a small animal model for studying the transmission and pathogenesis of SARS-CoV-2 and for the understanding of unexpected clinical manifestations of SARS-CoV-2 infection in humans. This model will also be valuable for testing vaccines and therapeutics to combat SARS-CoV-2.

STAR+ METHODS

Detailed methods are provided in the online version of this paper and include the following:

- KEY RESOURCESTABLE
- RESOURCEAVAILABILITY
  - Lead Contact
  - Materials Availability
  - Data and Code Availability
- EXPERIMENTALMODEL AND SUBJECT DETAILS
  - Experimental Animals
  - Cell Lines
  - SARS-CoV-2 Propagation and Titeration
- METHOD DETAILS
  - Generation of hACE2 Mice
  - RNA Extraction and Real-Time Quantitative PCR
  - Western Blotting
  - Mouse Challenge Experiments
  - Measurement of Viral RNA Loads
  - Histopathological Analysis
  - Multiplex Immunofluorescent Assay
  - Immunohistochemistry
  - Cytokine Assay
- QUANTIFICATIONAND STATISTICALANALYSIS

This study did not generate any unique datasets or code.

EXPERIMENTAL MODEL AND SUBJECT DETAILS

Experimental Animals

Groups of 4.5 weeks and 30 weeks old hACE2 and wild-type C57BL/6 female mice for SARS-CoV-2 infection were maintained in animal biosafety level 3 (ABSL3) containment laboratory of AMMS at 23 C. All animals were allowed free access to water and diet and provided with a 12 h light/dark cycle. All animal experiments were approved by the Experimental Animal Committee of NIFDC (approval number: 2018-B-002) and Laboratory Animal Center, AMMS (approval number: IACUC-DWZX-2020-001).

Cell Lines

Vero Cells for SARS-CoV-2 propagation and titeration were maintained in DMEM medium (GIBCO) supplemented with 2% FBS (PAN Biotech), 1% Penecillin Streptomycin (GIBCO) and 1% HEPES (GIBCO) at 37 C.

SARS-CoV-2 Propagation and Titeration

SARS-CoV-2 strain BetaCoV/wuhan/AMMS01/2020 was originally isolated by CFQ's lab, AMMS, from a patient returning from Wuhan. The virus was amplified on Vero cells and titerated by standard plaque forming assay. Briefly, Vero cells in 12-well plates were infected with a 10-fold serial dilution of viruses. The plates were incubated at 37 C for 1 h and cells were overlaid with 1% low-melting point agarose (Promega) in DMEM containing 2% FBS. After further incubation at 37 C for 2 days, the cells were fixed with 4% formaldehyde and stained with 0.2% crystal violet to visualize the plaques. All experiments involving infectious SARS-CoV-2 were performed in biosafety level 3 (BSL3) containment laboratory in AMMS.

METHOD DETAILS

Generation of hACE2 Mice

To construct the targeting vector, cDNAs encoding hACE2 linked to the red fluorescent protein tdTomato by an IRES sequence, flowed with WPRE and ployA, was inserted into the first coding exon of m*ACE2* by homologous recombination. The expression

Pleasecite this article in press as: Sun et al., A Mouse Model of SARS-CoV-2 Infection and Pathogenesis,Cell Host & Microbe (2020),https://doi.org/10.1016/j.chom.2020.05.020

CellPress

of inserted h*ACE2* and tdTomato gene were driven by the mouse mACE2 promoter. The specific targeting sgRNA (5^0-gaaagatgtc-cagctcctcctgg-3 ^{0}) and Cas9 mRNA were microinjected into C57BL/6 zygotes, which were subsequently implanted into pseudo-pregnant mice. F0 offspring were genotyped using two pairs of primers L-GT-F1, L-GT-R1 and R-GT-F1, R-GT-R1 (Table S2). The expected size of amplicons was 4188 bp and 4405 bp, respectively. Genotype-positive founders were backcrossed with C57BL/6 mice to produce generation F1. DNA samples of F1-positive mice were subjected to Southern blotting to confirm off-targeting (by WPRE 3^0 probe) and correct insertion (by 5^0 probe). Two endonucleases, *NcoI* (Thermo) and *StuI* (Thermo), were used to digest DNA for identifying the right insertion and no random recombinant.

RNA Extraction and Real-Time Quantitative PCR

To confirm the expression of hACE2 and mACE2 in humanized mice, tissues from 4.5 weeks old and 30 weeks old mice were dissected, immediately immersed in RNAlater (Invitrogen) stabilization reagent and stored at 80 C. Total RNA was extracted from individual tissues using TRIzol and quantified using a spectrophotometer. Real-time quantitative PCR (RT-qPCR) was performed using a reverse transcription (RT)-PCR kit (Takara) containing SYBR green dye. Each reaction was performed in triplicate. Relative expression level of hACE2 and mACE2 was determined using primer pairs ehACE2 F1, ehACE2 R1 and emACE2-F1, emACE2-R1 (Table S2). Amplicons were normalized to expression of GAPDH (glyceraldehyde 3-phosphate dehydrogenase).

Western Blotting

Mouse tissues were homogenized in Cell lysis buffer for Western and IP (20 mM Tris-HCl, pH 7.5, containing 150 mM NaCl, 100 mM EDTA, and 1% Triton X-100) supplemented with Phenylmethanesulfonyl fluoride (PMSF) (Beyotime). The denatured protein lysates were separated using 10% SDS-PAGE gels. After transfer, ACE2 antibody (Huabio, 1:1000) and GAPDH antibody (Abcam, 1:1000) were added, followed by horseradish peroxidase (HRP)-conjugated anti-mouse and rabbit IgG (Abcam, 1:2,000). The Pierce ECL Western Blotting Substrate (Thermo) was used for development. Bioluminescence imaging (BLI) Mice were anesthetized by intraperitoneal injection of pelltobarbitalum natricum (Sigma, 240 mg/kg body weight). tdTomato bioluminescence imaging was performed with IVIS-Lumina II imaging system (Xenogen). The relative intensities were presented as pseudocolored images as photon flux in photon (p/s/cm^2/sr).

Mouse Challenge Experiments

For intranasal infection, wild-type C57BL/6 mice, young (4.5 weeks old) and aged (30 weeks old) hACE2 mice were anesthetized with sodium pentobarbital at a dose of 50 mg/kg though intraperitoneal route, and then intranasally infected with 4 3 10^5 pfu of SARS-CoV-2, respectively. For intragastric infection, all animals were fed with 4 3 10^6 pfu of SARS-CoV-2 (in 200 ml) via intragastric gavage using a ball-tipped 6-gauge feeding needle. Mice were then weighed and monitored daily, and sacrificed on day 5 or 6 post infection for serum collection and tissue processing.

Measurement of Viral RNA Loads

Viral RNA in each sample was extracted with an RNeasy Mini kit (QIAGEN) according to the protocols. The viral RNA quantification was performed by RT-qPCR targeting the S gene of SARS-CoV-2. RT-qPCR was performed using One Step PrimeScript RT-PCR Kit (Takara) with the following primers and probes: CoV-F3, CoV-R3 and CoV-P3 (Table S2).

Histopathological Analysis

Mouse tissues were excised and fixed with 10% neutral buffered formaline, dehydrated and embedded in paraffin. Each embedded tissue was sectioned into 4 mm thickness longitudinal sections. Three tissue sections derived from different parts of each tissue were stained with hematoxylin and eosin (H&E) according to standard procedures for examination by light microscopy. The degree of lung damage under the light microscopy was assessed by the degeneration of alveolar epithelial cells, the expansion of parenchymal wall, edema, hemorrhage, and inflammatory cells infiltration. The semiquantitative assessment were performed as reported previously and described briefly as the following (Haagmans et al., 2004; van den Brand et al., 2010). For the degree of degeneration of alveolar epithelial cells, we scored 0 when no alveolar epithelial cells degeneration was observed, scored 1 when the alveolar epithelial cells degeneration was less than 10%, and scored 2 when the degeneration was 10%–50%. For the degree parenchymal wall expansion, we scored 0 when no parenchymal wall expanded, scored 1 when the area of the expanded parenchymal wall was less than 10% but no focal fusion was observed, and scored 2 when the area was 10%–50% but no focal fusion was observed. For the degree of edema, we scored 0 when no edema was observed, scored 1 when the area of edema was less than 10%, and scored 2 when the area was 10%–50%. For the degree of inflammatory cells infiltration, we scored 0 when no inflammatory cell infiltration, scored 1 when occasional infiltration of single inflammatory cell was visible, and scored 2 when focal infiltration of inflammatory cells was visible. The lesion of lung was observed by an experienced experimental pathologist who focuses on the pathogenesis study of virus infection. The cumulative scores of the severity of the three sections provided the total score per animal, and the average of the three animals was taken as the total score for that group.

Multiplex Immunofluorescent Assay

3 mM paraffin sections were deparaffinised in xylene and rehydrated in a series of graded alcohols. Antigen retrievals were performed in citrate buffer (pH6) with a microwave for 20 min at 95 C followed by a 20 min cool down at room temperature. Multiplex

Pleasecite this article in press as: Sun et al., A Mouse Model of SARS-CoV-2 Infection and Pathogenesis, Cell Host & Microbe (2020), https://doi.org/10.1016/j.chom.2020.05.020

fluorescence labeling was performed using TSA-dendron-fluorophores with NEON 7-color Allround Discovery Kit for FFPE (Histova Biotechnology). Briefly, endogenous peroxidase was quenched in 3% H_2O_2 for 20 min, followed by blocking reagent for 30 min at room temperature. Primary antibody was incubated for 2 h in a humidified chamber at 37 C, followed by detection using the HRP-conjugated secondary antibody and TSA-dendronfluorophores. Afterward, the primary and secondary antibodies were thoroughly eliminated by heating the slides in retrieval/elution buffer (Abcracker) for 10 s at 95 C using microwave. In a serial fashion, each antigen was labeled by distinct fluorophores. Multiplex antibody panels applied in this study are: ACE2 (Abcam, 1:200), SARS-CoV Spike (Sinobiological, 1:2000); b-IV-tubulin (Abcam, 1:1000), CC10 (Millipore, 1:500), Podoplanin (Sinobiological, 1:1000), SPC (Abcam, 1:500), CD68 (Abcam, 1:1000), Cleaved Caspase-3 (C-Casp3,CST, 1:200). After all the antibodies were detected sequentially, the slices were imaged using the confocal laser scanning microscopy platform Zeiss LSM880.

Immunohistochemistry

Paraffin-embedded tissues were sectioned at a thickness of 4 mm for immunohistochemistry staining. Sections were deparaffinized and rehydrated, endogenous peroxidases were inactivated with methanol containing 0.3% hydrogen peroxide for 30 min. Antigen retrieval was performed with citrate buffer (pH6) at 95 C for 30 min. After incubation in blocking solution (5% normal goat serum) for 10 min at room temperature, the slides were incubated with Neutrophil Marker antibody (Santa Cruz Biotechnology, 1:200) and rabbit anti- CD68 polyclonal antibody (Abcam, 1:800) overnight at 4 C. After three washes, the sections were incubated with biotinylated anti-IgG at 37 C for 1 h, followed by Streptavidin-peroxidase conjugate (Zhongshan Biotechnology). Immunoreactivity was detected using 3, 3^0diaminobenzidine and the sections were counterstained with hematoxylin for observation by microscopy. To measure the macrophage and neutrophil infiltration semiquantitatively, 10 arbitrarily chosen 40 3 (neutrophil) or 100 3 (macrophage) objective fields of the lung parenchyma in each lung section were examined by light microscopy for the presence of neutrophils or macrophages. This assessment was performed in a blinded fashion. The cumulative scores for each animal were expressed as the number of positive fields per 100 fields (%).

Cytokine Assay

A total of 25 mL serum from each mouse was adopt for cytokine analysis with Bio-Plex Pro Mouse Cytokine Grp I Panel 23-Plex (BIO-RAD) according to the manufacturer's instructions. The data were collected on Luminex 200 and analyzed by Luminex PONENT (Thermo Fisher).

QUANTIFICATION AND STATISTICAL ANALYSIS

Statistical analyses were carried out using Prism software (GraphPad Prism 7.0). Data of semiquantitative analysis of the H&E-stained lung sections are presented as mean, and the statistical significance between the WT and hACE2 mice was assessed by Mann Whitney test of Student's t tests. The other data are presented as mean ± sem, and the statistical significance of IHC staining analysis between the WT and hACE2 mice was assessed by unpaired Student's t tests. Before the statistical significance was assessed, Shapiro-Wilk normality test was used to determine whether the data met normal distribution. Statistical details of experiments and animal replication numbers (n) are stated in the relevant figure legends and method details. A p value less than 0.05 is considered statistically significant.

Abstract

Objective: To provide an update on key safety metrics after transfusion of convalescent plasma in hospitalized COVID-19 patients, having previously demonstrated safety in 5,000 hospitalized patients.

Patients and Methods: From April 3 to June 2, 2020, the US FDA Expanded Access Program for COVID-19 convalescent plasma transfused a convenience sample of 20,000 hospitalized patients with COVID-19 convalescent plasma.

Results: The incidence of all serious adverse events was low; these included transfusion reactions (*n*=89; <1%), thromboembolic or thrombotic events (*n*=87; <1%), and cardiac events (*n*=680, ~3%). Notably, the vast majority of the thromboembolic or thrombotic events (*n*=55) and cardiac events (*n*=562) were judged to be unrelated to the plasma transfusion *per se*. The seven-day mortality rate was 8.6% (8.2%, 9.0%), and was higher among more critically-ill patients relative to less ill counterparts, including patients admitted to the intensive care unit vs. not admitted (10.5% vs. 6.0%), mechanically ventilated vs. not ventilated (12.1% vs. 6.2%), and with septic shock or multiple organ dysfunction/failure vs. those without dysfunction/failure (14.0% vs. 7.6%).

Conclusion: These updated data provide robust evidence that transfusion of convalescent plasma is safe in hospitalized patients with COVID-19, and support the notion that earlier administration of plasma within the clinical course of COVID-19 is more likely to reduce mortality.

Introduction

Coronavirus disease 2019 (COVID-19) continues to be a world-wide pandemic, and the number of deaths attributed to COVID-19 in the US at the time of this writing (~110,000) exceed that of any other nation in the world[1]. The overall case fatality rate for diagnosed COVID-19 ranges from about 4% to greater than 50%[2-6], with higher mortality rates observed in more critically ill patients. In response to the COVID-19 outbreak in the US and reportedly high case-fatality rates, the US Food and Drug Administration (FDA) in collaboration with the Mayo Clinic and national blood banking community developed a national Expanded Access Program (EAP) to collect and distribute COVID-19 convalescent plasma. Historical precedent indicates that human convalescent plasma is a viable option for mitigation and treatment of COVID-19[7, 8]. The premise of human convalescent plasma therapy is that plasma of recently-infected and currently-recovered COVID-19 patients contains anti-viral antibodies and other bioactive elements that can be used to treat patients with COVID-19. Convalescent plasma has a strong historical record of some efficacy during acute infectious pandemics[7, 9]. As recently summarized[7], convalescent plasma represents a promising treatment strategy with strong historical precedence, biological plausibility, and limited barriers for rapid development and deployment of this investigational therapy.

Recently, our investigation of key safety indicators in 5,000 patients transfused with COVID-19 convalescent plasma demonstrated an incidence of transfusion-related serious adverse events (SAE) of less than 1% and a mortality rate of 14.9%[10]. These early indicators suggest that transfusion of convalescent plasma is safe in hospitalized adults with COVID-19. Because an additional 15,000 hospitalized patients have been transfused with convalescent plasma under the purview of the EAP, a subsequent safety update is warranted. These new data may provide novel insights into the incidence of emerging adverse events associated with COVID-19, including thromboembolic[11, 12] and cardiac events[13]. Further, these data may provide better understanding of the clinical features contributing to the seven-day mortality rate among transfused patients with COVID-19.

Thus, we analyzed key safety metrics following transfusion of convalescent plasma in 20,000 hospitalized adults with severe or life-threatening COVID-19. These data represent a deeper and larger analysis relative to our initial report of 5,000 transfused patients under the EAP. We hypothesized that both the seven-day mortality rate and the number of serious adverse events related to the transfusion of convalescent plasma would continue to be low. Additionally, we hypothesized that higher mortality rates would be observed in more critically-ill patients.

Methods

As described previously[10], the program is a FDA-initiated, national, multicenter, open-label EAP in hospitalized adults that had (or were judged to have high risk of progression to) severe or life-threatening COVID-19. The US COVID-19 Convalescent Plasma EAP was conducted as a pragmatic treatment study, empowering local acute care facilities to use the emerging best evidence for care while allowing for administration of convalescent plasma. It was conducted within a modified clinical trial framework: All participants were allowed access to convalescent plasma per the discretion of the treating physician/ principal investigator given the nature of the

Journal Pre-Proof

pandemic and the lack of any effective therapies at the time of design. It was the intent *a priori* to create a control comparator group to determine potential efficacy using patients hospitalized with COVID-19 infections during the same time period. This decision was made after collaboration with the US FDA. This report is only on safety of the convalescent plasma for the initial 20,000 subjects. A future publication will discuss potential efficacy.

Between the date of initial Institutional Review Board (IRB) approval of the EAP (April 1st 2020) and June 11 2020, more than 20,000 patients were transfused with COVID-19 convalescent plasma, **Figure 1**. The Mayo Clinic IRB served as the central IRB and empaneled an independent Data and Safety Monitoring Board (DSMB) to oversee the safety analyses. Written informed consent was obtained from the participant or a legally-authorized representative prior to enrollment, or with use of emergency consent procedures recommended by the US FDA and approved by the Mayo Clinic IRB. The protocol was modified to allow inclusion of incarcerated participants once it became clear that this group was especially vulnerable and at risk.

Participants. Eligible patients were aged 18 years or older, hospitalized with a laboratory confirmed diagnosis of infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), and had (or were judged by a healthcare provider to be at high risk of progression to) severe or life-threatening COVID-19. The clinical symptoms defining severe or life-threatening COVID-19 are outlined in **Table 1**.

Procedures. As described previously[10], ABO-compatible COVID-19 convalescent plasma had no minimum neutralizing-antibody titer level and was donated by recently-recovered, COVID-19 survivors. Approximately 200 – 500 mL of convalescent plasma was administered intravenously according to institutional transfusion guidelines. Web-based, standardized data reporting surveys were completed to assess clinical status of patients at regular time intervals (four-hours and seven-days after convalescent plasma transfusion) using the Research Electronic Data Capture system (REDCap, v.9.1.15 Vanderbilt University, Nashville, TN)[14, 15].

Serious Adverse Event Reporting. Separate REDCap data collection forms were used to report each SAE that occurred within seven days following the convalescent plasma transfusion. Two primary data capture forms were used to report SAEs: a transfusion form and a SAE form. Serious adverse events which occurred during the time window beginning at the onset of the plasma transfusion and including the four-hour time-period following the transfusion were reported on the transfusion form. By definition, the primary SAEs related to transfusion (including transfusion associated circulatory overload [TACO] and transfusion-related acute lung injury [TRALI]) occurred within six hours of the transfusion. All transfusion-related SAEs occurred within four hours of the transfusion and thus, were all reported on the transfusion form. All other SAEs were reported on the SAE form. The attribution scale used by treating physicians for evaluating SAE relatedness to convalescent plasma transfusion included unrelated, possibility related, probably related, or definitely related. All transfusion-related SAEs were independently adjudicated over the course of the study by the IND Sponsor (MJJ) and trained designee (AMK) using the National

Journal Pre-Proof

 © 2020 Mayo Foundation for Medical Education and Research.

Healthcare Safety Network Biovigilance Component Hemovigilance Module Surveillance Protocol as a conceptual framework[16].

Statistics. Data presented in this safety report may undergo additional data quality control measures as the study continues. The cumulative incidence of each of a series of SAEs was summarized using a point estimate and 95% score confidence interval (CI), as outlined in **Table 2**. To assess mortality, time (in days) between transfusion and mortality was examined using the Kaplan Meier product limit estimator. Participants were censored at their last known vital status and all reported mortalities through seven days were used to estimate the survival function. Data were censored at 0.25 days for patients who did not have follow-up beyond the initial report at four hours post transfusion at time of the analysis. For patients who expired within 24 hours, a survival time of 0.5 days was assigned. Precise time of day for key events was not recorded in the data collection system; thus, these imprecise time estimates were used. The point estimate and 95% CI for mortality were estimated at day seven based on the estimated survival function. All analyses and graphics were produced with R version 3.6.2 (Vienna, Austria).

Results

From April 3 to June 11, 2020, a total of 30,117 patients were enrolled in the EAP and a total of 21,987 enrolled patients received a COVID-19 convalescent plasma transfusion (**Figure 1**). Data from the first 5,000 transfused patients have been reported previously[10]. This update reports data from 20,000 patients including the initial 5,000 and subsequent 15,000 transfused patients. By June 2, 2020, a total of 20,000 patients had been transfused with COVID-19 convalescent plasma, thus, 7-day mortality data is presented for all 20,000 patients.

Patient Characteristics. Key patient characteristics are presented in **Table 1**. The patient enrollment indicates a wide age range of hospitalized patients with COVID-19, consistent with prior CDC published data[17]. The study population was diverse, with 20% of patients being African American, nearly 35% Hispanic and 5% Asian. The recruitment of a diverse population has improved over the time course of the study. Nearly 40% of our subjects were women. Most of the patients enrolled were overweight or obese, consistent with early reports of risk[18]. Nearly all of the patients had severe or life-threatening COVID-19, by design of the investigational protocol. Nearly two-thirds had respiratory failure as well as dyspnea as a primary symptom. Most were hypoxic and nearly half had pulmonary infiltrates. At least one-third had severe respiratory compromise. Equal numbers appeared to have multi-organ failure or septic shock, but these were a small percentage of the total population.

Serious Adverse Events. Key serious adverse events (SAE) related to the transfusion of convalescent plasma are reported in **Table 2**. Our report is not a comprehensive summary of all risks associated with hospitalization of COVID-19 but did assume that convalescent plasma potentially could cause life-threatening cardiac events and thrombotic events, so these were collected with an underlying assumption of attribution. Within four hours of completion of the COVID-19 convalescent plasma transfusion, 146 SAEs classified as transfusion reactions were reported (<1% of all

Journal Pre-Proof

 © 2020 Mayo Foundation for Medical Education and Research.

transfusions). Of these SAEs, there were 83 non-mortality events reported, with 37 reports of transfusion-associated circulatory overload (TACO), 20 reports of transfusion-related acute lung injury (TRALI), and 26 reports of severe allergic transfusion reaction. Of the SAEs reported within four hours of plasma transfusion, there were 63 mortalities (0.3% of all transfusions) and 13 of these mortalities were judged as related (possibly, *n*=12; probably, *n*=1; definitely, *n*=0) to the transfusion of COVID-19 convalescent plasma.

Within seven days of completion of the COVID-19 convalescent plasma transfusion, 1,136 other SAEs were reported. Of these SAEs, 87 thromboembolic or thrombotic events were reported, 406 sustained hypotensive events requiring intravenous pressor support were reported, and 643 patients suffered a cardiac event. Notably, the vast majority of the thromboembolic or thrombotic complications (*n*=55) and cardiac events (*n*=569) were judged to be unrelated to the plasma transfusion.

Seven-day Mortality. Seven-day mortality rates stratified by key clinical status indicators are presented in **Table 2**. Over the first seven days after the COVID-19 convalescent plasma transfusion, a total of 1,711 deaths were observed. The overall seven-day mortality rate was 8.56% (95% CI: 8.18%, 8.95%), **Figure 2**. The seven-day mortality rate was higher among the sickest of our critically-ill patients, including patients *admitted* to the intensive care unit (ICU) vs. not admitted to the ICU (10.5% vs. 6.0%), mechanically ventilated vs. not mechanically ventilated (12.1% vs. 6.2%), and those with septic shock or multiple organ dysfunction/failure vs. without septic shock or multiple organ dysfunction/failure (14.0% vs. 7.6%).

Discussion

In this safety update of the US Convalescent Plasma Expanded Access Program of 20,000 hospitalized patients in the US with severe or life-threatening COVID-19, the overall frequency of SAEs classified as attributable or likely secondary to convalescent plasma transfusion continued to be low (<1% of all transfusions) and the seven-day mortality rate in this extremely high risk cohort was 8.6%. Despite the potential risks associated with plasma transfusion in critically-ill patients[16, 19], these data provide continued optimism for the safety of COVID-19 convalescent plasma.

Emerging COVID-19 Clinical Complications. Although thrombotic and thromboembolic events are emerging clinical complications of COVID-19[11, 12, 20], our data demonstrate a low rate (<1%) of these events within the first seven days after COVID-19 convalescent plasma transfusion. Cardiac events represent another novel clinical concern of COVID-19[13], particularly in the context of open-label use of experimental treatments such as hydroxychloroquine [21]. In aggregate, adverse cardiac events occurred in ~3% of patients transfused with COVID-19 convalescent plasma. The vast majority of adverse cardiac events of interest were deemed unrelated to the plasma transfusion (88%) by the treating physicians. Collectively, these data suggest that transfusion of COVID-19 convalescent plasma *per se* does not demonstrably increase the risk of adverse cardiac events. We note that the incidence of TRALI and TACO reported in this study of 0.18% and 0.10%, respectively is significantly lower than those reported in previous studies, which ranged from 5-8% and 1-4%, respectively[22],

Journal Pre-Proof

 © 2020 Mayo Foundation for Medical Education and Research.

despite the fact that many of the COVID-19 patients receiving plasma were critically ill and likely at risk for clinical conditions which mimic TACO.

Limitations. Although this study was not designed to evaluate efficacy of convalescent plasma, we note with optimism that after 20,000 transfused patients the seven-day mortality rate (8.6%) is lower than the mortality rate observed in the first 5,000 transfused patients (12.0%), **Table 2**. While the mortality rate has fallen (**Figure 2**), we note that the clinical characteristics of the transfused patients in the EAP have shifted toward less critically-ill patients and lower proportions of apparent "rescue therapy". No therapy has been introduced into clinical use during this time period which reduces (to our knowledge) mortality in hospitalized patients with COVID-19. We postulate that several potential explanations may explain the observed decline in mortality. The ability and success of the US Healthcare community at managing hospitalized COVID-19 patients is likely improving. Second, the blood banking communities have enhanced the availability of convalescent plasma such that more patients received plasma earlier in their hospital course compared to the initial cohort of 5000 participants. The more expeditious delivery of plasma to patients reflects improved logistics for the collection, deployment and use of convalescent plasma, and a larger COVID-19 recovered population that may be potential plasma donors. In this regard it is remarkable that there was no system in place for convalescent plasma use in March 2020 and yet within months the nation is now able to meet most of the demand, despite complex logistics[23]. Given the historical experience that antibody therapies are most effective when given earlier and that convalescent plasma has reduced mortality in prior epidemics[7], the lower mortality in more recently treated patients would be consistent with greater efficacy from earlier use. Finally, as recovered COVID-19 patients were more quickly recruited for convalescent plasma donation, the plasma may contain higher levels of neutralizing antibodies or other bioactive elements. However, additional data are required to evaluate these potential explanations for the observed trends.

Conclusion

Data from the first 20,000 patients transfused with COVID-19 convalescent plasma demonstrate that use of convalescent plasma is safe and carries no excess risk of complications. Indeed, convalescent plasma may be associated with improvement in survival, however, this report does not establish efficacy. Additionally, our data demonstrate that the US Health care system is improving in its care for those hospitalized for COVID-19 including managing those critically-ill patients with multiple comorbidities included in these analyses. Overall, the mortality observed has fallen with our observations and continued use of convalescent plasma. Given the accelerating deployment of this therapy, these emerging data provide early safety indicators of convalescent plasma for COVID-19 treatment and suggest research should shift focus from safety toward determining the efficacy of convalescent plasma.

Table 2. SAE Characteristics in Patients Transfused with COVID-19 Convalescent Plasma. (*n* = 20,000)			
Serious Adverse Events (SAE): Transfusion Reactions	**Reported**	**Related**	**Estimate[a] (95% CI)**
Mortality within four hours of transfusion	63	13	0.06% (0.04%, 0.11%)
Transfusion-Associated Circulatory Overload (TACO)	37	37	0.18% (0.13%, 0.25%)
Transfusion-Related Acute Lung Injury (TRALI)	20	20	0.10% (0.06%, 0.15%)
Severe allergic transfusion reaction	26	26	0.13% (0.09%, 0.19%)
Seven-day SAE Reports			
Thrombolic or thromboembolic complication	87	32	0.16% (0.11%, 0.23%)
Sustained Hypotension[b]	406	54	0.27% (0.21%, 0.35%)
Cardiac Events[c]	643	74	0.37% (0.29%, 0.46%)
Seven Day Mortality	**Reported**		**Estimate (95% CI)**
Overall (5,000)[d]	602		12.04% (11.17%, 12.97%)
Overall (20,000)	1,711		8.56% (8.18%, 8.95%)
Clinical Status			
No ICU admission (*n* = 8,323)	501		6.02% (5.53%, 6.55%)
ICU admission (*n* = 11,468)	1,202		10.48% (9.93%, 11.06%)
No Mechanical Ventilation (*n* = 12,147)	749		6.17% (5.75%, 6.61%)
Mechanical Ventilation (*n* = 6,337)	767		12.10% (11.32%, 12.93%)
Clinical Symptoms			
No MOF or Septic Shock (*n* = 17,081)	1,302		7.62% (7.23%, 8.03%)
MOF or Septic Shock (*n* = 2,919)	409		14.01% (12.80%, 15.32%)

Abbreviations: ICU, intensive care unit; MOF, multiple organ failure or dysfunction.

[a] Point estimate of *related* serious adverse event incidence relative to 20,000 transfusions.
[b] Sustained hypotension included events requiring intravenous pressor support.
[c] Cardiac events included ventricular or atrial fibrillation or arrhythmia requiring treatment, and cardiac arrest.
[d] These data were previously published[10] and reported for comparison with current data.

Journal Pre-Proof

Figure 1. Participation in the US COVID-19 Convalescent Plasma Expanded Access Program (EAP) including data extracted on June 11, 2020. Choropleth map displaying the number of cumulatively enrolled patients in the EAP within each state, with lower enrollment values displayed in a lighter hue of green and higher enrollment values displayed in a darker hue of green. Registered acute care facilities are represented as filled yellow circles, with larger circles indicating greater number of registered facilities within the metropolitan area of a city. The choropleth map does not display data from US territories, including registered facilities in Puerto Rico, Guam and Northern Mariana Islands.

© 2020 Mayo Foundation for Medical Education and Research.

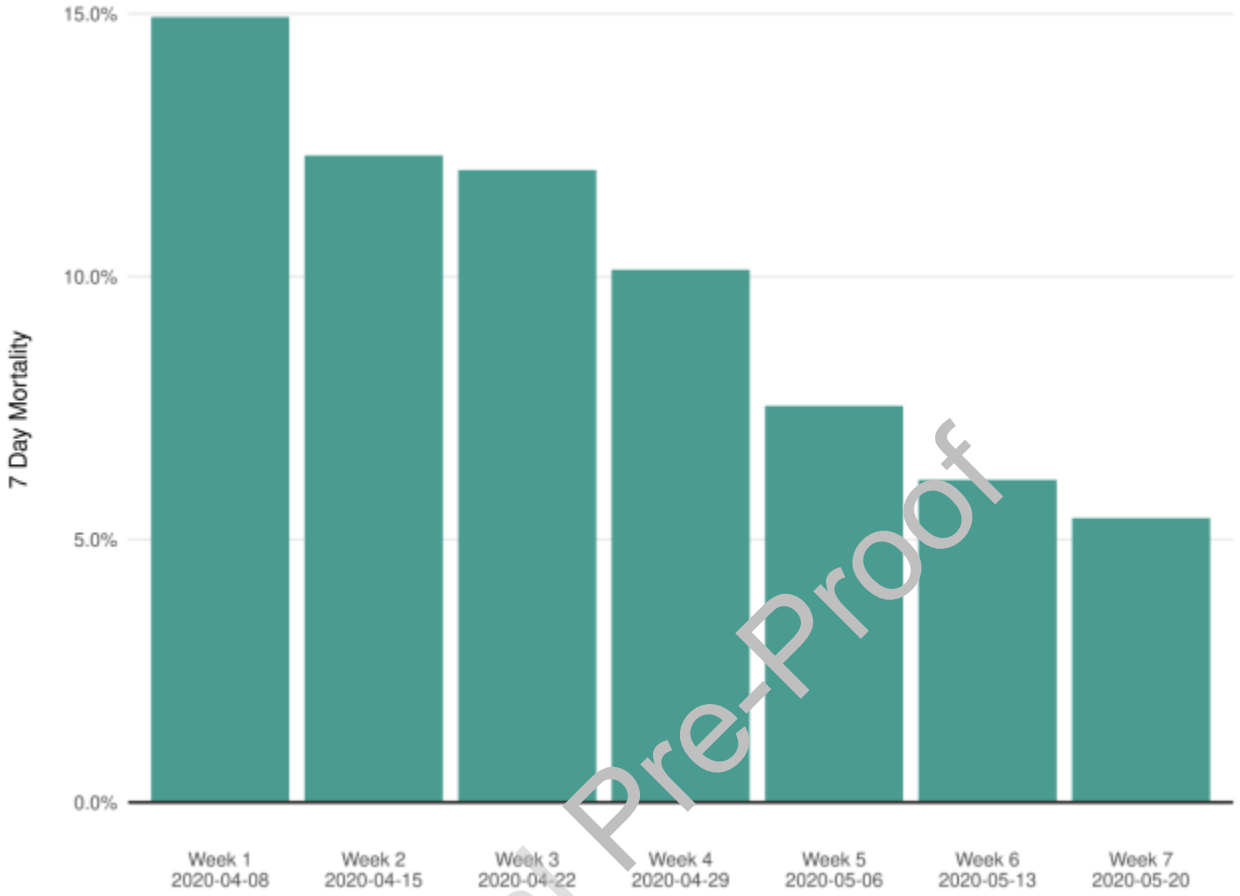

Figure 2. Seven-day Mortality rate in patients transfused with COVID-19 convalescent plasma stratified by week since initiation of the US COVID-19 Convalescent Plasma Expanded Access Program (EAP). Each green bar indicates the seven-day mortality rate stratified by the patients enrolled during a given week since the initiation of the EAP.

COVID-19 Convalescent Plasma Project (CCPP19)

"No one cares how much you know until they know how much you care……"

MINUTES

Date: June 26, 2020	**3:00-4:00 PM (CDT)**	**Location: Teleconference**
Facilitators:	Michael Joyner, MD Arturo Casadevall, MD, PhD Nigel Paneth, MD, MPH	Mayo Clinic-Rochester Johns Hopkins Michigan State University
	Safety Update: COVID-19 Convalescent Plasma in 20,000 Hospitalized Patients | Mayo Proceedings: Joyner et al Safety Update Formatted Pr	**Resources:** Website: https://CCPP19.org (barebones for now with protocols and IND available for download) Facebook: https://www.facebook.com/CCPP19/ Twitter (CCPP19): https://twitter.com/CCPP_19 Twitter (Pre-Prints Page): https://twitter.com/SARSCoV192
Note Takers:	• Chad Wiggins, PhD • Stephen Klassen, PhD • Jonathan (Jack) Senefeld, PhD • John-Roger Shepherd, MD	

Introduction — **Arturo Casadevall, M.D., Ph.D.**

- The FDA commissioner testified before congress that convalescent plasma is safe and the signals of efficacy are encouraging
- The second publication from the Mayo Clinic EAP of 20,000 transfused patients indicates that convalescent plasma is safe and there is no evidence of antibody-dependent enhancement (ADE) of COVID-19 (see PDF attached above)

Blood Bank and Transfusion Medicine — **Evan Bloch, M.D.**

- Convalescent plasma is being shared across state lines and amongst blood centers

BARDA Funding — **Ruchika Goel M.D., and Dan Waxman, M.D.**

- BARDA funding is confirmed and will provide an additional $202 million in funding to support ~200,000 additional units of convalescent plasma
- This new BARDA funding will support convalescent plasma that is collected and stockpiled

Clinical Trials — **Shmuel Shoham, M.D.**

- Several positive reports on the regulatory and funding front
  - The FDA has loosened exclusion criteria for randomized-controlled trials, enabling the recruitment of individuals with some co-morbidities
  - Federal funding has increased to allow a larger number of sites to participate in randomized-controlled trials
  - There is nation-wide participation in randomized-controlled trials including sites in Houston, southern California, and Alabama etc. which are currently experiencing COVID-19 spikes

Pediatrics — **Flor Munoz-Rivas, M.D.**

- Convalescent plasma is being used in pediatric cases, although sporadically — most sites have transfused <10 patients
- There are seven sites participating in the Children's National Hospital convalescent plasma study registry
- The main concern in pediatric trials continues to be the lack of funding

Communications — **Nigel Paneth, M.D., M.P.H.**

- There are 20+ sites participating in the Mayo Clinic EAP treatment-control study that will investigate the efficacy of convalescent plasma. For those participating or interested, please contact us if you have any questions about the process including questions about uploading de-identified data from your site to Mayo

	• servers (paneth@msu.edu)
Final Word	**Arturo Casadevall, M.D., Ph.D.**

	• *There is a constellation of information suggesting convalescent plasma has potential to be a promising therapy for COVID-19*
	  ○ New BARDA funding for convalescent plasma collection ($202 million)
	  ○ The Department of Defense has funded sites to investigate the efficacy of convalescent plasma for outpatient treatment
	  ○ New loosened restrictions on exclusion criteria for RCT enrollment
	  ○ The FDA commissioner provided very encouraging support for convalescent plasma in his Congressional testimony

Board on Health Sciences Policy

Host Genomics Research and Data Collection Efforts Related to COVID-19

Joint Meeting
of the
Roundtable on Genomics and Precision Health
and the
Standing Committee on Emerging Infectious Diseases and 21st Century Health Threats

A VIRTUAL MEETING
July 1, 2020
1:00 PM – 2:45 PM ET
Zoom Link: https://nasem.zoom.us/j/95540901323

Aims for the meeting:

- To understand the scientific challenges that the field of genomics is facing
  - What has been the effect of the pandemic on genomics research and data collection and sharing? What is the role of the genomics community during the pandemic? What research is underway? What research still needs to be done?
  - What gaps and challenges in the field is this crisis highlighting? What unique contributions of the field are not being leveraged effectively?
- To explore innovative approaches to overcoming those challenges
  - What new approaches are you using to solve a problem? Could these be applied to the field of genomics? Are there lessons from genomics that are being used in light of the pandemic? What are the opportunities for connecting efforts and data sets (e.g. across institutions, genotype and phenotype data)?
- To discuss opportunities for the Genomics Roundtable and for the Standing Committee on Emerging Infectious Diseases and 21st Century Health Threats to facilitate progress
  - Are there opportunities for the Roundtable and Standing Committee to act that align with strategic priorities?
  - Are the Roundtable and Standing Committee uniquely positioned to address specific challenges?

AGENDA:

1:00 p.m. ET Welcoming Remarks

GEOFFREY GINSBURG, *Roundtable Co-Chair*
Director, Duke Center for Applied Genomics & Precision Medicine
Professor, Medicine, Pathology, and Biomedical Engineering
Duke University Medical Center

MICHELLE PENNY, *Roundtable Co-Chair*
Vice President and Head of Genomics
Goldfinch Bio

HARVEY FINEBERG, *Standing Committee Chair*
President
Gordon and Betty Moore Foundation

1:15 p.m. **An Introduction to the Host Genetics of COVID-19**

MAXIMILIAN MUENKE
CEO
American College of Medical Genetics and Genomics (ACMG)

Understanding Host Genetics and Genomics Related to COVID-19 and Opportunities for Forming Data Sharing COVID-19 Communities

1:25 p.m. SHARON TERRY
Founder and CEO
Genetic Alliance

1:35 p.m. JOYCE TUNG
Vice President, Research
23andMe

1:45 p.m. GEOFFREY GINSBURG, *Roundtable Co-Chair*
Director, Duke Center for Applied Genomics & Precision Medicine
Professor, Medicine, Pathology, and Biomedical Engineering
Duke University Medical Center

1:55 p.m. **Discussion with Roundtable and Standing Committee Members**

2:30 p.m. **Next Steps**

Questions:

- What challenges or gaps were exposed today?
- Is there an area that should be incorporated into the Roundtable's strategic planning or the Standing Committee's work?

GEOFFREY GINSBURG, *Roundtable Co-Chair*
Director, Duke Center for Applied Genomics & Precision Medicine
Professor, Medicine, Pathology, and Biomedical Engineering
Duke University Medical Center

MICHELLE PENNY, *Roundtable Co-Chair*
Vice President and Head of Genomics
Goldfinch Bio

HARVEY FINEBERG, *Standing Committee Chair*
President
Gordon and Betty Moore Foundation

2:45 p.m. Adjourn

ROUNDTABLE AND STANDING COMMITTEE INFORMATION

The National Academies of
SCIENCES • ENGINEERING • MEDICINE

Roundtable on GENOMICS and PRECISION HEALTH

The sequencing of the human genome is rapidly opening new doors to research and progress in biology, medicine, and health care. At the same time, these developments have produced a diversity of new issues to be addressed.

The National Academies of Sciences, Engineering, and Medicine has convened a Roundtable on Genomics and Precision Health (previously the Roundtable on Translating Genomic-Based Research for Health) that brings together leaders from academia, industry, government, foundations and associations, and representatives of patient and consumer interests who have a mutual concern and interest in addressing the issues surrounding the translation of genome-based research for use in maintaining and improving health. The mission of the Roundtable is to advance the field of genomics and improve the translation of research findings to health care, education, and policy. The Roundtable will discuss the translation process, identify challenges at various points in the process, and discuss approaches to address those challenges.

The field of genomics and its translation involves many disciplines, and takes place within different economic, social, and cultural contexts, necessitating a need for increased communication and understanding across these fields. As a convening mechanism for interested parties from diverse perspectives to meet and discuss complex issues of mutual concern in a neutral setting, the Roundtable: fosters dialogue across sectors and institutions; illuminates issues, but does not necessarily resolve them; and fosters collaboration among stakeholders.

To achieve its objectives, the Roundtable conducts structured discussions, workshops, and symposia. Workshop summaries will be published and collaborative efforts among members are encouraged (e.g., journal articles). Specific issues and agenda topics are determined by the Roundtable membership, and span a broad range of issues relevant to the translation process.

Issues may include the integration and coordination of genomic information into health care and public health including encompassing standards for genetic screening and testing, improving information technology for use in clinical decision making, ensuring access while protecting privacy, and using genomic information to reduce health disparities. The patient and family perspective on the use of genomic information for translation includes social and behavioral issues for target populations. There are evolving requirements for the health professional community, and the need to be able to understand and responsibly apply genomics to medicine and public health.

Of increasing importance is the need to identify the economic implications of using genome-based research for health. Such issues include incentives, cost-effectiveness, and sustainability.

Issues related to the developing science base are also important in the translation process. Such issues could include studies of gene-environment interactions, as well as the implications of genomics for complex disorders such as addiction, mental illness, and chronic diseases.

Roundtable sponsors include federal agencies, pharmaceutical companies, medical and scientific associations, foundations, and patient/public representatives. For more information about the Roundtable on Genomics and Precision Health, please visit our website at nationalacademies.org/GenomicsRT or contact Sarah Beachy at 202-334-2217, or by e-mail at sbeachy@nas.edu.

The National Academy of Sciences, National Academy of Engineering, and National Academy of Medicine work together as the National Academies of Sciences, Engineering, and Medicine ("the Academies") to provide independent, objective analysis and advice to the nation and conduct other activities to solve complex problems and inform public policy decisions. The Academies also encourage education and research, recognize outstanding contributions to knowledge, and increase public understanding in matters of science, engineering, and medicine.

Roundtable on Genomics and Precision Health Membership

Health and Medicine Division

Standing Committee on Emerging Infectious Diseases and 21st Century Health Threats

In response to a request from the Office of Science and Technology Policy (OSTP) and the Office of the Assistant Secretary for Preparedness and Response (ASPR), the National Academies of Sciences, Engineering, and Medicine will convene a standing committee of experts to help inform the federal government on critical science and policy issues related to emerging infectious diseases and other 21st century health threats. The standing committee will include members with expertise in emerging infectious diseases, public health, public health preparedness and response, biological sciences, clinical care and crisis standards of care, risk communication, epidemiology, and regulatory issues, as well as veterinary science, One Health, ethics, and community engagement. The standing committee will provide a venue for the exchange of ideas among federal government agencies, the private sector, and the academic community, as well as other relevant stakeholders.

The standing committee will:

- Stand ready to respond on short notice to requests from the federal government to assess and consider the science and policy implications of an emerging infectious disease or significant public health threat;
- Provide a venue to enable science and policy discussions relevant to the federal government on emerging issues, research, and activities through in-depth knowledge of the sponsor's programs, goals, and objectives;
- Identify opportunities to integrate science into national preparedness and response decision making;
- Explore lessons learned and best practices from previous preparedness and response efforts, and identify opportunities to disseminate that information to a variety of stakeholders;
- Serve as a focal point for national policy discussions by experts and other leaders in the field;
- Consider, identify, and discuss strategies for addressing misinformation; and
- Respond to the federal government's needs for continuing dialog related to strategic planning and program development to address emerging infectious diseases, biosecurity, and public health and medical preparedness.

At the request of the sponsors, the standing committee will be involved in the planning, development, and oversight of related ad hoc activities undertaken by separately appointed committees operating under its auspices.

The standing committee will serve as a focal point for the discussion of scientific, technical, and policy issues relevant to emerging infectious diseases and public health preparedness and response that warrant detailed examination. Topics for discussion with the standing committee may include:

- Technical assistance and/or assessment of response to emerging infectious diseases;
- Availability of and access to information, samples, and other materials to determine the origin and evolution of emerging infectious diseases;
- International coordination and engagement;
- Technical assessment of ecological and evolutionary drivers of disease emergence;
- Approaches to proactive public messaging and strategies to address misinformation;
- Other science and policy issues relevant to emerging infectious diseases and 21st century health threats.

The committee will carry out its charge at its in-person and virtual meetings by gathering evidence from experts, deliberating, and, when necessary, by preparing short reports.

SPEAKER AND CHAIR BIOGRAPHIES

Harvey V. Fineberg, M.D., Ph.D. ***(Standing Committee Chair)***
Dr. Fineberg is the president of the Gordon and Betty Moore Foundation, which fosters path-breaking scientific discovery, environmental conservation, improvements in patient care and preservation of the special character of the San Francisco Bay Area. He previously held the Presidential Chair for 2014-2015 as visiting professor at the University of California, San Francisco. Prior to that, he served as president of the Institute of Medicine from 2002 to 2014 and as provost of Harvard University from 1997 to 2001, following 13 years as dean of the Harvard School of Public Health. He has devoted most of his academic career to the fields of health policy and medical decision-making. His past research has focused on the process of policy development and implementation, assessment of medical technology, evaluation and use of vaccines, and dissemination of medical innovations. Fineberg chairs the board of the Carnegie Endowment for International Peace and serves on the boards of the William and Flora Hewlett Foundation and the China Medical Board. He helped found and served as president of the Society for Medical Decision Making and also served as consultant to the World Health Organization. Fineberg is co-author of the books Clinical Decision Analysis, Innovators in Physician Education and The Epidemic That Never Was, an analysis of the controversial federal immunization program against swine flu in 1976. He has co-edited several books on such diverse topics as AIDS prevention, vaccine safety, understanding risk in society and global health. He has also authored numerous articles published in professional journals. Fineberg is the recipient of several honorary degrees—the Frank A. Calderone Prize in Public Health, the Henry G. Friesen International Prize in Health Research and the Harvard Medal, awarded by the alumni association of the university from which he earned his bachelor's and doctoral degrees.

Geoffrey Ginsburg, M.D., Ph.D. (Roundtable *Co-Chair*)
Dr. Ginsburg is the founding director for the Center for Applied Genomics & Precision Medicine at the Duke University Medical Center and for MEDx, a partnership between the Schools of Medicine and Engineering to spark and translate innovation. His research addresses the challenges for translating genomic and digital information into medical practice and the integration of precision medicine into healthcare. In 2017 he received Duke's Translational Research Mentorship Award and is a finalist in the NIH/BARDA Antimicrobial Resistance Prize.

He is a member of the Advisory Council to the Director of NIH and is co-chair of the National Academies Roundtable on Genomics and Precision Health and is founder and president of the Global Genomic Medicine

Collaborative, a not for profit organization aimed creating international partnerships to advance the implementation of precision medicine. He has recently served as a member of the Board of External Experts for the NHLBI, the advisory council for the National Center for Accelerating Translational Science, the chair of the review for Genome Canada's Large Scale Applied Research Competition in Genomics and Precision Medicine, and the World Economic Forum's Global Agenda Council on the Future of the Health Sector. He is a founder of Predigen Inc and MeTree&You Inc. He was previously Vice President of Molecular Medicine at Millennium Pharmaceuticals, Inc and a faculty member at Harvard Medical School.

Maximilian Muenke, M.D., FACMG
Dr. Muenke joined the American College of Medical Genomics (ACMG) as CEO in 2019. Recognized as a highly acclaimed physician-scientist and dedicated clinical and research mentor, Dr. Muenke has more than three decades of experience to the ACMG, including 10 years on the faculty of the University of Pennsylvania School of Medicine. Since 2000, Dr. Muenke has served as Senior Investigator, Head of the Human Development Section, and Chief of the Medical Genetics Branch at the National Human Genome Research Institute (NHGRI) of the National Institutes of Health (NIH). The focus of his laboratory's research was on the delineation and identification of the underlying causes of craniofacial and related anomalies in humans including holoprosencephaly as well as Muenke syndrome, a relatively common craniosynostosis syndrome. Dr. Muenke is passionate about training the next generation of leaders in the field of genetics and genomic medicine. He has directed medical genetics training since 1994, first at the University of Pennsylvania and then at the NIH, where he was the Director of the NIH Medical Genetics and Genomic Medicine Residency and Fellowship Training Programs.

Michelle Penny, Ph.D. ***(Roundtable Co-Chair)***
Dr. Penny is a Vice President and Head of Genomics at Golfich Bio. Prior to that, she was the Head of Translational Genome Sciences at Biogen. She received her Ph.D. in Genetics from the University of Birmingham, UK in 1993. After a postdoctoral fellowship in the Virology Division at the National Institute of Medical Research, Mill Hill, London, she joined Imperial College London, Department of Medical and Community Genetics where she was a postdoctoral research scientist until taking a lectureship in Human Molecular Genetics in 1998. Her academic research career focused on the study of complex polygenic diseases particularly autoimmune disease and susceptibility to infection. In 2002, Dr. Penny joined the Clinical Pharmacogenomics group at Pfizer in Sandwich, UK, and moved to New London, CT in 2006 to take on the role of Oncology Molecular Medicine Lead until 2009 when she moved to Indianapolis to lead the Pharmacogenomics work at Eli Lilly and Company.

Sharon Terry, M.A.
Sharon Terry is President and CEO of Genetic Alliance, a large network engaging individuals, families and communities to transform health. Genetic Alliance works to provide programs, products and tools for ordinary people to take charge of their health.

As 'just a Mom' with a master's degree in Theology, she cofounded PXE International, a research advocacy organization for the genetic condition pseudoxanthoma elasticum (PXE), in response to the diagnosis of PXE in her two children in 1994. With her husband, she co-discovered the ABCC6 gene, patented it to ensure ethical stewardship in 2000, and assigned their rights to the foundation. She subsequently developed a diagnostic test and conducts clinical trials. She is the author of 140 peer-reviewed papers, of which 30 are clinical PXE studies.

In her focus at the forefront of consumer participation in genetics research, services and policy, she serves in a leadership role on many of the major international and national organizations, including the Precision Medicine Initiative Cohort Advisory Panel, Accelerating Medicines Partnership, Institute of Medicine (IOM) Science and Policy Board, the IOM Roundtable on Translating Genomic-Based Research for Health, the PubMed Central National Advisory Committee, the PhenX scientific advisory board, the Global Alliance for Genomics and Health, the International Rare Disease Research Consortium Executive Committee and as Founding President of EspeRare Foundation of Geneva, Switzerland. Terry is co-founder of the Genetic Alliance Registry and Biobank. She is on the editorial boards of several journals. She led the coalition that was instrumental in the passage of the Genetic Information Nondiscrimination Act. She received an honorary doctorate from Iona College for her

community engagement work in 2006; the Research!America Distinguished Organization Advocacy Award in 2009; and the Clinical Research Forum and Foundation's Annual Award for Leadership in Public Advocacy in 2011. She was named one of FDA's "30 Heroes for the Thirtieth Anniversary of the Orphan Drug Act" in 2013. She is co-inventor of the Platform for Engaging Everyone Responsibly (PEER). PEER received $500,000 from the Robert Wood Johnson Foundation in 2014. PEER undergirds the Community Engaged Network for All (CENA), a PCORnet member funded in 2013 for Phase I and in 2015 for Phase II. She is Co-PI of the PCORnet Coordinating Center and Chair of the PCORnet Engagment Committee.

Joyce Tung, Ph.D.
Joyce joined 23andMe in 2007 and manages the 23andMe research team, which is responsible for consumer health and ancestry research and development, academic and industry collaborations, computational analyses for therapeutics, and new research methods and tools development. While a postdoctoral fellow at Stanford University, Joyce studied the genetics of mouse and human pigmentation. She graduated from Stanford with honors and distinction with a B.S. in Biological Sciences and a minor in computer science, and earned her Ph.D. in Genetics from the University of California, San Francisco where she was a National Science Foundation graduate research fellow.

Genomewide Association Study of Severe Covid-19 with Respiratory Failure

BACKGROUND

There is considerable variation in disease behavior among patients infected with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the virus that causes coronavirus disease 2019 (Covid-19). Genomewide association analysis may allow for the identification of potential genetic factors involved in the development of Covid-19.

A Host Transcriptional Signature for Presymptomatic Detection of Infection in Humans Exposed to Influenza H1N1 or H3N2

BACKGROUND

There is great potential for host-based gene expression analysis to impact the early diagnosis of infectious diseases. In particular, the influenza pandemic of 2009 highlighted the challenges and limitations of traditional pathogen-based testing for suspected upper respiratory viral infection.

A crowdsourced analysis to identify ab initio molecular signatures predictive of susceptibility to viral infection

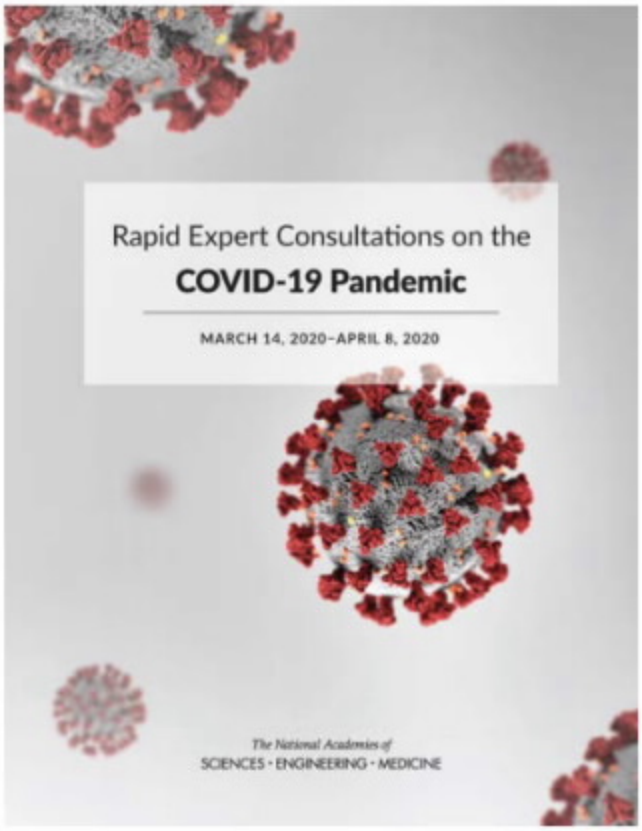
BACKGROUND

The response to respiratory viruses varies substantially between individuals, and there are currently no known molecular predictors from the early stages of infection. Here we conduct a community-based analysis to determine whether pre- or early post-exposure molecular factors could predict physiologic responses to viral exposure.

A Host-Based RT-PCR Gene Expression Signature to Identify Acute Respiratory Viral Infection

Improved ways to diagnose acute respiratory viral infections could decrease inappropriate antibacterial use and serve as a vital triage mechanism in the event of a potential viral pandemic. Measurement of the host response to infection is an alternative to pathogen-based

diagnostic testing and may improve diagnostic accuracy. We have developed a host-based assay with a reverse transcription polymerase chain reaction (RT-PCR) TaqMan low-density array (TLDA) platform for classifying respiratory viral infection.



Rapid Expert Consultations on the COVID-19 Pandemic

In response to a request from the Office of Science and Technology Policy and the Office of the Assistant Secretary for Preparedness and Response, the National Academies of Sciences, Engineering, and Medicine convened a standing committee of experts to help inform the federal government on critical science and policy issues related to emerging infectious diseases and other 21st century health threats. This set of Rapid Expert Consultations are the first of their kind and represent the best evidence available to the Committee at the time each publication was released.

Research in context

Evidence before this study

An increasing body of research has demonstrated that host gene expression patterns in peripheral blood offer a high degree of accuracy for diagnosis of acute infections at the time of clinical presentation.

Added value of this study

For the first time we demonstrate in a real-world setting that a blood-based gene expression test can accurately predict impending viral infection even before typical symptoms are present.

Implications of all the available evidence

These data show that biomarkers of viral infection are present and detectable even before clinical disease develops, opening the door to novel approaches to early treatment and outbreak management.

Abstract

Background

Early and accurate identification of persons with viral infections can be of critical importance for clinical management and public health interventions. Measuring host responses through gene signature-based biomarkers offer promise for improved diagnosis of respiratory viral infections, but little is known how early in disease such measures may be effective.

Methods

We performed a modified index-cluster study in 1465 university dormitory residents over five years. Each year, we monitored for symptomatic Index Cases (IC) and identified clusters of their Close Contacts (CC) who would be at presumed increased risk of developing symptomatic respiratory tract infection (RTI) while under observation. We then monitored each CC for 5 days for development of RTI and measured transcriptomic responses at each timepoint via a blood-based 36-gene RT-PCR assay.

Findings

Of 264 ICs with RTI symptoms, 150 (56%) had a confirmed viral etiology detected. Of their 555 CCs, 106 (19%) developed symptomatic RTI with a proven viral etiology during the observation window. The transcriptomic assay accurately predicts infection at the time of peak symptoms despite heterogeneity of hosts and nine different viral etiologies (auROC 0·96). Furthermore, these genomic biomarkers are capable of identifying early disease one, two and three days prior to peak illness when minimal to no symptoms are present (auROC 0·87, 0·86, and 0·77, respectively), and when nearly two-thirds of subjects (62%) are not yet producing detectable viral shedding.

Interpretation

Transcriptional biomarkers accurately predict and diagnose infection across diverse viral etiologies and stages of disease, and may prove useful for guiding administration of early effective therapy, quarantine decisions, and other clinical and public health interventions in the setting of endemic and pandemic infectious disease.

Funding: US Defense Advanced Research Projects Agency

Introduction

Acute viral infections are among the most common causes of acute physician visits in the United States[1]. In a given year, influenza alone affects 5-20% of the population in the US, causes over 400,000 hospitalizations, and as many as 56,000 deaths.[2,3] Outbreaks of viral infection continue to plague modern society, including heavy resource-requiring outbreaks of measles in the developed world, global pandemics like the novel H1N1 outbreak of 2009, or the deadly epidemics of SARS and MERS-CoV.[4-6] However, molecular tools that can contribute to outbreak investigation or directing early clinical management are often lacking. Traditional pathogen-focused diagnostic modalities for viral infection (culture, serology, antigen detection, PCR) offer considerable utility but can also be slow, costly, limited in terms of breadth of pathogen detection, require an *a priori* knowledge of the pathogen to be tested, may not detect emerging strains (as with the 2009 influenza pandemic[7]), or are incapable of distinguishing between active infection and colonization, all of which can minimize the impact of their use. Therefore, there is increasing interest in host-derived biomarkers to aid in the determination of the presence and/or type of infection in at-risk hosts - from single-analyte biomarkers like procalcitonin to composite, multiplex biomarker panels such as those included in a growing number of gene expression-based studies.[8-21] However, the published works on diagnostics for naturally-acquired infection focus on identifying symptomatic subjects at the time of clinical presentation for medical care[19], which is often late in the time course of many viral diseases. Identification of infectious etiologies in earlier, even pre-symptomatic phases of illness, offers the ability to optimize and deliver timely and thus more effective therapy, refine prophylaxis decisions, and guide public health interventions such as isolation and quarantine.[13,22] However, identifying subjects who have been exposed to infectious virus but are not yet exhibiting symptoms of clinical illness is logistically challenging, resulting in a dearth of literature to address these problems.

We have previously shown that during experimental influenza infection of healthy volunteers the host genomic response is robust and detectable well before typical symptoms become apparent.[16,22,23] Other

investigators have confirmed that transcriptomic markers can be indicative of early viral infection in experimental human challenge models as well as animal models of disease.[24-27] However, the mechanism of challenge infection is contrived rather than natural, typically consists of highly egg-adapted viral strains, and the severity of clinical illness does not fully replicate that seen in naturally-acquired infection, all of which can limit the broad applicability of findings from this approach.[16,22,28-31] To date there has been no significant description of the host response to infection during the pre-symptomatic phase of naturally-occurring disease. Here we have utilized a unique index-cluster study design with a focus on serial sampling of 'real world', healthy close contacts of infected individuals to enrich for cases of naturally-occurring infection during these early, post-exposure, but pre-symptomatic time points. This unique design has permitted real-world validation of a transcriptomic signature in peripheral blood that is capable of accurately identifying exposed but apparently healthy individuals who will go on to develop symptomatic viral infection.

Methods

Surveillance Cohort

Over five academic years, we enrolled 1465 Duke University undergraduate students (age 18-24, most of whom live in dormitories on campus) in a modified index-cluster study design (Figure 1). At the time of enrollment, we collected baseline biospecimens and standardized questionnaires to ascertain demographic, behavioral, and other medical characteristics. After enrollment, participating students completed a daily, web-based survey to describe the presence and severity of eight symptoms of RTI (scored 0-4) on a daily basis (see eMethods for details). We monitored the surveys daily for a 6-point increase in a subject's cumulative daily symptom score which would trigger a sample and data collection event for a potential Index Case. Suspected ICs were then assessed for confirmation of illness and biospecimen collection. Using these sentinel cases of RTI suggestive of viral etiology we then identified and monitored a prospective observational cohort of asymptomatic but potentially exposed Close Contacts (people living in the same dormitory or identified by the IC as a Close Contact), who were then monitored and sampled for up to 5 days (the Observation Window).

Sample and data collection

Confirmed IC's provided blood and nasal swab samples at the time of illness identification. Viral etiology was assessed using a commercial multiplex PCR assay (QIAGEN ResPlex II v2·0, Luminex RVP, or Biofire FilmArray RP). Healthy CCs living in proximity to an IC provided blood and respiratory samples for up to five consecutive days and were monitored for symptomatic conversion and viral shedding.

Real-time PCR

Peripheral blood was collected in PAXgene™ Blood RNA tubes (PreAnalytiX), and total RNA extracted using the PAXgene™ Blood miRNA Kit (QIAGEN). cDNA synthesis was performed using SuperScript VILO™ Master Mix (Invitrogen) according to manufacturer's instructions. Real-time PCR was performed using custom TLDA 384-well microfluidic cards with TaqMan Gene Expression Master Mix, and run on a ViiA7 Real-Time PCR System (Applied Biosystems).

Statistical Analysis

For RT-PCR data the Cq values were transformed into normalized relative quantities using reference genes - those with the most stable combined coefficient of variation across all samples - FPGS and TRAP1 were used for the first batch, and DECR1 and TRAP1 were used for the second batch, and data was normalized as previously described.[8,9] We utilized a regularized (2-norm) logistic regression model to discriminate cases from controls (see eMethods for complete details). The data was split into training and testing sets 25 times using repeated random subsampling and each of the 25 models was trained using all timepoints. We evaluated the model's performance separately at each individual timepoint. All model analyses were implemented in Python and Tensorflow.[32]

Results

Brief Description of Study

Healthy first year students at Duke University (n=1465) were enrolled into a surveillance cohort at the beginning of each academic year. After enrollment, we electronically monitored self-reported daily symptoms throughout the duration of the academic year via an online portal. When one or more subjects indicated a change in respiratory symptoms, the sample collection protocol was initiated for individuals (Index Cases, ICs) that met the clinical case definition for acute, community-acquired RTI (see Methods), as well as for a subset of other currently healthy study participants who were in close proximity to the Index Case (Close Contacts, CCs). CCs were monitored for symptoms and serially sampled for serum, whole blood PAXgene RNA, and respiratory samples for 5 days from identification of their Index Case, regardless of symptomatology (Figure 1). This design permitted enrichment for, and collection of, samples from CCs during the timeframe between exposure (which occurred at an unknown time) and subsequent development of symptomatic disease (which occurred under observation).

Prevalence, Transmission, and Clinical Outcomes of Viral Respiratory Tract Infection

We identified 264 clinical ICs, of whom 150 had a confirmed respiratory viral etiology by multiplex PCR testing of NP samples, and 555 CCs, 19% (106) of whom developed symptomatic RTI with concomitant confirmatory viral PCR. Only 57% of the CCs were infected with the same virus as their associated IC. Nine different viral pathogens were detected, and there was marked variation in viral etiologies detected from year to year (Table 1). Infection resulted in many common symptoms of upper respiratory tract infection with clinical variation amongst viral etiologies (Figure 2). For example, symptoms were almost twice as severe in individuals with influenza infection compared to all other viruses (mean symptom score of 20 for influenza vs 13 for all others ($p=0.005$)), although all subjects in the study remained well enough to be managed in the outpatient setting.

Since the exact time of exposure/transmission during naturally-acquired infection is unknown, for analysis CC days were aligned to the time of maximal illness (day of highest symptom score) for each subject (Time "T") in order to attempt to place subjects on broadly similar time scales in terms of the host response to infection. The average total symptom score for all CCs at Time T was 14·8, although this varied by viral etiology (Figures 1,2). For each individual CC, the day before their day of maximal symptoms was termed T-minus 1 ("T-1"), 48 hours prior to symptom max was "T-2" and 72 hours prior to symptom max was time "T-3". At times prior to maximal illness the average total symptom score for CCs was 7·0 (T-1), 4·1 (T-2), and 1·7 (T-3). In our studies a daily symptom score of 6 represents mild clinical illness and was the threshold for defining a 'symptomatic' day. Thus, at days T-2 and earlier, most subjects exhibited subclinical or absent illness (65% asymptomatic at Time T-3, 32% at T-2).

An RT-PCR signature identifies symptomatic subjects with naturally-acquired viral RTI

We previously developed a host response-derived transcriptomic signature of symptomatic viral infection using microarray data[30]. However, microarray and bulk RNA sequencing platforms are impractical for rapid clinical testing. We therefore migrated our prior 'pan-viral' signature to an RT-PCR platform with potential for more direct translation to point-of-care testing [8,9]. Using sparsity-imposing techniques (see eMethods), we selected 36 pre-designed TaqMan probes representing genes comprising the acute respiratory viral signature (and normalization controls) to be used on a TaqMan Low Density Array (TLDA) platform[8]. We then utilized a regularized (2-norm) logistic regression model to determine coefficients for each gene in the signature[33], such that the output of the model is a probability that a given subject will go on to have a symptomatic, viral PCR-positive event during the observation window. The performance of the RT-PCR signature for classification of symptomatic individuals was evaluated using a repeated random subsampling validation strategy on relevant participants across all study years. Overall, the RT-PCR-based host gene expression assay distinguished symptomatic, virus-infected subjects from asymptomatic, viral PCR-negative controls with 92% accuracy (Figure 3). However, accuracy varied depending on viral etiology, ranging from 99% accuracy in influenza infection (where symptoms are

typically more severe) to 92% with Coronavirus and 81% accuracy with metapneumovirus infections (eFigure 1). Interestingly, analysis of individual gene components of the model demonstrates that many individual genes performed similar to the aggregate model across all iterations (eFigure 2-3). In fact, many individual gene targets alone had mean area under Receiver Operating Characteristic (auROC) of >0·90 at the time of maximal illness with the top performing genes at time T being IFIT3 (0·97), HERC5 (0·97), and RSAD2 (0·96)

The gene expression signature identifies naturally-acquired viral RTI during the pre-symptomatic phase.

In order to evaluate performance of the gene signature early in the course of natural infection, we selected CCs with positive microbiology and at least three days of sampling prior to the development of maximal symptoms. As noted previously, the RT-PCR gene signature correctly identified symptomatic subjects with 92% accuracy on the day of maximal symptoms. This decreased to 88% on day T-1 (24 hours before maximal symptoms), and 83% accuracy on day T-2 (48 hours before maximal symptoms) (Figure 3), although performance varies from virus to virus. Only one case of influenza infection had available pre-symptomatic samples at all times, and the signature correctly classified that individual at each timepoint (T-1, T-2, T-3, and T-4). For a fixed FPR of 0·2 (specificity 0·8), the model achieves greater sensitivity than either symptoms alone or viral PCR at all timepoints other than time T and for ICs (where symptom-based diagnosis by definition has a 100% sensitivity, eFigures 4-6). Critically, 62% of subjects who would develop proven viral RTI lacked detectable viral shedding at time T-3, and 44% were still negative for virus by routine clinical testing at day T-2, times where the gene signature outperforms the clinical standards of care - symptom evaluation and viral PCR.

Discussion

The unique design of this community study has allowed us to identify individuals (CCs) at increased risk for developing viral RTI while under observation. This approach has enabled us to demonstrate for the first time that host responses to naturally-acquired respiratory viral infection, as measured by gene expression in peripheral blood, are present well before the time of maximal illness and can be used to predict those at highest risk for developing active infection.

This study demonstrates that conserved genomic responses can be used to correctly classify individuals with a broad array of naturally-acquired respiratory viral infections well before the time when they would present for clinical evaluation, and even before detectable viral shedding begins for the majority of subjects (62%). The promise of this approach is manifested by the discriminative ability of the genomic signature from two and three days prior to maximal illness, when many individuals (65% at Time T-3, 32% at T-2) have no symptoms at all. Even the mild symptoms some subjects do have at early times are clinically vague and would be typical of seasonal allergies, mild COPD flares, or even symptoms due to sequelae of chronic smoking.[34] The potential utility of genomic analysis to classify viral infection among asymptomatic individuals or those with common, nonspecific upper respiratory symptoms is profound. That this holds true across 9 different respiratory viruses, each with its own incubation times and variable clinical progression and duration, also speaks to the potential power of this approach. Additionally, it is important to note that the signature utilized represents conserved underlying antiviral response pathways that are active, and thus discriminatory, across a wide range of illness and not just at early times. This is vital as any real-world use of such a biomarker assay would often be agnostic to where in the course of infection an individual exists at the moment of testing.

While this transcriptomic signature accurately classifies a wide spectrum of viral RTIs, it performs best in a subset of viruses including influenza and coronavirus, where it performs with a high degree of accuracy even during early and pre-symptomatic phases of disease. Influenza is one of the most important viral etiologies to identify early given its importance in pandemics where existing diagnostics may perform

poorly (especially for emerging strains as in 2009[35]), where questions of triage and quarantine are paramount, and where effective therapeutic options are readily available and most effective when given early in disease. Similarly, a number of novel highly virulent coronaviruses, including SARS-CoV and MERS-CoV, have recently arisen and driven global outbreaks, highlighting another area of need for such diagnostics.[5,36].It seems likely that our ability to accurately detect exposure to these types of emerging infections will only become more critical over time. Availability of tools that can aid in assessment of those with potential exposure, especially those that offer diagnostic utility prior to the time of detectable viral shedding, would be a valuable aid to existing epidemiologic and molecular approaches in outbreak settings.

A number of other studies have described interferon response-based transcriptomic signatures of acute respiratory infections which vary by target population, pathogens, modelling approaches, and numbers of genes required to discriminate disease states. [9,10,13-18,30] Some of this work has also been validated, combined, or expanded upon by secondary *ex vivo* analysis of publicly available data. [11,12,37] While the focused signature described here clearly represents a limited subset of all discriminating genes, some observations regarding simplified, IFN-driven signatures can be made. Our data confirm that that some genes from these prior works (such as IFI44L and IFI27[10,38]) both perform well as classifiers distinguishing between viral illness and the healthy state (median auROC = 0·92 and 0·87), being strongly upregulated in cases of viral infection. The data further suggest that a number of other single targets also perform this task well including RSAD2 (0·96), IFIT3 (0·97), and IFI44 (0·93). Based on our experience and the published literature, it seems that relatively simple classification tasks - where the biological responses are highly conserved, unique in character, and of great magnitude - may be reasonably addressed with pauci-analyte biomarker panels.[10,12,39-41] However, as complexity increases by adding more powerful interhost variability (such as immunosuppression), discriminating clinically similar groups with more varied underlying pathophysiology, or discriminating multiple clinical mimics at once,

more intricate biomarker panels will likely be required to maintain high fidelity in real-world settings.[9,14,42]

Our study has several limitations. This project was designed to validate the predictive power of a small set of genes which already had proven discriminatory capability during maximal illness, and thus was not designed to discover whether additional, untested gene sets may offer improved discriminatory performance at early times. Future work with RNASeq on whole blood, single cell sequencing, or other methods will be needed to more completely define early genomic changes in the naturally-infected host. Additionally, our patient cohort was comprised of otherwise young, healthy individuals with community-acquired viral RTI of mild to moderate severity. Therefore, application to patient populations from other age groups, those with immunologic comorbidities, or with more severe viral infections will need to be evaluated. Finally, we did not identify any confirmed infections due to bacterial or other pathogens. As a result, while these transcriptomic markers show great promise for differentiating early infection and pre-symptomatic viral exposure from noninfectious states (which it may mimic at early times), this study did not directly validate the ability of these markers to differentiate viral exposure from early forms of other types of infection[9,10,14,43]. As we move towards bringing transcriptomic biomarkers to the bedside, consideration of broad applicability and performance across a wide array of clinical settings will continue to be paramount.

We have for the first time defined the pre-symptomatic and temporal dynamics of transcriptomic biomarkers characterizing the host response to naturally-acquired viral infections in humans. Clinic-ready platforms capable of operationalizing PCR-based signatures of the size tested herein already exist, some of which are CLIA-approved with point-of-care functionality, offering a proximal pathway to clinical application of these findings. Thus, analysis of the evolution of gene expression-based biomarkers over time shows promise for driving development of diagnostics for early detection of viral exposure and infection which may prove useful for guiding administration of early effective therapy, quarantine

decisions, and other clinical and public health interventions in the setting of endemic and pandemic infectious disease.

Acknowledgements

Special thanks to Debra Freeman, Sara Hoffman, Olga M. Better, Mert Aydin, Stephanie Dobos, Kyle R. Breitschwert, Ashlee M. Valente for their tireless work enrolling subjects, processing samples and data, and engaging with the undergraduate campus.

Funding

Funding for this study was provided by the US Defense Advanced Research Projects Agency (DARPA), project # N66001-07-C-2024 and W911NF1410052. The statements and conclusions herein are those of the authors and do not reflect the position or policy of the United States Government.

Author contributions

MTM, ELT, GSG and CWW drafted the manuscript, which was critically revised by all remaining authors. MTM, BPN, TB, TV, GSG, and CWW helped conceive and implement the study. All authors helped acquire, analyze, or interpret data. Statistical analyses were performed by FJC, RH, SS, MN, and LP.

Figures

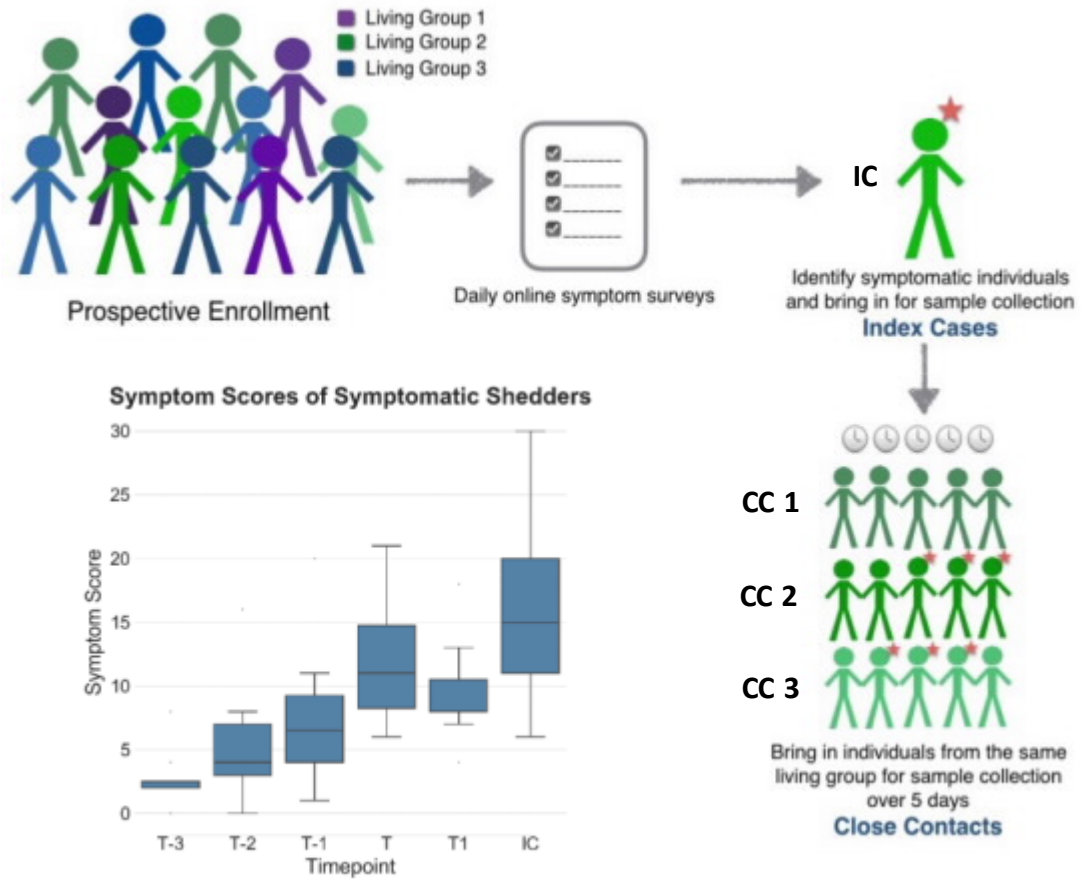

Figure 1: Study design. Students were enrolled at the beginning of the school year. Index Cases were identified when daily symptom surveys indicated potential respiratory illness. This flagged serial sampling of their Close Contacts, some of whom would also develop RTI during the 5-day observation window (red stars). This unique model permits blood sampling of some Close Contacts during early and presymptomatic phases of illness. Mean symptom scores of Close Contacts who developed PCR-proven RTI under observation are presented.

A

	Cough	Fever	Headache	Malaise	Nasal Congestion	Nasal Discharge	Sneezing	Sore Throat	Total Symptoms
Influenza*	3.2	1.9	2.4	3.0	2.5	2.4	1.8	2.7	20.0
RSV	2.1	0.7	1.6	2.9	2.6	2.6	1.5	2.6	16.6
Human Metapneumovirus	2.6	0.8	1.5	2.5	2.4	2.5	1.9	2.2	16.3
Rhinovirus	2.2	0.5	1.1	2.1	2.3	2.3	1.5	2.1	14.0
Coxsackie/Echovirus	2.1	0.5	1.1	2.2	2.4	2.4	1.6	1.8	14.0

Host Genomics Research and Data Collection Efforts Related to COVID-19

Joint Meeting
of the
Roundtable on Genomics and Precision Health
and the
Standing Committee on Emerging Infectious Diseases and 21st Century Health Threats

A VIRTUAL MEETING
July 1, 2020
1:00 PM – 2:45 PM ET
Zoom Link: https://nasem.zoom.us/j/95540901323

Aims for the meeting:

- To understand the scientific challenges that the field of genomics is facing
  - What has been the effect of the pandemic on genomics research and data collection and sharing? What is the role of the genomics community during the pandemic? What research is underway? What research still needs to be done?
  - What gaps and challenges in the field is this crisis highlighting? What unique contributions of the field are not being leveraged effectively?
- To explore innovative approaches to overcoming those challenges
  - What new approaches are you using to solve a problem? Could these be applied to the field of genomics? Are there lessons from genomics that are being used in light of the pandemic? What are the opportunities for connecting efforts and data sets (e.g. across institutions, genotype and phenotype data)?
- To discuss opportunities for the Genomics Roundtable and for the Standing Committee on Emerging Infectious Diseases and 21st Century Health Threats to facilitate progress
  - Are there opportunities for the Roundtable and Standing Committee to act that align with strategic priorities?
  - Are the Roundtable and Standing Committee uniquely positioned to address specific challenges?

AGENDA:

1:00 p.m. ET Welcoming Remarks

GEOFFREY GINSBURG, *Roundtable Co-Chair*
Director, Duke Center for Applied Genomics & Precision Medicine
Professor, Medicine, Pathology, and Biomedical Engineering
Duke University Medical Center

MICHELLE PENNY, *Roundtable Co-Chair*
Vice President and Head of Genomics
Goldfinch Bio

HARVEY FINEBERG, *Standing Committee Chair*
President
Gordon and Betty Moore Foundation

1:15 p.m. **An Introduction to the Host Genetics of COVID-19**

MAXIMILIAN MUENKE
CEO
American College of Medical Genetics and Genomics (ACMG)

Understanding Host Genetics and Genomics Related to COVID-19 and Opportunities for Forming Data Sharing COVID-19 Communities

1:25 p.m. SHARON TERRY
Founder and CEO
Genetic Alliance

1:35 p.m. JOYCE TUNG
Vice President, Research
23andMe

1:45 p.m. GEOFFREY GINSBURG, *Roundtable Co-Chair*
Director, Duke Center for Applied Genomics & Precision Medicine
Professor, Medicine, Pathology, and Biomedical Engineering
Duke University Medical Center

1:55 p.m. **Discussion with Roundtable and Standing Committee Members**

2:30 p.m. **Next Steps**

Questions:

- What challenges or gaps were exposed today?
- Is there an area that should be incorporated into the Roundtable's strategic planning or the Standing Committee's work?

GEOFFREY GINSBURG, *Roundtable Co-Chair*
Director, Duke Center for Applied Genomics & Precision Medicine
Professor, Medicine, Pathology, and Biomedical Engineering
Duke University Medical Center

MICHELLE PENNY, *Roundtable Co-Chair*
Vice President and Head of Genomics
Goldfinch Bio

HARVEY FINEBERG, *Standing Committee Chair*
President
Gordon and Betty Moore Foundation

2:45 p.m. Adjourn

ROUNDTABLE AND STANDING COMMITTEE INFORMATION

The National Academies of
SCIENCES • ENGINEERING • MEDICINE

Roundtable on GENOMICS and PRECISION HEALTH

The sequencing of the human genome is rapidly opening new doors to research and progress in biology, medicine, and health care. At the same time, these developments have produced a diversity of new issues to be addressed.

The National Academies of Sciences, Engineering, and Medicine has convened a Roundtable on Genomics and Precision Health (previously the Roundtable on Translating Genomic-Based Research for Health) that brings together leaders from academia, industry, government, foundations and associations, and representatives of patient and consumer interests who have a mutual concern and interest in addressing the issues surrounding the translation of genome-based research for use in maintaining and improving health. The mission of the Roundtable is to advance the field of genomics and improve the translation of research findings to health care, education, and policy. The Roundtable will discuss the translation process, identify challenges at various points in the process, and discuss approaches to address those challenges.

The field of genomics and its translation involves many disciplines, and takes place within different economic, social, and cultural contexts, necessitating a need for increased communication and understanding across these fields. As a convening mechanism for interested parties from diverse perspectives to meet and discuss complex issues of mutual concern in a neutral setting, the Roundtable: fosters dialogue across sectors and institutions; illuminates issues, but does not necessarily resolve them; and fosters collaboration among stakeholders.

To achieve its objectives, the Roundtable conducts structured discussions, workshops, and symposia. Workshop summaries will be published and collaborative efforts among members are encouraged (e.g., journal articles). Specific issues and agenda topics are determined by the Roundtable membership, and span a broad range of issues relevant to the translation process.

Issues may include the integration and coordination of genomic information into health care and public health including encompassing standards for genetic screening and testing, improving information technology for use in clinical decision making, ensuring access while protecting privacy, and using genomic information to reduce health disparities. The patient and family perspective on the use of genomic information for translation includes social and behavioral issues for target populations. There are evolving requirements for the health professional community, and the need to be able to understand and responsibly apply genomics to medicine and public health.

Of increasing importance is the need to identify the economic implications of using genome-based research for health. Such issues include incentives, cost-effectiveness, and sustainability.

Issues related to the developing science base are also important in the translation process. Such issues could include studies of gene-environment interactions, as well as the implications of genomics for complex disorders such as addiction, mental illness, and chronic diseases.

Roundtable sponsors include federal agencies, pharmaceutical companies, medical and scientific associations, foundations, and patient/public representatives. For more information about the Roundtable on Genomics and Precision Health, please visit our website at nationalacademies.org/GenomicsRT or contact Sarah Beachy at 202-334-2217, or by e-mail at sbeachy@nas.edu.

The National Academy of Sciences, National Academy of Engineering, and National Academy of Medicine work together as the National Academies of Sciences, Engineering, and Medicine ("the Academies") to provide independent, objective analysis and advice to the nation and conduct other activities to solve complex problems and inform public policy decisions. The Academies also encourage education and research, recognize outstanding contributions to knowledge, and increase public understanding in matters of science, engineering, and medicine.

Health and Medicine Division

Standing Committee on Emerging Infectious Diseases and 21st Century Health Threats

In response to a request from the Office of Science and Technology Policy (OSTP) and the Office of the Assistant Secretary for Preparedness and Response (ASPR), the National Academies of Sciences, Engineering, and Medicine will convene a standing committee of experts to help inform the federal government on critical science and policy issues related to emerging infectious diseases and other 21st century health threats. The standing committee will include members with expertise in emerging infectious diseases, public health, public health preparedness and response, biological sciences, clinical care and crisis standards of care, risk communication, epidemiology, and regulatory issues, as well as veterinary science, One Health, ethics, and community engagement. The standing committee will provide a venue for the exchange of ideas among federal government agencies, the private sector, and the academic community, as well as other relevant stakeholders.

The standing committee will:

- Stand ready to respond on short notice to requests from the federal government to assess and consider the science and policy implications of an emerging infectious disease or significant public health threat;
- Provide a venue to enable science and policy discussions relevant to the federal government on emerging issues, research, and activities through in-depth knowledge of the sponsor's programs, goals, and objectives;
- Identify opportunities to integrate science into national preparedness and response decision making;
- Explore lessons learned and best practices from previous preparedness and response efforts, and identify opportunities to disseminate that information to a variety of stakeholders;
- Serve as a focal point for national policy discussions by experts and other leaders in the field;
- Consider, identify, and discuss strategies for addressing misinformation; and
- Respond to the federal government's needs for continuing dialog related to strategic planning and program development to address emerging infectious diseases, biosecurity, and public health and medical preparedness.

At the request of the sponsors, the standing committee will be involved in the planning, development, and oversight of related ad hoc activities undertaken by separately appointed committees operating under its auspices.

The standing committee will serve as a focal point for the discussion of scientific, technical, and policy issues relevant to emerging infectious diseases and public health preparedness and response that warrant detailed examination. Topics for discussion with the standing committee may include:

- Technical assistance and/or assessment of response to emerging infectious diseases;
- Availability of and access to information, samples, and other materials to determine the origin and evolution of emerging infectious diseases;
- International coordination and engagement;
- Technical assessment of ecological and evolutionary drivers of disease emergence;
- Approaches to proactive public messaging and strategies to address misinformation;
- Other science and policy issues relevant to emerging infectious diseases and 21st century health threats.

The committee will carry out its charge at its in-person and virtual meetings by gathering evidence from experts, deliberating, and, when necessary, by preparing short reports.

COMMITTEE SPONSORS

White House Office of Science and Technology Policy and HHS Office of Assistant Secretary for Preparedness and Response

COMMITTEE ROSTER

Harvey Fineberg, M.D., Ph.D. ***(Chair)***
President
Gordon and Betty Moore Foundation

Kristian Andersen, Ph.D.
Associate Professor and Director of Infectious Disease Genomics, Scripps Research Translational Institute
The Scripps Research Institute

Ralph Steven Baric, Ph.D.
William R. Kenan, Jr. Distinguished Professor
The University of North Carolina at Chapel Hill

Mary Bassett, M.D., M.P.H.
Director of the François-Xavier Bagnoud Center for Health and Human Rights
Harvard School of Public Health

Trevor Bedford, Ph.D.
Associate Faculty Member, Vaccine and Infectious Disease Division, Public Health Sciences Division, and Human Biology Division
Fred Hutchinson Cancer Research Center

Georges Benjamin, M.D.
Executive Director
American Public Health Association

Donald Berwick, M.D., M.P.P., F.R.C.P, KBE
Lecturer of Health Care Policy
Harvard Medical School

Richard Besser, M.D.
President and CEO
Robert Wood Johnson Foundation

R. Alta Charo, J.D.
Warren P. Knowles Professor of Law and Bioethics
University of Wisconsin at Madison

Peter Daszak, Ph.D.
President and CEO
EcoHealth Alliance

SPEAKER AND CHAIR BIOGRAPHIES

Harvey V. Fineberg, M.D., Ph.D. ***(Standing Committee Chair)***
Dr. Fineberg is the president of the Gordon and Betty Moore Foundation, which fosters path-breaking scientific discovery, environmental conservation, improvements in patient care and preservation of the special character of the San Francisco Bay Area. He previously held the Presidential Chair for 2014-2015 as visiting professor at the University of California, San Francisco. Prior to that, he served as president of the Institute of Medicine from 2002 to 2014 and as provost of Harvard University from 1997 to 2001, following 13 years as dean of the Harvard School of Public Health. He has devoted most of his academic career to the fields of health policy and medical decision-making. His past research has focused on the process of policy development and implementation, assessment of medical technology, evaluation and use of vaccines, and dissemination of medical innovations. Fineberg chairs the board of the Carnegie Endowment for International Peace and serves on the boards of the William and Flora Hewlett Foundation and the China Medical Board. He helped found and served as president of the Society for Medical Decision Making and also served as consultant to the World Health Organization. Fineberg is co-author of the books Clinical Decision Analysis, Innovators in Physician Education and The Epidemic That Never Was, an analysis of the controversial federal immunization program against swine flu in 1976. He has co-edited several books on such diverse topics as AIDS prevention, vaccine safety, understanding risk in society and global health. He has also authored numerous articles published in professional journals. Fineberg is the recipient of several honorary degrees—the Frank A. Calderone Prize in Public Health, the Henry G. Friesen International Prize in Health Research and the Harvard Medal, awarded by the alumni association of the university from which he earned his bachelor's and doctoral degrees.

Geoffrey Ginsburg, M.D., Ph.D. (Roundtable *Co-Chair*)
Dr. Ginsburg is the founding director for the Center for Applied Genomics & Precision Medicine at the Duke University Medical Center and for MEDx, a partnership between the Schools of Medicine and Engineering to spark and translate innovation. His research addresses the challenges for translating genomic and digital information into medical practice and the integration of precision medicine into healthcare. In 2017 he received Duke's Translational Research Mentorship Award and is a finalist in the NIH/BARDA Antimicrobial Resistance Prize.

He is a member of the Advisory Council to the Director of NIH and is co-chair of the National Academies Roundtable on Genomics and Precision Health and is founder and president of the Global Genomic Medicine

Collaborative, a not for profit organization aimed creating international partnerships to advance the implementation of precision medicine. He has recently served as a member of the Board of External Experts for the NHLBI, the advisory council for the National Center for Accelerating Translational Science, the chair of the review for Genome Canada's Large Scale Applied Research Competition in Genomics and Precision Medicine, and the World Economic Forum's Global Agenda Council on the Future of the Health Sector. He is a founder of Predigen Inc and MeTree&You Inc. He was previously Vice President of Molecular Medicine at Millennium Pharmaceuticals, Inc and a faculty member at Harvard Medical School.

Maximilian Muenke, M.D., FACMG
Dr. Muenke joined the American College of Medical Genomics (ACMG) as CEO in 2019. Recognized as a highly acclaimed physician-scientist and dedicated clinical and research mentor, Dr. Muenke has more than three decades of experience to the ACMG, including 10 years on the faculty of the University of Pennsylvania School of Medicine. Since 2000, Dr. Muenke has served as Senior Investigator, Head of the Human Development Section, and Chief of the Medical Genetics Branch at the National Human Genome Research Institute (NHGRI) of the National Institutes of Health (NIH). The focus of his laboratory's research was on the delineation and identification of the underlying causes of craniofacial and related anomalies in humans including holoprosencephaly as well as Muenke syndrome, a relatively common craniosynostosis syndrome. Dr. Muenke is passionate about training the next generation of leaders in the field of genetics and genomic medicine. He has directed medical genetics training since 1994, first at the University of Pennsylvania and then at the NIH, where he was the Director of the NIH Medical Genetics and Genomic Medicine Residency and Fellowship Training Programs.

Michelle Penny, Ph.D. ***(Roundtable Co-Chair)***
Dr. Penny is a Vice President and Head of Genomics at Golfich Bio. Prior to that, she was the Head of Translational Genome Sciences at Biogen. She received her Ph.D. in Genetics from the University of Birmingham, UK in 1993. After a postdoctoral fellowship in the Virology Division at the National Institute of Medical Research, Mill Hill, London, she joined Imperial College London, Department of Medical and Community Genetics where she was a postdoctoral research scientist until taking a lectureship in Human Molecular Genetics in 1998. Her academic research career focused on the study of complex polygenic diseases particularly autoimmune disease and susceptibility to infection. In 2002, Dr. Penny joined the Clinical Pharmacogenomics group at Pfizer in Sandwich, UK, and moved to New London, CT in 2006 to take on the role of Oncology Molecular Medicine Lead until 2009 when she moved to Indianapolis to lead the Pharmacogenomics work at Eli Lilly and Company.

Sharon Terry, M.A.
Sharon Terry is President and CEO of Genetic Alliance, a large network engaging individuals, families and communities to transform health. Genetic Alliance works to provide programs, products and tools for ordinary people to take charge of their health.

As 'just a Mom' with a master's degree in Theology, she cofounded PXE International, a research advocacy organization for the genetic condition pseudoxanthoma elasticum (PXE), in response to the diagnosis of PXE in her two children in 1994. With her husband, she co-discovered the ABCC6 gene, patented it to ensure ethical stewardship in 2000, and assigned their rights to the foundation. She subsequently developed a diagnostic test and conducts clinical trials. She is the author of 140 peer-reviewed papers, of which 30 are clinical PXE studies.

In her focus at the forefront of consumer participation in genetics research, services and policy, she serves in a leadership role on many of the major international and national organizations, including the Precision Medicine Initiative Cohort Advisory Panel, Accelerating Medicines Partnership, Institute of Medicine (IOM) Science and Policy Board, the IOM Roundtable on Translating Genomic-Based Research for Health, the PubMed Central National Advisory Committee, the PhenX scientific advisory board, the Global Alliance for Genomics and Health, the International Rare Disease Research Consortium Executive Committee and as Founding President of EspeRare Foundation of Geneva, Switzerland. Terry is co-founder of the Genetic Alliance Registry and Biobank. She is on the editorial boards of several journals. She led the coalition that was instrumental in the passage of the Genetic Information Nondiscrimination Act. She received an honorary doctorate from Iona College for her

community engagement work in 2006; the Research!America Distinguished Organization Advocacy Award in 2009; and the Clinical Research Forum and Foundation's Annual Award for Leadership in Public Advocacy in 2011. She was named one of FDA's "30 Heroes for the Thirtieth Anniversary of the Orphan Drug Act" in 2013. She is co-inventor of the Platform for Engaging Everyone Responsibly (PEER). PEER received $500,000 from the Robert Wood Johnson Foundation in 2014. PEER undergirds the Community Engaged Network for All (CENA), a PCORnet member funded in 2013 for Phase I and in 2015 for Phase II. She is Co-PI of the PCORnet Coordinating Center and Chair of the PCORnet Engagment Committee.

Joyce Tung, Ph.D.
Joyce joined 23andMe in 2007 and manages the 23andMe research team, which is responsible for consumer health and ancestry research and development, academic and industry collaborations, computational analyses for therapeutics, and new research methods and tools development. While a postdoctoral fellow at Stanford University, Joyce studied the genetics of mouse and human pigmentation. She graduated from Stanford with honors and distinction with a B.S. in Biological Sciences and a minor in computer science, and earned her Ph.D. in Genetics from the University of California, San Francisco where she was a National Science Foundation graduate research fellow.

Genomewide Association Study of Severe Covid-19 with Respiratory Failure

BACKGROUND

There is considerable variation in disease behavior among patients infected with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the virus that causes coronavirus disease 2019 (Covid-19). Genomewide association analysis may allow for the identification of potential genetic factors involved in the development of Covid-19.

A Host Transcriptional Signature for Presymptomatic Detection of Infection in Humans Exposed to Influenza H1N1 or H3N2

BACKGROUND

There is great potential for host-based gene expression analysis to impact the early diagnosis of infectious diseases. In particular, the influenza pandemic of 2009 highlighted the challenges and limitations of traditional pathogen-based testing for suspected upper respiratory viral infection.

A crowdsourced analysis to identify ab initio molecular signatures predictive of susceptibility to viral infection

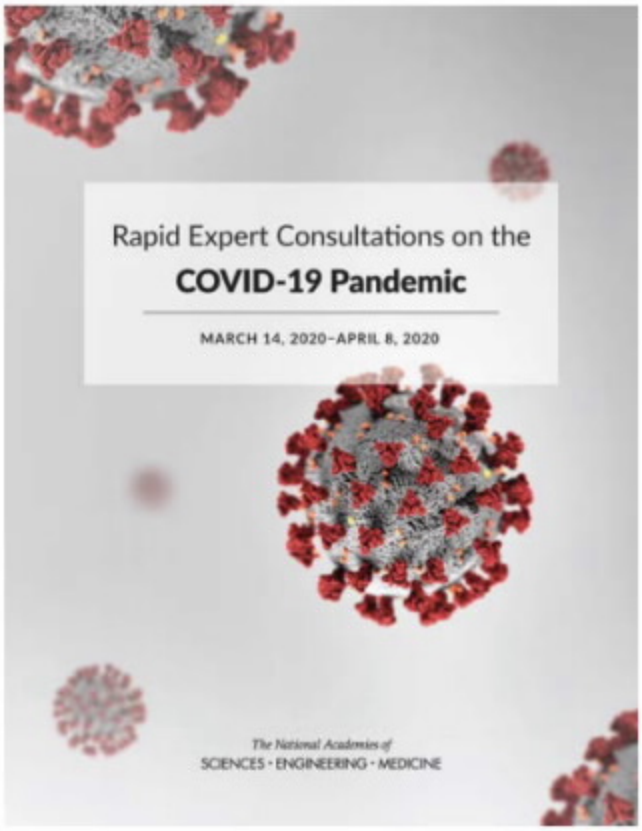
BACKGROUND

The response to respiratory viruses varies substantially between individuals, and there are currently no known molecular predictors from the early stages of infection. Here we conduct a community-based analysis to determine whether pre- or early post-exposure molecular factors could predict physiologic responses to viral exposure.

A Host-Based RT-PCR Gene Expression Signature to Identify Acute Respiratory Viral Infection

Improved ways to diagnose acute respiratory viral infections could decrease inappropriate antibacterial use and serve as a vital triage mechanism in the event of a potential viral pandemic. Measurement of the host response to infection is an alternative to pathogen-based

diagnostic testing and may improve diagnostic accuracy. We have developed a host-based assay with a reverse transcription polymerase chain reaction (RT-PCR) TaqMan low-density array (TLDA) platform for classifying respiratory viral infection.



Rapid Expert Consultations on the COVID-19 Pandemic

In response to a request from the Office of Science and Technology Policy and the Office of the Assistant Secretary for Preparedness and Response, the National Academies of Sciences, Engineering, and Medicine convened a standing committee of experts to help inform the federal government on critical science and policy issues related to emerging infectious diseases and other 21st century health threats. This set of Rapid Expert Consultations are the first of their kind and represent the best evidence available to the Committee at the time each publication was released.

Research in context

Evidence before this study

An increasing body of research has demonstrated that host gene expression patterns in peripheral blood offer a high degree of accuracy for diagnosis of acute infections at the time of clinical presentation.

Added value of this study

For the first time we demonstrate in a real-world setting that a blood-based gene expression test can accurately predict impending viral infection even before typical symptoms are present.

Implications of all the available evidence

These data show that biomarkers of viral infection are present and detectable even before clinical disease develops, opening the door to novel approaches to early treatment and outbreak management.

Abstract

Background

Early and accurate identification of persons with viral infections can be of critical importance for clinical management and public health interventions. Measuring host responses through gene signature-based biomarkers offer promise for improved diagnosis of respiratory viral infections, but little is known how early in disease such measures may be effective.

Methods

We performed a modified index-cluster study in 1465 university dormitory residents over five years. Each year, we monitored for symptomatic Index Cases (IC) and identified clusters of their Close Contacts (CC) who would be at presumed increased risk of developing symptomatic respiratory tract infection (RTI) while under observation. We then monitored each CC for 5 days for development of RTI and measured transcriptomic responses at each timepoint via a blood-based 36-gene RT-PCR assay.

Findings

Of 264 ICs with RTI symptoms, 150 (56%) had a confirmed viral etiology detected. Of their 555 CCs, 106 (19%) developed symptomatic RTI with a proven viral etiology during the observation window. The transcriptomic assay accurately predicts infection at the time of peak symptoms despite heterogeneity of hosts and nine different viral etiologies (auROC 0·96). Furthermore, these genomic biomarkers are capable of identifying early disease one, two and three days prior to peak illness when minimal to no symptoms are present (auROC 0·87, 0·86, and 0·77, respectively), and when nearly two-thirds of subjects (62%) are not yet producing detectable viral shedding.

Interpretation

Transcriptional biomarkers accurately predict and diagnose infection across diverse viral etiologies and stages of disease, and may prove useful for guiding administration of early effective therapy, quarantine decisions, and other clinical and public health interventions in the setting of endemic and pandemic infectious disease.

Funding: US Defense Advanced Research Projects Agency

Introduction

Acute viral infections are among the most common causes of acute physician visits in the United States[1]. In a given year, influenza alone affects 5-20% of the population in the US, causes over 400,000 hospitalizations, and as many as 56,000 deaths.[2,3] Outbreaks of viral infection continue to plague modern society, including heavy resource-requiring outbreaks of measles in the developed world, global pandemics like the novel H1N1 outbreak of 2009, or the deadly epidemics of SARS and MERS-CoV.[4-6] However, molecular tools that can contribute to outbreak investigation or directing early clinical management are often lacking. Traditional pathogen-focused diagnostic modalities for viral infection (culture, serology, antigen detection, PCR) offer considerable utility but can also be slow, costly, limited in terms of breadth of pathogen detection, require an *a priori* knowledge of the pathogen to be tested, may not detect emerging strains (as with the 2009 influenza pandemic[7]), or are incapable of distinguishing between active infection and colonization, all of which can minimize the impact of their use. Therefore, there is increasing interest in host-derived biomarkers to aid in the determination of the presence and/or type of infection in at-risk hosts - from single-analyte biomarkers like procalcitonin to composite, multiplex biomarker panels such as those included in a growing number of gene expression-based studies.[8-21] However, the published works on diagnostics for naturally-acquired infection focus on identifying symptomatic subjects at the time of clinical presentation for medical care[19], which is often late in the time course of many viral diseases. Identification of infectious etiologies in earlier, even pre-symptomatic phases of illness, offers the ability to optimize and deliver timely and thus more effective therapy, refine prophylaxis decisions, and guide public health interventions such as isolation and quarantine.[13,22] However, identifying subjects who have been exposed to infectious virus but are not yet exhibiting symptoms of clinical illness is logistically challenging, resulting in a dearth of literature to address these problems.

We have previously shown that during experimental influenza infection of healthy volunteers the host genomic response is robust and detectable well before typical symptoms become apparent.[16,22,23] Other

investigators have confirmed that transcriptomic markers can be indicative of early viral infection in experimental human challenge models as well as animal models of disease.[24-27] However, the mechanism of challenge infection is contrived rather than natural, typically consists of highly egg-adapted viral strains, and the severity of clinical illness does not fully replicate that seen in naturally-acquired infection, all of which can limit the broad applicability of findings from this approach.[16,22,28-31] To date there has been no significant description of the host response to infection during the pre-symptomatic phase of naturally-occurring disease. Here we have utilized a unique index-cluster study design with a focus on serial sampling of 'real world', healthy close contacts of infected individuals to enrich for cases of naturally-occurring infection during these early, post-exposure, but pre-symptomatic time points. This unique design has permitted real-world validation of a transcriptomic signature in peripheral blood that is capable of accurately identifying exposed but apparently healthy individuals who will go on to develop symptomatic viral infection.

Methods

Surveillance Cohort

Over five academic years, we enrolled 1465 Duke University undergraduate students (age 18-24, most of whom live in dormitories on campus) in a modified index-cluster study design (Figure 1). At the time of enrollment, we collected baseline biospecimens and standardized questionnaires to ascertain demographic, behavioral, and other medical characteristics. After enrollment, participating students completed a daily, web-based survey to describe the presence and severity of eight symptoms of RTI (scored 0-4) on a daily basis (see eMethods for details). We monitored the surveys daily for a 6-point increase in a subject's cumulative daily symptom score which would trigger a sample and data collection event for a potential Index Case. Suspected ICs were then assessed for confirmation of illness and biospecimen collection. Using these sentinel cases of RTI suggestive of viral etiology we then identified and monitored a prospective observational cohort of asymptomatic but potentially exposed Close Contacts (people living in the same dormitory or identified by the IC as a Close Contact), who were then monitored and sampled for up to 5 days (the Observation Window).

Sample and data collection

Confirmed IC's provided blood and nasal swab samples at the time of illness identification. Viral etiology was assessed using a commercial multiplex PCR assay (QIAGEN ResPlex II v2·0, Luminex RVP, or Biofire FilmArray RP). Healthy CCs living in proximity to an IC provided blood and respiratory samples for up to five consecutive days and were monitored for symptomatic conversion and viral shedding.

Real-time PCR

Peripheral blood was collected in PAXgene™ Blood RNA tubes (PreAnalytiX), and total RNA extracted using the PAXgene™ Blood miRNA Kit (QIAGEN). cDNA synthesis was performed using SuperScript VILO™ Master Mix (Invitrogen) according to manufacturer's instructions. Real-time PCR was performed using custom TLDA 384-well microfluidic cards with TaqMan Gene Expression Master Mix, and run on a ViiA7 Real-Time PCR System (Applied Biosystems).

Statistical Analysis

For RT-PCR data the Cq values were transformed into normalized relative quantities using reference genes - those with the most stable combined coefficient of variation across all samples - FPGS and TRAP1 were used for the first batch, and DECR1 and TRAP1 were used for the second batch, and data was normalized as previously described.[8,9] We utilized a regularized (2-norm) logistic regression model to discriminate cases from controls (see eMethods for complete details). The data was split into training and testing sets 25 times using repeated random subsampling and each of the 25 models was trained using all timepoints. We evaluated the model's performance separately at each individual timepoint. All model analyses were implemented in Python and Tensorflow.[32]

Results

Brief Description of Study

Healthy first year students at Duke University (n=1465) were enrolled into a surveillance cohort at the beginning of each academic year. After enrollment, we electronically monitored self-reported daily symptoms throughout the duration of the academic year via an online portal. When one or more subjects indicated a change in respiratory symptoms, the sample collection protocol was initiated for individuals (Index Cases, ICs) that met the clinical case definition for acute, community-acquired RTI (see Methods), as well as for a subset of other currently healthy study participants who were in close proximity to the Index Case (Close Contacts, CCs). CCs were monitored for symptoms and serially sampled for serum, whole blood PAXgene RNA, and respiratory samples for 5 days from identification of their Index Case, regardless of symptomatology (Figure 1). This design permitted enrichment for, and collection of, samples from CCs during the timeframe between exposure (which occurred at an unknown time) and subsequent development of symptomatic disease (which occurred under observation).

Prevalence, Transmission, and Clinical Outcomes of Viral Respiratory Tract Infection

We identified 264 clinical ICs, of whom 150 had a confirmed respiratory viral etiology by multiplex PCR testing of NP samples, and 555 CCs, 19% (106) of whom developed symptomatic RTI with concomitant confirmatory viral PCR. Only 57% of the CCs were infected with the same virus as their associated IC. Nine different viral pathogens were detected, and there was marked variation in viral etiologies detected from year to year (Table 1). Infection resulted in many common symptoms of upper respiratory tract infection with clinical variation amongst viral etiologies (Figure 2). For example, symptoms were almost twice as severe in individuals with influenza infection compared to all other viruses (mean symptom score of 20 for influenza vs 13 for all others ($p=0.005$)), although all subjects in the study remained well enough to be managed in the outpatient setting.

Since the exact time of exposure/transmission during naturally-acquired infection is unknown, for analysis CC days were aligned to the time of maximal illness (day of highest symptom score) for each subject (Time "T") in order to attempt to place subjects on broadly similar time scales in terms of the host response to infection. The average total symptom score for all CCs at Time T was 14·8, although this varied by viral etiology (Figures 1,2). For each individual CC, the day before their day of maximal symptoms was termed T-minus 1 ("T-1"), 48 hours prior to symptom max was "T-2" and 72 hours prior to symptom max was time "T-3". At times prior to maximal illness the average total symptom score for CCs was 7·0 (T-1), 4·1 (T-2), and 1·7 (T-3). In our studies a daily symptom score of 6 represents mild clinical illness and was the threshold for defining a 'symptomatic' day. Thus, at days T-2 and earlier, most subjects exhibited subclinical or absent illness (65% asymptomatic at Time T-3, 32% at T-2).

An RT-PCR signature identifies symptomatic subjects with naturally-acquired viral RTI

We previously developed a host response-derived transcriptomic signature of symptomatic viral infection using microarray data[30]. However, microarray and bulk RNA sequencing platforms are impractical for rapid clinical testing. We therefore migrated our prior 'pan-viral' signature to an RT-PCR platform with potential for more direct translation to point-of-care testing [8,9]. Using sparsity-imposing techniques (see eMethods), we selected 36 pre-designed TaqMan probes representing genes comprising the acute respiratory viral signature (and normalization controls) to be used on a TaqMan Low Density Array (TLDA) platform[8]. We then utilized a regularized (2-norm) logistic regression model to determine coefficients for each gene in the signature[33], such that the output of the model is a probability that a given subject will go on to have a symptomatic, viral PCR-positive event during the observation window. The performance of the RT-PCR signature for classification of symptomatic individuals was evaluated using a repeated random subsampling validation strategy on relevant participants across all study years. Overall, the RT-PCR-based host gene expression assay distinguished symptomatic, virus-infected subjects from asymptomatic, viral PCR-negative controls with 92% accuracy (Figure 3). However, accuracy varied depending on viral etiology, ranging from 99% accuracy in influenza infection (where symptoms are

typically more severe) to 92% with Coronavirus and 81% accuracy with metapneumovirus infections (eFigure 1). Interestingly, analysis of individual gene components of the model demonstrates that many individual genes performed similar to the aggregate model across all iterations (eFigure 2-3). In fact, many individual gene targets alone had mean area under Receiver Operating Characteristic (auROC) of >0·90 at the time of maximal illness with the top performing genes at time T being IFIT3 (0·97), HERC5 (0·97), and RSAD2 (0·96)

The gene expression signature identifies naturally-acquired viral RTI during the pre-symptomatic phase.

In order to evaluate performance of the gene signature early in the course of natural infection, we selected CCs with positive microbiology and at least three days of sampling prior to the development of maximal symptoms. As noted previously, the RT-PCR gene signature correctly identified symptomatic subjects with 92% accuracy on the day of maximal symptoms. This decreased to 88% on day T-1 (24 hours before maximal symptoms), and 83% accuracy on day T-2 (48 hours before maximal symptoms) (Figure 3), although performance varies from virus to virus. Only one case of influenza infection had available pre-symptomatic samples at all times, and the signature correctly classified that individual at each timepoint (T-1, T-2, T-3, and T-4). For a fixed FPR of 0·2 (specificity 0·8), the model achieves greater sensitivity than either symptoms alone or viral PCR at all timepoints other than time T and for ICs (where symptom-based diagnosis by definition has a 100% sensitivity, eFigures 4-6). Critically, 62% of subjects who would develop proven viral RTI lacked detectable viral shedding at time T-3, and 44% were still negative for virus by routine clinical testing at day T-2, times where the gene signature outperforms the clinical standards of care - symptom evaluation and viral PCR.

Discussion

The unique design of this community study has allowed us to identify individuals (CCs) at increased risk for developing viral RTI while under observation. This approach has enabled us to demonstrate for the first time that host responses to naturally-acquired respiratory viral infection, as measured by gene expression in peripheral blood, are present well before the time of maximal illness and can be used to predict those at highest risk for developing active infection.

This study demonstrates that conserved genomic responses can be used to correctly classify individuals with a broad array of naturally-acquired respiratory viral infections well before the time when they would present for clinical evaluation, and even before detectable viral shedding begins for the majority of subjects (62%). The promise of this approach is manifested by the discriminative ability of the genomic signature from two and three days prior to maximal illness, when many individuals (65% at Time T-3, 32% at T-2) have no symptoms at all. Even the mild symptoms some subjects do have at early times are clinically vague and would be typical of seasonal allergies, mild COPD flares, or even symptoms due to sequelae of chronic smoking.[34] The potential utility of genomic analysis to classify viral infection among asymptomatic individuals or those with common, nonspecific upper respiratory symptoms is profound. That this holds true across 9 different respiratory viruses, each with its own incubation times and variable clinical progression and duration, also speaks to the potential power of this approach. Additionally, it is important to note that the signature utilized represents conserved underlying antiviral response pathways that are active, and thus discriminatory, across a wide range of illness and not just at early times. This is vital as any real-world use of such a biomarker assay would often be agnostic to where in the course of infection an individual exists at the moment of testing.

While this transcriptomic signature accurately classifies a wide spectrum of viral RTIs, it performs best in a subset of viruses including influenza and coronavirus, where it performs with a high degree of accuracy even during early and pre-symptomatic phases of disease. Influenza is one of the most important viral etiologies to identify early given its importance in pandemics where existing diagnostics may perform

poorly (especially for emerging strains as in 2009[35]), where questions of triage and quarantine are paramount, and where effective therapeutic options are readily available and most effective when given early in disease. Similarly, a number of novel highly virulent coronaviruses, including SARS-CoV and MERS-CoV, have recently arisen and driven global outbreaks, highlighting another area of need for such diagnostics.[5,36].It seems likely that our ability to accurately detect exposure to these types of emerging infections will only become more critical over time. Availability of tools that can aid in assessment of those with potential exposure, especially those that offer diagnostic utility prior to the time of detectable viral shedding, would be a valuable aid to existing epidemiologic and molecular approaches in outbreak settings.

A number of other studies have described interferon response-based transcriptomic signatures of acute respiratory infections which vary by target population, pathogens, modelling approaches, and numbers of genes required to discriminate disease states. [9,10,13-18,30] Some of this work has also been validated, combined, or expanded upon by secondary *ex vivo* analysis of publicly available data. [11,12,37] While the focused signature described here clearly represents a limited subset of all discriminating genes, some observations regarding simplified, IFN-driven signatures can be made. Our data confirm that that some genes from these prior works (such as IFI44L and IFI27[10,38]) both perform well as classifiers distinguishing between viral illness and the healthy state (median auROC = 0·92 and 0·87), being strongly upregulated in cases of viral infection. The data further suggest that a number of other single targets also perform this task well including RSAD2 (0·96), IFIT3 (0·97), and IFI44 (0·93). Based on our experience and the published literature, it seems that relatively simple classification tasks - where the biological responses are highly conserved, unique in character, and of great magnitude - may be reasonably addressed with pauci-analyte biomarker panels.[10,12,39-41] However, as complexity increases by adding more powerful interhost variability (such as immunosuppression), discriminating clinically similar groups with more varied underlying pathophysiology, or discriminating multiple clinical mimics at once,

more intricate biomarker panels will likely be required to maintain high fidelity in real-world settings.[9,14,42]

Our study has several limitations. This project was designed to validate the predictive power of a small set of genes which already had proven discriminatory capability during maximal illness, and thus was not designed to discover whether additional, untested gene sets may offer improved discriminatory performance at early times. Future work with RNASeq on whole blood, single cell sequencing, or other methods will be needed to more completely define early genomic changes in the naturally-infected host. Additionally, our patient cohort was comprised of otherwise young, healthy individuals with community-acquired viral RTI of mild to moderate severity. Therefore, application to patient populations from other age groups, those with immunologic comorbidities, or with more severe viral infections will need to be evaluated. Finally, we did not identify any confirmed infections due to bacterial or other pathogens. As a result, while these transcriptomic markers show great promise for differentiating early infection and pre-symptomatic viral exposure from noninfectious states (which it may mimic at early times), this study did not directly validate the ability of these markers to differentiate viral exposure from early forms of other types of infection[9,10,14,43]. As we move towards bringing transcriptomic biomarkers to the bedside, consideration of broad applicability and performance across a wide array of clinical settings will continue to be paramount.

We have for the first time defined the pre-symptomatic and temporal dynamics of transcriptomic biomarkers characterizing the host response to naturally-acquired viral infections in humans. Clinic-ready platforms capable of operationalizing PCR-based signatures of the size tested herein already exist, some of which are CLIA-approved with point-of-care functionality, offering a proximal pathway to clinical application of these findings. Thus, analysis of the evolution of gene expression-based biomarkers over time shows promise for driving development of diagnostics for early detection of viral exposure and infection which may prove useful for guiding administration of early effective therapy, quarantine

decisions, and other clinical and public health interventions in the setting of endemic and pandemic infectious disease.

Funding

Funding for this study was provided by the US Defense Advanced Research Projects Agency (DARPA), project # N66001-07-C-2024 and W911NF1410052. The statements and conclusions herein are those of the authors and do not reflect the position or policy of the United States Government.

Author contributions

MTM, ELT, GSG and CWW drafted the manuscript, which was critically revised by all remaining authors. MTM, BPN, TB, TV, GSG, and CWW helped conceive and implement the study. All authors helped acquire, analyze, or interpret data. Statistical analyses were performed by FJC, RH, SS, MN, and LP.

Figures

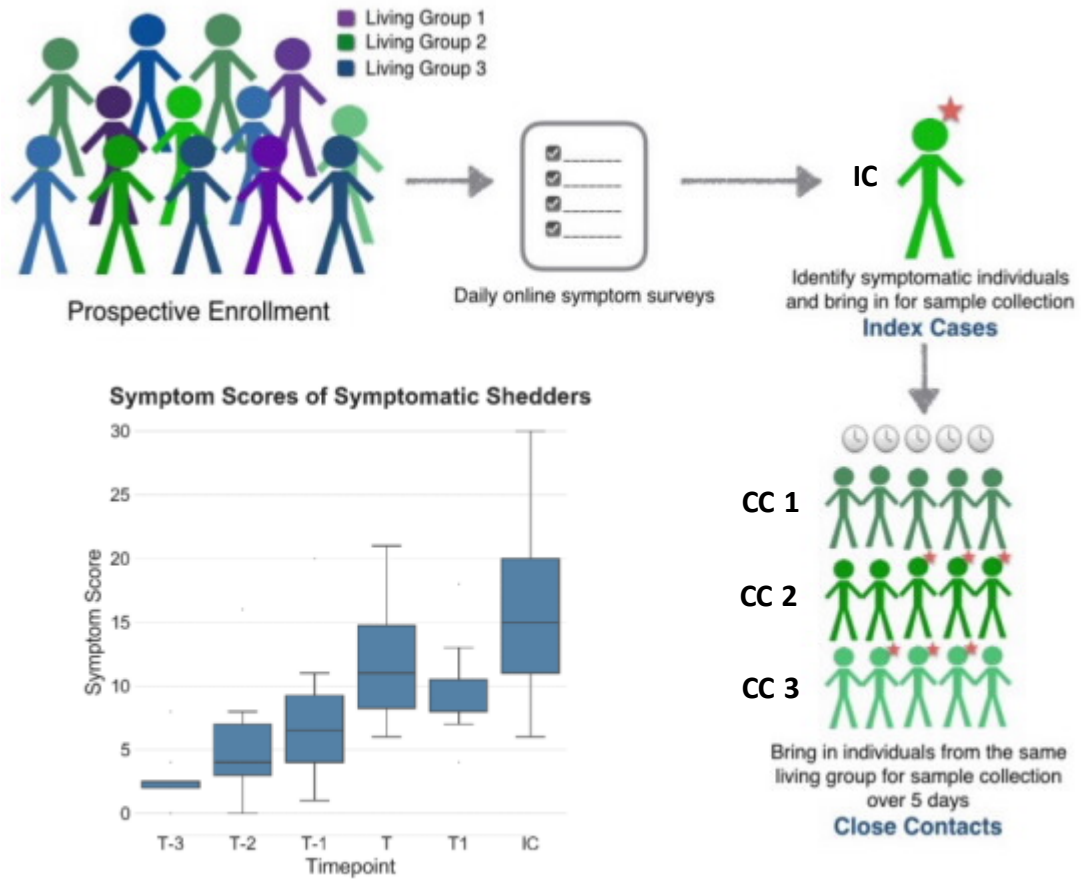

Figure 1: Study design. Students were enrolled at the beginning of the school year. Index Cases were identified when daily symptom surveys indicated potential respiratory illness. This flagged serial sampling of their Close Contacts, some of whom would also develop RTI during the 5-day observation window (red stars). This unique model permits blood sampling of some Close Contacts during early and presymptomatic phases of illness. Mean symptom scores of Close Contacts who developed PCR-proven RTI under observation are presented.

SUMMARY

The SARS-CoV-2 spike (S) protein variant D614G supplanted the ancestral virus worldwide in a matter of months. Here we show that D614G was more infectious than the ancestral form on human lung cells, colon cells, and cells rendered permissive by ectopic expression of various mammalian ACE2 orthologs. Nonetheless, D614G affinity for ACE2 was reduced due to a faster dissociation rate. Assessment of the S protein trimer by cryo-electron microscopy showed that D614G disrupts a critical interprotomer contact and that this dramatically shifts the S protein trimer conformation toward an ACE2-binding and fusion-competent state. Consistent with the more open conformation, neutralization potency of antibodies targeting the S protein receptor-binding domain was not attenuated. These results indicate that D614G adopts conformations that make virion membrane fusion with the target cell membrane more probable but that D614G retains susceptibility to therapies that disrupt interaction of the SARS-CoV-2 S protein with the ACE2 receptor.

INTRODUCTION

Next-generation sequencing permits real-time detection of genetic variants that appear in pathogens during disease outbreaks. Tracking viral variants now constitutes a requisite component of the epidemiologist's toolkit, one that can pinpoint the origin of a zoonotic virus and the trajectory it takes from one susceptible host to another (Hadfield et al., 2018; Shu and McCauley, 2017). Lagging behind sequence-based modeling of virus phylogenies and transmission chains is the ability to understand the effect of viral variants on the efficiency of transmission between hosts or on the clinical severity of infection. Most sequence variants that arise during virus replication are either detrimental to the fitness of the virus or without consequence. Even so, such variants can increase in frequency over the course of an outbreak by chance (Grubaugh et al., 2020). More rarely, though, increasing frequency of a variant can reflect competitive advantage due to higher intrinsic replication capacity, with increased viral load and transmissibility.

In December 2019, an outbreak of unexplained fatal pneumonia became apparent in Wuhan City, Hubei Province, China. By early January 2020, SARS-CoV-2 was identified as the virus causing the disease (Huang et al., 2020; Lu et al., 2020; Wu et al., 2020a, 2020b; Zhou et al., 2020b; Zhu et al., 2020). After SARS-CoV (Drosten et al., 2003; Ksiazek et al., 2003) and MERS-CoV (Zaki et al., 2012), SARS-CoV-2 is the third human coronavirus this century known to cause pneumonia with a significant case-fatality rate (Coronaviridae Study Group of the International Committee on Taxonomy of Viruses, 2020). Hundreds of coronaviruses have been identified in bats, including at least 50 SARS-like *Sarbecoviruses (Lu et al., 2020; Zhou et al., 2020a).* The virus closest in sequence to SARS-CoV-2 observed to date was isolated from a bat

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

(Zhou et al., 2020b) though the most proximal animal reservoir for SARS-CoV-2 remains unknown (Andersen et al., 2020; Lam et al., 2020).

Over the course of the SARS-CoV-2 pandemic, there have been reports of super-spreaders and transmission chains that have been more difficult to interrupt in some locations than in others (Hu et al., 2020). As few as 10% of SARS-CoV-2 infected people account for the majority of virus transmission events (Endo et al., 2020). Reported case fatality rates have varied by more than 10-fold (Center for Systems Science and Engineering at Johns Hopkins University; COVID-19 National Emergency Response Center, Epidemiology and Case Management Team, Korea Centers for Disease Control and Prevention, 2020; Grasselli et al., 2020; Onder et al., 2020). Such differences may reflect regional differences in the age of susceptible populations or the prevalence of comorbidities such as hypertension. Regional variation in diagnostic testing frequency, or in rate of reporting, is another likely explanation for these differences, since a wider net of diagnostic testing will capture milder cases (Zhao et al., 2020). Understanding the cause of these observed differences is critical for rational utilization of limited medical resources to counteract the pandemic.

Coronaviruses have the largest genomes of any known RNA viruses (Saberi et al., 2018) and they encode a 3'-to-5'-exoribonuclease required for high-fidelity replication by the viral RNA-dependent RNA polymerase (Denison et al., 2011; Smith et al., 2014). By preventing otherwise lethal mutagenesis (Smith et al., 2013), the repair function of the coronavirus exonuclease is thought necessary for the coronavirus genome size to extend beyond the theoretical limit imposed by error rates of viral RNA polymerases (Holmes, 2003). Though the rate of sequence variation among SARS-CoV-2 isolates is modest, over the course of the pandemic the virus has had opportunity to generate numerous sequence variants, many of which have been identified among the thousands of SARS-CoV-2 genomes posted for public

RESULTS

The SARS-CoV-2 D614G S protein variant supplanted the ancestral virus

Minimal genetic variation among SARS-CoV-2 genomes sequenced from the earliest COVID-19 cases suggests that a recent common ancestor gave rise to all SARS-CoV-2 genomes seen during the outbreak (Rambaut et al., 2020). Over the course of the pandemic, a total of 12,379 distinct single nucleotide polymorphisms (SNPs) have been identified in genomic data (relative to the ancestral genome NC_045512.2; GISAID download on 25 June 2020), 99.5% of which are within viral genes, and 63.3% of which encode amino acid changes. 6,077 of the SNPs were seen only once in the dataset and only four SNPs rose to high frequency. Among the latter, A23403G was first reported at the end of January 2020 in virus genomes from China (hCoV-19/Zhejiang/HZ103/2020; 24 January 2020) and Germany (hCoV-19/Germany/BavPat1-ChVir929/2020; 28 January 2020). Given how few SARS-CoV-2 genomes have been sequenced from early in the outbreak, the geographic origin of A23403G cannot be determined.

The frequency of A23403G has increased steadily over time. It is now present in approximately 74% of all published sequences (Figure 1A). Sequences that have become available over recent weeks indicate that it has nearly reached fixation globally (Figure 1A), as well as separately within Europe, North America, Oceania, and Asia (Figure 1B). A23403G emerged at higher frequency in Africa and South America, suggesting a founder effect where a plurality of introductions carried it to these regions. Although recent data for South America are sparse, available sequences suggest A23403G is approaching fixation in this continent as well. Thus, A23403G is now universally common on every continent except Antarctica.

The SARS-CoV-2 D614G S protein variant increases infectivity in cell culture

The non-synonymous nucleotide change A23403G encodes the SARS-CoV-2 spike (S) protein variant D614G. The ability of the D614G S protein variant to target virions for infection of ACE2-positive cells was assessed using single-cycle lentiviral vector pseudotypes in tissue culture. Mammalian expression plasmids were engineered to encode the ancestral S protein D614 or the D614G variant. Each S protein expression plasmid was separately transfected into HEK-293 cells with plasmids encoding HIV-1 structural proteins and enzymes. Separate plasmids were transfected that encode RNAs with HIV-1 *cis*-acting signals for packaging and replication, and either GFP or luciferase (Luc) reporter cassettes. For each condition tested, multiple virus stocks were produced and tested individually after vector particle normalization using reverse transcriptase activity. 48 hours after challenge with the vectors, the transduction efficiency of each virion preparation was assessed by measuring the percent GFP-positive cells using flow cytometry, or by quantitating target cell-associated luciferase activity.

When Calu-3 human lung epithelial cells were used as targets, challenge with virus bearing D614G resulted in 6-fold more GFP-positive cells, or 5-fold more bulk luciferase activity, than did particles bearing D614 S protein (Figure 2A). When Caco-2 human colon epithelial cells were used as target cells, 4-fold higher infectivity was observed with D614G (Figure 2A). Additionally, when HEK-293 cells or SupT1 cells had been rendered infectable by stable expression of exogenous ACE2 and TMPRSS2, D614G was 9-fold more infectious than D614 (Figure 2A).

D614G increases infectivity on target cells bearing different ACE2 orthologs

The likely zoonotic origin of SARS-CoV-2 raises the question whether D614G was selected during the pandemic as a result of human-to-human transmission. Structural and biochemical studies (Letko et al., 2020; Walls et al., 2020; Wrapp et al., 2020; Zhou et al., 2020b) have

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

shown that SARS-CoV-2 bears a receptor binding domain with high affinity for ACE2 from humans, ferrets, cats, and other species that encode similar ACE2 (Wan et al., 2020). In a heterologous expression system, human, civet, horse-shoe bat, and pig orthologs each conferred susceptibility to infection, while the mouse ortholog did not (Zhou et al., 2020b). To determine whether the increased infectivity of D614G is specific for certain ACE2 orthologs, HEK-293 were transfected separately with plasmids encoding ACE2 orthologs from human (*Homo sapiens*), Malayan pangolin (*Manis javanica*), pig (*Sus scrofa*), cat (*Felis catus*), dog (*Canis lupis*), rat (*Rattus norvegicus*), or mouse (*Mus musculus*). Each ACE2 transfectant was then challenged with luciferase reporter viruses bearing SARS-CoV-2 Spike protein, either D614 or D614G. Relative increase in infectivity due to D614G was comparable in cells expressing human, pangolin, pig, cat, or dog ACE2 orthologs (Figure 2B). The relative increase in infectivity due to D614G on cells bearing rat or mouse ACE2 orthologs could not be quantitated since, in both cases, the luciferase activity with D614 was too close to background. These results suggest that increased infectivity due to D614G is not specific for human ACE2.

D614G does not alter S protein synthesis, processing, and incorporation into SARS-CoV-2 particles

The effect of D614G on S protein synthesis, processing, and incorporation into virion particles produced by SARS-CoV-2 structural proteins was assessed next (Figure 3A). HEK-293T cells were transfected with plasmids expressing each of the four SARS-CoV-2 virion-associated structural proteins (Figure 3A). Western blots were then performed on the cell lysate and on proteins from the pellet after ultracentrifugation of the transfection cell supernatant. The minimal requirement for virion assembly by other coronaviruses is the membrane protein (M) and the envelope protein (E) (for mouse hepatitis virus (Bos et al., 1996; Vennema et al., 1996)), or the

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

M and nucleocapsid protein (N) (for SARS-CoV (Huang et al., 2004)). In the case of SARS-CoV-2, M protein production was sufficient to release particles from transfected cells, though particle release by M was increased by co-production of N (Figure 3B). The S proteins D614 and D614G were produced to comparable levels, processed to S1 and S2 with comparable efficiency, and incorporated into SARS-CoV-2 virus-like particles at similar levels (Figure 3B). These results suggest that increased infectivity due to D614G is primarily manifest after virion assembly, during entry into target cells.

D614G decreases the affinity for ACE2 by increasing the rate of dissociation

The receptor-binding domain of the S protein interacts directly with ACE2, the primary entry receptor for SARS-CoV and SARS-CoV-2 on susceptible target cells (Hoffmann et al., 2020; Letko et al., 2020; Tian et al., 2020; Wrapp et al., 2020; Zhou et al., 2020b). Though D614G is located outside of the receptor-binding domain, this non-conservative amino acid change might alter ACE2-binding properties via allosteric effects. Surface plasmon resonance (SPR) was used to determine if the kinetics of SARS-CoV-2 S protein binding to human ACE2 is changed by D614G. Human ACE2 was immobilized and the binding of soluble, trimeric SARS-CoV-2 S protein, either D614 or D614G, was detected. At 25°C, the rate of association with ACE2 was little different between D614G and D614, but D614G dissociated from ACE2 at a rate four-fold faster than D614, resulting in a 5.7-fold reduction in binding affinity (Figure 4). At 37°C, the association rate between D614G and ACE2 was slower than between D614 and ACE2, and the dissociation rate of D614G was faster, again resulting in five-fold reduction in binding affinity (Figure 4). These data demonstrate that the increased infectivity of D614G is not explained by greater ACE2 binding strength.

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

D614G and the ancestral S protein are equally sensitive to neutralization by monoclonal antibodies targeting the receptor binding domain

The global spread and enhanced infectivity of the SARS-CoV-2 D614G variant raises the question of whether this change in S protein structure may compromise the effectiveness of antiviral therapies targeting this viral protein, especially if they were designed to target D614. To determine if this is the case, the neutralization potency of four monoclonal antibodies that target the SARS-CoV-2 Spike protein receptor-binding domain was assessed. These fully human monoclonal antibodies are currently under evaluation in clinical trials (NCT04425629, NCT04426695) as therapeutics for COVID-19 (Hansen et al., 2020). Each of these monoclonal antibodies, whether tested individually or in various combinations, demonstrated similar neutralization potency against D614G as they did against D614 (Figure 5).

D614G changes the conformation of the S1 domain in the SARS-CoV-2 S protein

Structural studies of the trimeric S protein ectodomain demonstrate that the receptor-binding domain of each protomer can independently adopt either a closed or an open conformation, giving rise to asymmetric trimers (Walls et al., 2020; Wrapp et al., 2020). The open conformation is believed to be required for ACE2-binding and to be on-pathway for S protein-mediated fusion of the virion membrane with the target cell membrane (Tortorici and Veesler, 2019). Since the increased infectivity of D614G was not explained by increased affinity for ACE2 (Figure 4), cryo-electron microscopy (cryo-EM) was used to illuminate potential structural features that distinguish D614G from D614. Both S protein variants, D614 and D614G, were expressed in mammalian cells as soluble trimers. When enriched from culture media, and eluted from a size exclusion column, single peaks were observed for each variant protein at ~500 kD, the predicted mass of the homotrimer (Figure 6A, blue line). Enrichment of the protein complexes, and integrity of the full-length protomers, was additionally confirmed by SDS-PAGE (Figure 6B).

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

Well-defined particles of S protein trimers were evident by cryo-EM, and reference-free, two-dimensional clustering revealed structural details from different orientations (Figure 6C). Three-dimensional clustering and refinement generated the final density map for D614G (Figure 6D, EMD-22301), which showed a similar overall architecture to the published map of D614 (Figure 6E), but with distinct features, as discussed below. Unmasked Fourier shell correlation (FSC) analysis indicated that the D614G map had a mean resolution of 3.7 Å (gold-standard criteria, Figure 6F), which is sufficient to reveal fine differences from D614.

The SARS-CoV-2 S protein consists of S1 and S2 subunits, with multiple domains within S1 (Figure 6G). Comparing the map of D614G with that of D614, the N-terminal domain (NTD), the intermediary domain (INT), and the C-terminal domain (CTD) of the S1 subunit were clearly identified. However, the density corresponding to the receptor binding domain (RBD) that was well-resolved in D614 (arrows, Figure 6E), was missing in the D614G map, suggesting that the RBD is flexible and adopts multiple conformations (see section below).

Based on the resolved ensemble cryo-EM density map and the primary sequence, an atomic model of D614G without the RBD was built (Figure 6H, PDB: 6xs6). In the structural model, the S2 subunit of D614G overlapped well with the published structures for D614. In contrast, there was significant deviation within the S1 subunit (Figure 6I and 6J). When the S1 subunit of D614G was superimposed on the closed conformation of D614, the S1-NTD and S1-INT shifted away from each other by 6Å and 4Å, respectively (Figure 6I), revealing a wider space between these two domains. When the S1 subunit of D614G was superimposed on D614 in the open conformation, the S1-NTD was shifted outwards by 3Å, while the S1-INT overlapped well with that of D614 (Figure 6J). With respect to the ancestral protein, then, the D614G variant induces interdomain conformational changes, and likely leads to a more open conformation within the S1 subunit.

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

D614 localizes to the interface between two protomers where its side chain forms hydrogen bonds with the T859 side-chain in the adjacent protomer (Figure 6K). The effect of D614G on this interaction could be assessed since local resolution in the map generated here reaches 3.2Å. The atomic model showed that D614G has two consequences. First, D614G disrupts the inter-protomer hydrogen bond with Thr859 (Figure 6L and M), weakening the stability of the trimer. In effect, D614 acts as a "latch" that secures two protomers together, and D614G loosens this latch (Figure 6L and M). Second, the backbone amine of the glycine residue shortens the hydrogen bond with the carboxyl group of Ala647 within the same protomer, from 3.4 Å to 2.7 Å, and thus strengthens it. This interaction might internally stabilize the S1-CTD.

D614G shifts the probability that SARS-CoV-2 S protein trimers occupy open conformations

The RBD cannot be visualized in the ensemble-averaged map for D614G. To better assess the conformation of the RBD, the flexible region of S1 was subjected to masked 3D classification and refinement, with the aim of resolving the conformational heterogeneity in that region. Two distinct classes arose from this analysis of the dataset. 58% of the protomers adopted an open conformation in which the RBD is positioned to interact with ACE2, and 42% were in the closed conformation in which the RBD is buried (Fig. 7A and 7B). This ratio of the two conformations contrasted dramatically with assessment of D614 structural data (Walls et al., 2020), in which only 18% of the RBDs were in the open conformation and 82% in the closed conformation. The closed conformation of D614G overlapped well with the closed conformation of D614, while the open conformation of D614G showed significant deviation of all S1 domains away from the S2 subunit when compared with the open conformation of D614 (Fig. 7C). This suggests that the

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

D614-Thr859 hydrogen bond latches adjacent protomers together when one protomer is in the open conformation.

Further classification of D614G particles to determine the distribution of RBD conformations within trimers revealed four different categories (Figure 7D). 5% of the particles had all three protomers in the closed conformation. 36% had one open protomer. 39% had two open protomers. 20% of the particles had all three protomers in the open conformation (Fig. 7D). The same analysis of the D614 dataset (Walls et al., 2020) showed that 46% of particles were in the all closed conformation and 54% in the one open conformation. These data further emphasize the contrast between D614G conformational space and that of D614, and suggest that the greater flexibility of the D614G RBD confers increased infectivity to D614G.

DISCUSSION

The SARS-CoV-2 S protein variant D614G is one of only four SNPs, out of the more than 12,000 to be reported in GISAID, that has risen to high frequency (Figure 1). This suggests that D614G confers a replication advantage to SARS-CoV-2, such that it increases the likelihood of human-to-human transmission. Data in which the presence of D614G correlates with increased rates of transmission through human populations would support this hypothesis. To date, though, datasets that are powered sufficiently, and that are appropriately controlled for age and other important variables, have not been forthcoming. Prospective comparison of D614G transmission to that of D614 will be unlikely given that D614G has nearly gone to fixation world-wide (Figure 1), with only rare reports of D614 over recent weeks. It should be noted, however, that the roughly 53,000 high-quality SARS-CoV-2 genomic sequences available from GISAID as of 25 June 2020 are only a narrow snapshot of the pandemic, constituting approximately 0.5% of the 9.6 million cases confirmed as of that date (Dong et al., 2020). Additional sequencing of archived samples might provide opportunity to pinpoint the origin of D614G or to improve understanding of its trajectory.

Indirect evidence that D614G is more transmissible was provided here by experiments with pseudotyped viruses showing that D614G transduces 3 to 9-fold more efficiently than does the ancestral S protein (Figure 2A). This effect was seen with a range of cellular targets, including lung and colon epithelial cells, and required ACE2 on the target cell. The increased infectivity of D614G was evident whether or not TMPRSS2 was expressed on the target cells (Figure 2A). Efforts are underway to compare the replication efficiency of D614G with that of D614 in the context of the nearly 30,000 nucleotide SARS-CoV-2 genome. Such reverse genetic experiments, though, are technically difficult and potentially confounded by acquisition of unnatural, tissue culture-adapted mutations during genome rescue and expansion in

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

transformed cell lines, as has occurred during similar assessments of Ebola virus variants (Marzi et al., 2018; Ruedas et al., 2017). Consistent with the increased ability of D614G to infect cells in tissue culture, several studies suggest that D614G is associated with increased viral load in people with COVID-19 (Korber et al., 2020; McNamara et al., 2020; Wagner et al.), though these studies quantitated SARS-CoV-2 RNA and did not measure infectious virus.

If SARS-CoV-2 Spike D614G is an adaptive variant that was selected for increased human-to-human transmission, following spillover from an animal reservoir, one might expect that increased infectivity would only be evident on cells bearing ACE2 orthologs similar to the human. In contrast to the primate-specific increase in infectivity that was reported for the major clade-forming Ebola virus glycoprotein variant from the 2013-2016 West African outbreak (Diehl et al., 2016; Urbanowicz et al., 2016), the increased infectivity of D614G was equally evident on cells bearing ACE2 orthologs from a range of mammalian species (Figure 2B). Though absolute infectivity differed based on the affinity of the RBD for the particular ACE2 ortholog, the relative increase in infectivity due to D614G was the same (Figure 2B). The fact that mouse and rat ACE2 orthologs were non-permissive for D614, but gave detectable infection with D614G, underlines this point. Examination of D614G infectivity using ACE2 orthologs encoded by other mammalian species may provide further insight into the structure and function of the D614G variant.

Insight into the mechanism by which D614G increases infectivity was gleaned from cryo-EM studies of the SARS-CoV-2 S protein trimer. D614G exhibited striking conformational changes within individual S protein protomers (Figure 6I and J, Figure 7C) and within the trimers (Figure 7D), all of which may be attributable to disruption of the interprotomer latch between D614 in S1 and T859 in S2 (Figure 7K-M). Weakening of the interprotomer contacts results in increased distance between the protomers and a dramatic flip in the ratio of open to closed S

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

protein particles, from 82% closed and 18% open for D614, to 42% closed and 58% open for D614G. Perhaps the most remarkable conformational change was that, when the S protein trimers were examined, in addition to the all closed conformation and the one open conformation previously reported for D614 (Walls et al., 2020), a significant fraction of D614G trimers populated a two open conformation (39%) and an all open state (20%). Previous structural studies of SARS-CoV and MERS-CoV S proteins identified similar conformations, with only MERS-CoV S protein exhibiting an all open state like that reported here (Gui et al., 2017; Pallesen et al., 2017; Walls et al., 2019; Yuan et al., 2017). These studies suggested that only upon transition of an RBD to the open conformation is the protomer capable of binding the ACE2 receptor. Models of coronavirus S-mediated membrane fusion describe ACE2 binding to all three RBD domains in the open conformation as destabilizing the pre-fusion S trimer, leading to dissociation of S1 from S2 and promoting transition to the post-fusion conformation (Pallesen et al., 2017; Walls et al., 2019). Thus, the open conformation likely reflects an intermediate that is on-pathway to S-mediated membrane fusion. The well-populated all open conformation of D614G (Figure 7D) therefore suggests that this S protein variant increases infectivity by making virion membrane fusion with the target cell membrane more probable.

The D614G and D614 variants are equally sensitive to neutralization by four human monoclonal antibodies targeting the S protein RBD that are currently in clinical trials for people with COVID-19 (Figure 5). These results are in keeping with the fact that the location of D614G within the S protein is remote from the receptor binding domain and that D614G affinity for ACE2 is less than that of D614 (Figure 4). To date, no studies have demonstrated a worse clinical outcome for infection with D614G, and given the more open conformation of its receptor-binding domain, one might predict that D614G will be at least as immunogenic as the ancestral form.

Methods

Analysis of D614G frequency in published data

The frequency of the SARS-CoV-2 D614G S protein variant in published genomic data was examined using the full Nextstrain-curated set of sequences available from GISAID as of 25 June 2020 (Hadfield et al., 2018; Shu and McCauley, 2017). Sequences were aligned to the ancestral reference sequence (NCBI GenBank accession NC_045512.2) using mafft v7.464 (Katoh and Standley, 2013) with the "--keeplength" and "--addfragments" parameters, which preserve the coordinate space of the reference sequence. To remove lower-quality sequences from the dataset, all sequences in the alignment were masked with ambiguous bases ('N') in the regions spanning the first 100bp and the last 50bp, as well as at error-prone sites located at the (1-indexed, NC_045512.2 coordinate space) positions 13402, 24389, 24390. Sequences shorter than 28kb or with >2% ambiguous bases were removed from the alignment. The frequency of D614G was calculated in the resulting data by extracting the sequence region corresponding to the gene for the S protein, spanning 21563-25384bp. These sequences were processed using a script importing biopython (Cock et al., 2009) to remove any gaps introduced by the alignment process and translate the sequence to protein space. The identity of the variant at amino acid position 614 was tabulated for the full dataset and reported as frequency by date using the collection dates reported in the Nextstrain-curated metadata file available from GISAID (Hadfield et al., 2018; Shu and McCauley, 2017). The frequency was calculated as (# sequences with D614G)/(# sequences). Frequency within the six continental regions was calculated based on the "region" geographic classification associated with each sample in the metadata. Frequency values were linearly interpolated for dates surrounded by valid data. The frequency of the last date with data was carried forward where recent dates lack data. The bresulting values were rendered as plots using matplotlib (Hunter, 2007). The script for

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

analyzing and plotting D614G variant frequency is available via GitHub: https://github.com/broadinstitute/sc2-variation-scripts

The diversity of SNPs and their functional effects based on the same GISAID sequences and MAFFT alignment used to plot the frequency of D614G over time, with the 5' and 3' ends not masked. In the alignment, ambiguous nucleotide codes (R,Y,W,S,M,K,H,B,V,D) were all masked with "N" values. SNPs were calculated from the alignment using the *snp-sites* tool (Page et al., 2016). The resulting VCF-format file was normalized using *bcftools* (Li et al., 2009) to include only SNPs. The VCF file with SNPs was annotated for functional effects using *SnpEff* (Cingolani et al., 2012).

Plasmids

The plasmids used here were either previously described or were generated using standard cloning methods. The full list of plasmids used here is provided in the Key Resources Table. All newly engineered plasmids are available from public repositories, along with full sequences, at either https://www.addgene.org/Jeremy_Luban/ or https://www.aidsreagent.org (search under Jeremy Luban).

Cell culture

All cells were cultured in humidified incubators with 5% CO_2 at 37º C, and monitored for mycoplasma contamination using the Mycoplasma Detection kit (Lonza LT07-318). HEK293 cells (ATCC CRL-1573), and HEK-293T cells (CRL-3216 or CRL-11268) were cultured in DMEM supplemented with 10% heat-inactivated FBS, 1 mM sodium pyruvate, 20 mM GlutaMAX, 1× MEM non-essential amino acids, and 25 mM HEPES, pH 7.2. Calu3 cells (ATCC HTB-55) were maintained in EMEM supplemented with 10% FBS. Caco2 cells (ATCC HTB-37)

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

were maintained in EMEM supplemented with 20% FBS. SUP-T1 [VB] cells (ATCC CRL-1942) were cultured in RPMI supplemented with 10% heat-inactivated FBS, 1mM sodium pyruvate, 20mM GlutaMAX, 1xMEM non-essential amino acids, and 25 mM HEPES, pH7.2. Vero cells (ATCC CCL-81) were cultured in DMEM high glucose media containing 10% heat-inactivated fetal bovine serum, and 1X Penicillin/Streptomycin/L-Glutamine.

Virus production

24 hrs prior to transfection, 6 × 10^5 HEK-293 cells were plated per well in 6 well plates. All transfections used 2.49 µg plasmid DNA with 6.25 µL TransIT LT1 transfection reagent (Mirus, Madison, WI) in 250 µL Opti-MEM (Gibco).

Single-cycle HIV-1 vectors pseudotyped with SARS-CoV-2 Spike protein, either D614 or D614G, were produced by transfection of either HIV-1 pNL4-3 Δenv Δvpr luciferase reporter plasmid (pNL4-3.Luc.R-E-), or pUC57mini NL4-3 Δenv eGFP reporter plasmid, in combination with the indicated Spike expression plasmid, at a ratio of 4:1.

ACE2 expression vectors were produced by transfecting cells with one of the pscALPSpuro-ACE2 plasmids, along with the HIV-1 *gag-pol* expression plasmid psPAX2, and the VSV glycoprotein expression plasmid pMD2.G (4:3:1 ratio of plasmids).. 16 hrs post-transfection, culture media was changed. Viral supernatant was harvested 48 hours after media change, passed through a 0.45 µm filter, and stored at 4ºC. TMPRSS2 expression transfer vector was produced similarly but with pscALPSblasti-TMPRSS2.

Exogenous reverse transcriptase assay

5 µL transfection supernatant was mixed with 5 µL 0.25% Triton X-100, 50 mM KCl, 100 mM Tris-HCl pH 7.4, and 0.4 U/µL RiboLock RNase inhibitor, and then diluted 1:100 in 5 mM

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

$(NH_4)_2SO_4$, 20 mM KCl, and 20 mM Tris-HCl pH 8.3. 10 µL of this was then added to a single-step, RT-PCR assay with 35 nM MS2 RNA (IDT) as template, 500 nM of each primer (5'-TCCTGCTCAACTTCCTGTCGAG-3' and 5'-CACAGGTCAAACCTCCTAGGAATG-3'), and 0.1 µL hot-start Taq DNA polymerase (Promega, Madison, WI) in 20 mM Tris-Cl pH 8.3, 5 mM $(NH_4)_2SO_4$, 20 mM KCl, 5 mM $MgCl_2$, 0.1 mg/ml BSA, 1/20,000 SYBR Green I (Invitrogen), and 200 µM dNTPs in total 20 µL reaction. The RT-PCR reaction was carried out in a Biorad CFX96 real-time PCR detection system with the following parameters: 42ºC for 20 min, 95ºC for 2 min, and 40 cycles [95ºC for 5 sec, 60ºC for 5 sec, 72ºC for 15 sec, and acquisition at 80ºC for 5 sec].

Generation of cell lines expressing ACE2 and TMPRSS2

2.5 x 10^5 HEK-293 cells were plated per well in a 12 well plate. The next day cells were transduced with 250 uL of supernatant containing TMPRSS2-encoding lentivirus for 16 hr at 37°C, after which fresh media was added to cells. 48 hrs after transduction cells were replated and selected with blasticidin (InvivoGen, catalogue #ant-bl-1) at 10 ug/ml. After selection, cells were transduced similarly with supernatant containing ACE2-encoding lentivirus and selected with 1 ug/mL of puromycin (InvivoGen, San Diego, CA, catalogue #ant-pr-1).

1 x 10^6 SupT1 cells were transduced with 400 uL of supernatant containing TMPRSS2-encoding virus followed by selection with 10 ug/mL blasticidin 48 hrs later. TMPRSS2 expressing SupT1 cells were then transduced with a second vector expressing ACE2, followed by puromycin selection at 1 ug/mL.

Virus Infectivity Assays

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

16 hours prior to transduction, adherent cells were seeded in 96 well plates. HEK-293 cells were plated at 5 x 10^4 cells per well. Calu3 and Caco2 were plated at 3 x 10^4 per well. Cells were incubated in virus-containing media for 16 hrs at 37°C when fresh medium was added to cells. 48 to 72 hours after transduction cells were assessed for luciferase activity or for GFP by flow cytometry. For transfection of SupT1 cells, 1 x 10^5 cells were plated in a U-bottom 96 well plate and spinfected at 30ºC with 100 uL of virus-containing media for 2 hours at 1,200 x g. Fresh media was added after spinfection and cells were incubated 48-72 hours prior to analysis. Cells transduced with GFP virus were fixed with BD Cytofix (BD Biosciences, San Jose, CA, Cat number 554655) and analyzed using the Accuri C6system. Data was analyzed using FlowJo 10.5 (FlowJo, LLC, Ashland, OR). Cells transduced with luciferase expressing virus were assessed using Promega Steady-Glo system (Promega Madison, WI)

Neutralizations assays with human monoclonal antibodies targeting the SARS-CoV-2 S protein receptor binding domain

VSV-SARS-CoV-2-S pseudoparticle generation and neutralization assays were performed as previously described (Baum et al., 2020; Hansen et al., 2020). HEK293T cells were seeded overnight in DMEM high glucose media (Life Technologies) containing 10% heat-inactivated fetal bovine serum (Life Technologies), and Penicillin/- Streptomycin-L-Glutamine (Life Technologies). The following day, Spike expression plasmids were transfected with Lipofectamine LTX (Life Technologies) following the manufacturer's protocol. At 24 hours post transfection, the cells were washed with phosphate buffered saline (PBS) and infected at an MOI of 1 with the VSVΔG:mNeon/VSV-G virus diluted in 10 mL Opti-MEM (Life Technologies). The cells were incubated 1 hour at 37°C with 5% CO2. Cells were washed three times with PBS to remove residual input virus and overlaid with DMEM high glucose media (Life Technologies)

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

with 0.7% low IgG BSA (Sigma), sodium pyruvate (Life Technologies), and gentamicin (Life Technologies). After 24 hours at 37° C with 5% CO2, the supernatant containing pseudoparticles was collected, centrifuged at 3,000 x g for 5 minutes to clarify, aliquoted, and frozen at -80° C.

For neutralization assays, Vero cells were seeded in 96-well plates 24 hours prior to assay and grown to 85% confluence before challenge. Antibodies were diluted in DMEM high 3 glucose media containing 0.7% Low IgG BSA (Sigma), 1X Sodium Pyruvate, and 0.5% Gentamicin (this will be referred to as “Infection Media”) to 2X assay concentration and diluted 3-fold down in Infection Media, for an 11-point dilution curve in the assay beginning at 10 ug/mL (66.67 nM). pVSV-SARS-CoV-2-S pseudoparticles were diluted 1:1 in Infection Media for a fluorescent focus (ffu) count in the assay of ~1000 ffu. Antibody dilutions were mixed 1:1 with pseudoparticles for 30 minutes at room temperature prior to addition onto Vero cells. Cells were incubated at 37° C, 5% CO2 for 24 hours. Supernatant was removed from cells and replaced with 100 uL PBS, and fluorescent foci were quantitated using the SpectraMax i3 plate reader with MiniMax imaging cytometer.

Production of SARS-CoV-2 virus-like particles (VLPs)

HEK-293T cells were cultured in DMEM supplemented with 10% heat-inactivated bovine serum, and transfected with pcDNA3.1 plasmids encoding the SARS-CoV-2 M, E, N, and S proteins, in different combinations, as indicated. 1 ug of each plasmid was used, with 5 ug of total plasmid in each transfection, normalized using empty vectors, in 400 ul Opti-MEM and 18 ul of PEI. The transfection mixture was incubated at room temperature for 15 minutes and dropped into a 50% confluent 10 cm plate of HEK-293T cells. The media and cell lysate were collected after 60 hours. 10 ml of supernatant was passed through a 0.45 um syringe filter, layered on top of a

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

20% sucrose cushion in PBS, and spun at 30,000 rpm in an SW41 rotor (111,000 x g, average) for two hours. The pellet was washed once with ice cold PBS, resuspended in 150 ul of 2x SDS loading buffer (Morris formulation), and sonicated in an ice-water bath (Branson 2800) for 15 minutes. After removal of the supernatant, the transfected cells were lysed in 800 ul PBS with 1% Triton and protease inhibitor (Roche cOmplete EDTA-free tablets), and cleared of debris by spinning in a table-top centrifuge (Eppendorf 5424R) at top speed (20,000 x g, average) for 10 minutes.

Immunoblots of SARS-CoV-2 VLPs

Proteins in VLP and cell lysate samples were separated by SDS-PAGE, as follows: 20 ul of unboiled VLP and cell lysate samples on a 10-20% Tris-Glycine gel to probe for the M protein; 2 ul of boiled cell lysate and 5 ul of boiled VLP samples on a 12% Tris-Glycine gel to probe for the N protein; 20 ul of boiled lysate and VLP samples on a 10% Tris-Glycine gel to probe for the S protein; 5 ul of boiled lysate on a 10% Tris-Glycine gel to probe for Raptor, as a loading control. Proteins were electro-transferred from the gels to PVDF membrane, which was blocked with 5% milk in Tris-Buffered Saline, pH 8.0, with 0.1% Tween-20, and detected with the indicated antibodies.

Surface plasmon resonance analysis

Binding kinetics and affinities for ACE2.Fc were assessed using surface plasmon resonance technology on a Biacore T200 instrument (GE Healthcare, Marlborough, MA) using a Series S CM5 sensor chip in filtered and degassed HBS-EP running buffer (10 mM HEPES, 150 mM NaCl, 3mM EDTA, 0.05% (v/v) polysorbate 20, pH 7.4). Capture sensor surfaces were prepared by covalently immobilizing with a mouse anti-human Fc mAb (REGN2567) on the chip

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

surface using the standard amine coupling chemistry, reported previously (Johnsson et al., 1991). Following surface activation, the remaining active carboxyl groups on the CM5 chip surface were blocked by injecting 1 M ethanolamine, pH 8.0 for 7 minutes. A typical resonance unit (RU) signal of ~12,000 RU was achieved after the immobilization procedure. At the end of each cycle, the anti-human Fc surface was regenerated using a 12 second injection of 20 mM phosphoric acid. Following the capture of the ACE2.Fc on the anti-human Fc mAb immobilized surface, 0.78 nM - 50 nM, two-fold serial dilutions, in duplicate, of soluble SARS-CoV-2 spike trimer protein, D614 or D614G, were injected for 3 minutes at a flow rate of 50 mL/min, with a 2 minute dissociation phase in the running buffer. All specific SPR binding sensorgrams were double-reference subtracted as reported previously (Myszka, 1999) and the kinetic parameters were obtained by globally fitting the double-reference subtracted data to a 1:1 binding model with mass transport limitation using Biacore T200 Evaluation software v 3.1 (GE Healthcare). The dissociation rate constant (k_d) was determined by fitting the change in the binding response during the dissociation phase and the association rate constant (k_a) was determined by globally fitting analyte binding at different concentrations. The equilibrium dissociation constant (K_D) was calculated from the ratio of the k_d and k_a. The dissociative half-life ($t_{½}$) in minutes was calculated as ln2/(k_d*60). The steady state analysis was performed using Scrubber software and the K_D value was determined.

Production and enrichment of soluble SARS-CoV-2 S Protein trimers

FreeStyle 293-F cells were cultured in SMM-293 TII serum-free media (SinoBiological) and maintained in a 37°C shaker with 8% CO_2 and 80% humidity. 600 ug of plasmid encoding His-tagged SARS-CoV-2 S protein was transfected into 400 ml of 293 FreeStyle cells at 10^6 cells/ml, using 25 ml Opti-MEM and 1.8 ml PEI. 60 hours later, the media was collected and

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

applied to 3 ml of Ni-NTA resin (Qiagen). The resin was collected and washed with PBS supplemented with 20 mM imidazole. Soluble S protein was eluted in PBS supplemented with 200 mM imidazole, and further enriched using a Superose 6 gel-filtration column (GE healthcare), in a buffer containing 25 mM NaHEPES (pH 7.4) and 150 mM NaCl. Yield was roughly 600 ug of soluble S protein homotrimer per liter of culture.

CryoEM sample preparation and data collection

3 µL of enriched D614G trimers, at 2.5 mg/mL, was deposited on an UltrAuFoil R1.2/1.3 300 mesh grid that had been glow discharged for 30 seconds in a GloQube Plus Glow Discharge System. Plunge freezing was performed with a Vitrobot Mark IV using a blot force 0 and 5s blot time at 100% humidity and 4℃. Frozen grids were imaged with a Thermo Scientific Krios transmission electron microscope operated at 300 kV. Movies were acquired using EPU 2 software. 10,264 micrographs were automatically collected with a defocus ranging between 0.6 and 1.8 µm, at a nominal magnification of 155,000x with a pixel size of 0.52Å. 7,653 micrographs were collected with a tilt-angle of 30° to overcome the preferred orientation. The dose rate was set at 20.3 electron/Å^2/s and total exposure time was 1.81s. With a dose fraction set at 62 frames, each movie series contained 62 frames and each frame received a dose of 0.6 electron/Å^2.

CryoEM data processing

Movie frame alignment, estimation of microscope contrast-transfer function parameters, particle picking, 2D classification, and homogeneous refinement using the published structure EMD-21452 as initial model were carried out in cryoSPARC. Ensemble averaging of 266,356 particles resulted in a 3.7Å map with C3 symmetry imposed according to “gold standard” Fourier

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

shell correlation of 0.143. Local resolution was estimated using cryoSPARC to extend from 3Å to 6 Å. Particle stacks with well-refined orientation parameters were imported in Relion3.1. Focused 3D classifications with a soft mask on the S1 subunit of the protomer were performed on the C3 symmetry expanded particles. Two monomer conformations, namely the closed state (a) and the open state (b) were identified after 3 rounds of classification. Four trimer classes were identified by 3D classification on the trimer particles: class_3a (13,555 particles), class_3b (51,600 particles), class_2a1b (96,029 particles), class_1a2b (105,118 particles). Homogeneous refinements were then performed on these 4 classes, with EMD-21452 as the initial model in Relion3.1. C3 symmetry was imposed on the refinement of particles from class_3a and class_3b; C1 symmetry was imposed on the refinement of particles from class_2a1b and class_1a2b. The final resolutions were class_1a2b with 4Å, class_2a1b with 3.9Å, class_3a with 4.2Å and class_3b with 3.9Å. The final map was deposited with the accession code EMD-22301.

Model building

Atomic models were prepared with Coot based on the resolved structure of D614 SARS-CoV-2 Spike (PDB: 6vxx and 6vsb). Real-space refinements were performed using PHENIX with secondary structure restraints. MolProbity was used to evaluate the geometries of the structural model. Corrected Fourier shell correlation curves were calculated using the refined atomic model and the cryo-EM density map. The coordinates were deposited with the accession code 6xs6.

ACKNOWLEDGEMENTS

We thank all the members of the Sabeti, Shen, and Luban labs, and Thermo Fisher Scientific Workflow solutions team for technical assistance and helpful discussions. This work was supported by NIH grants R37AI147868 and R01AI148784 to J.L., NIH/NIAID U19AI110818 to P.C.S., 7DP2AI124384-02 to J.B.M., NCI K22CA241362 to K.S., a grant from the Evergrande COVID-19 Response Fund Award from the Massachusetts Consortium on Pathogen Readiness to J.L., a grant from the Worcester Foundation to K.S., a Sara Elizabeth O'Brien Fellowship Award/King Trust to L.Y., and a National Science Foundation Graduate Research Fellowship (Grant No. 1745303) to C.T.-T. A portion of this project has been funded in whole or in part with Federal funds from the Department of Health and Human Services; Office of the Assistant Secretary for Preparedness and Response; Biomedical Advanced Research and Development Authority, under OT number: HHSO100201700020C.

AUTHOR CONTRIBUTIONS

P.S., C.A.K., K.S., and J.L. conceived the experiments. C.T.-T., S.F.S, J.E.L., and P.C.S. analyzed the SARS-CoV-2 sequence data. L.Y., T.N., Y.W., W.E.D., A.D., C.A.K., K.S., and J.L. designed and cloned the expression plasmids. L.Y., C.C., A.D., K.E.P., and A.B. performed the virology experiments. L.Y., A.D., and K.S. performed the virus biochemistry. A.R. performed the SPR experiments. K.V., S.B.E., and K.S. purified the proteins. X.W., A.B., and N.D. collected and processed cryo-EM data. S.B.E. and K.S. built the structural model. L.Y., C.H.T.-T., S.F.S, C.A.K., A.B., A.R., J.B.M., K.S., and J.L. wrote and edited the manuscript with input from all authors.

DECLARATION OF INTERESTS

P.C.S. is a co-founder and shareholder of Sherlock Biosciences, and a Board member and shareholder of Danaher Corporation. J.E.L. consulted for Sherlock Biosciences. C.A.K., K.E.P., and A.B. are employed by Regeneron Pharmaceuticals and own stock options in the company. C.A.K. is an officer at Regeneron. X.W., A.B., and N.D. are employees of Thermo Fisher Scientific.

Figure 1. Over the course of the COVID-19 pandemic the frequency of the SARS-CoV-2 S protein D614G variant has risen to near fixation

(A) The global frequency of the S protein D614G variant over time in sequences published via the GISAID SARS-CoV-2 database, as of 25 June 2020. The filled plot (blue) represents a 7-day rolling average of the fraction of sequences bearing the D614G variant for each collection date. Dates without published sequences are linearly interpolated. The cumulative frequency of the D614G variant (black line) is overlaid, showing the frequency of D614G in sequences from samples collected up to and including each date.

(B) The frequency of the D614G variant over time (blue) in sequences collected from six continental regions, using the same dataset as in (A), plotted as a 7-day rolling average. Frequencies are interpolated for dates without published sequence. The frequency of the last date with data is carried forward where recent dates lack data to indicate the most recent calculated frequency (light blue). The number of samples collected, sequenced, and published is overlaid (red bars) to provide the denominator used in calculating the frequency for each date, and to illustrate the non-uniformity of sampling.

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

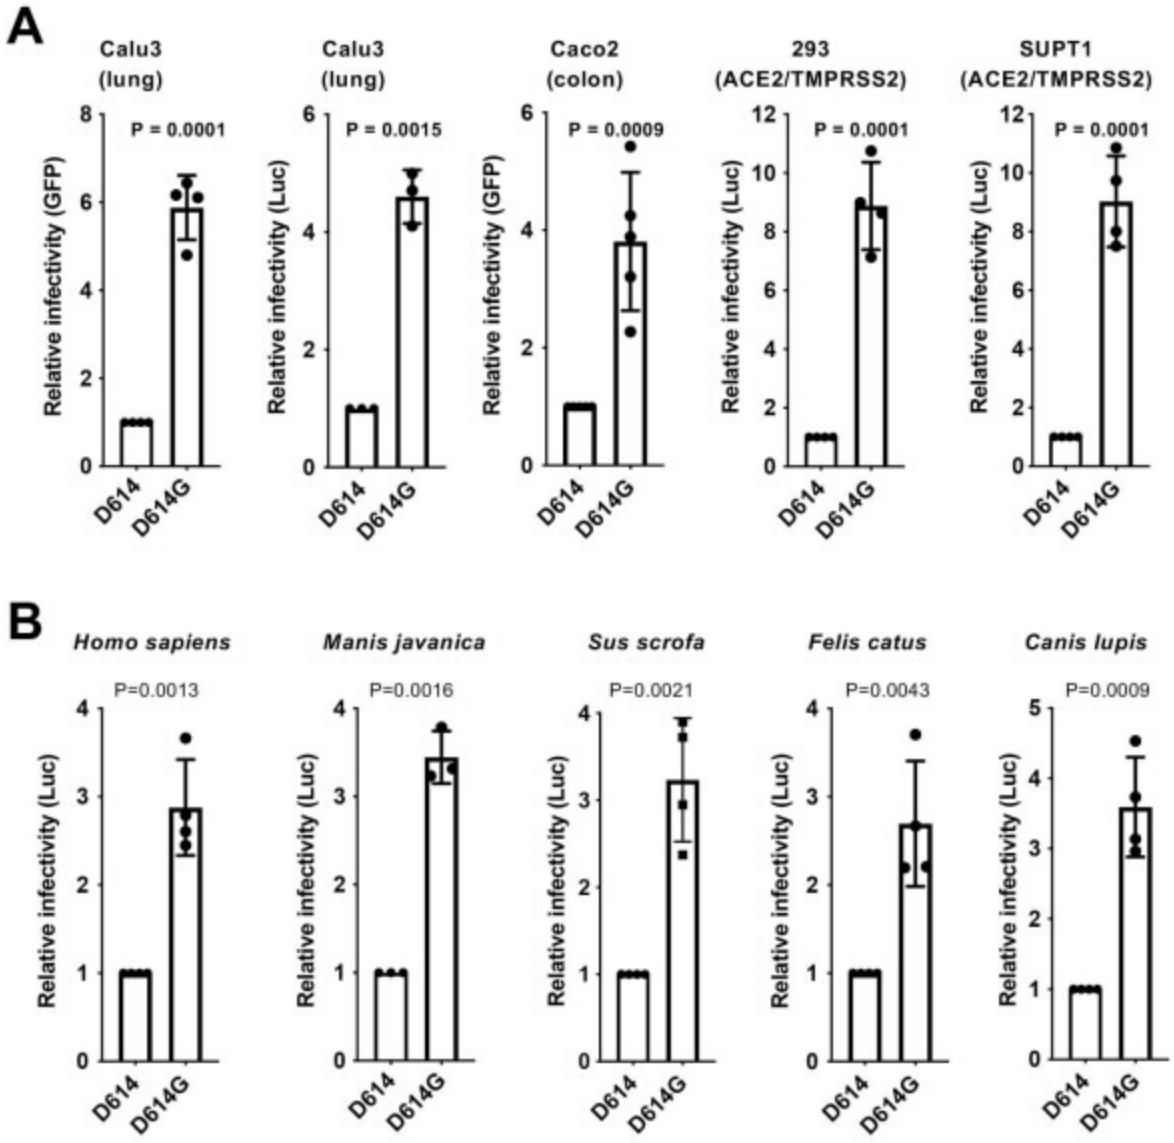

Figure 2. SARS-CoV-2 D614G S protein variant enhances infectivity

A. Lentiviral virions bearing either GFP or Luciferase transgenes, and pseudotyped with either SARS-CoV-2 D614 or D614G S proteins, were produced by transfection of HEK293 cells, and used to transduce human Calu3 lung cells, Caco2 colon cells, and either HEK293 or SupT1 cells stably expressing ACE2 and TMPRSS2. Relative infectivity of D614G vs D614, with D614 set at 1, was determined based on flow cytometry for percent GFP-positivity or bulk luciferase activity. Each point represents transduction with a lentiviral stock that was derived from an independent transfection. Shown are the mean +/- SD.

B. Lentiviral virions bearing a luciferase transgene, pseudotyped with either SARS-CoV-2 D614 or D614G S proteins, were produced by transfection of HEK293 cells, and used to transduce human HEK293 cells transiently transfected with plasmids encoding the indicated ACE2 orthologs. Relative infectivity of D614G vs D614, with D614 set at 1, was determined based on bulk luciferase activity. Each point represents transduction using lentiviral stock derived from an independent transfection. Shown are the mean +/- SD.

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

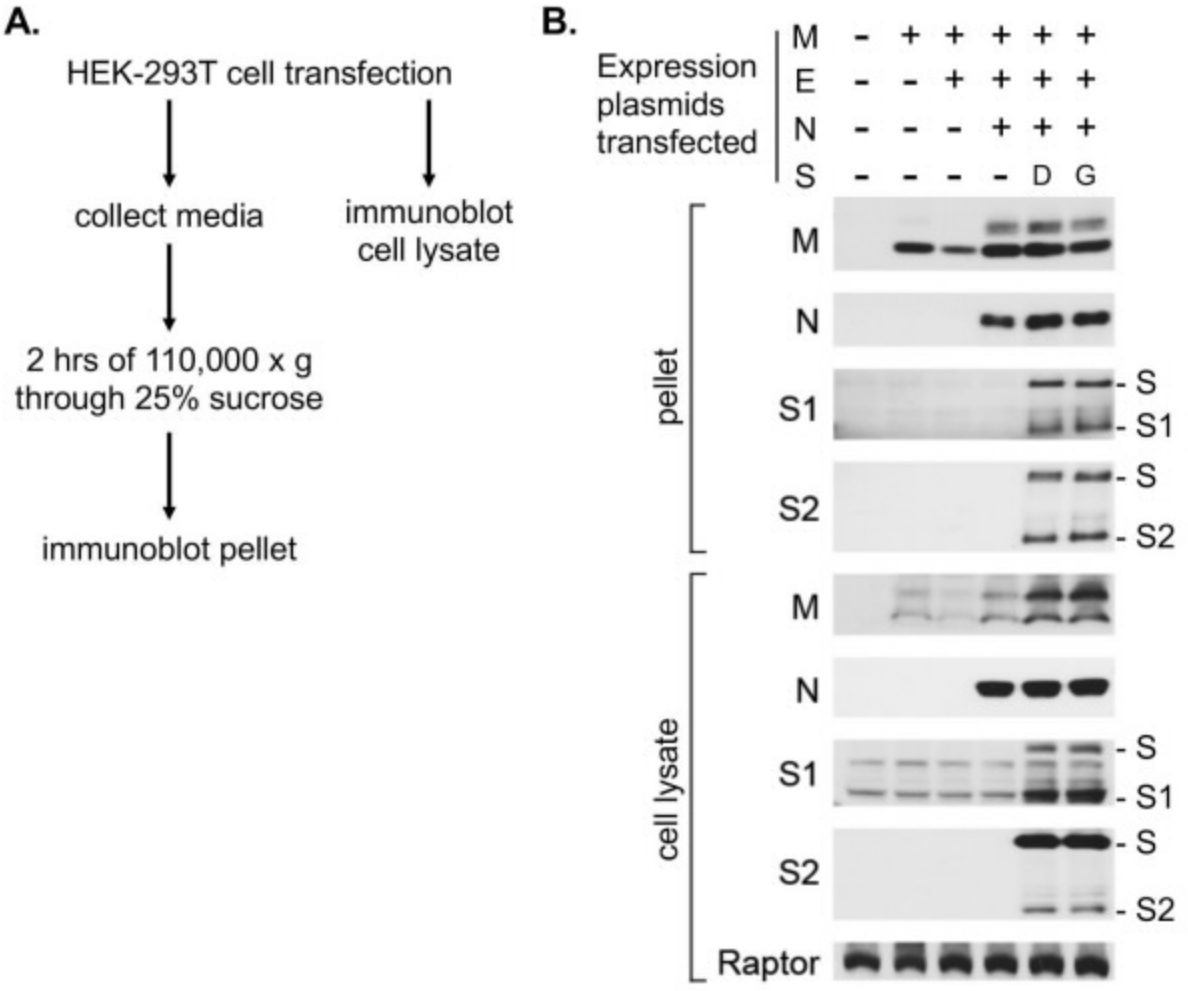

Figure 3. Synthesis, processing, and incorporation of S protein variants into SARS-CoV-2 virus-like particles

(A) Schematic showing how SARS-CoV-2 structural proteins were produced in HEK-293T cells and virus-like particles were enriched from the supernatant by ultracentrifugation.

(B) HEK-293T cells were transfected with plasmids encoding the proteins indicated at the top. Western blots were then performed on cell lysate and on ultracentrifuge pellets from cell culture supernatant with the primary antibodies indicated on the left of the blots. Anti-Raptor antibody was used as a loading control for the cell lysate. Uncleaved S protein, as well as the S1 and S2 cleavage products, are indicated on the right.

Figure 5. Neutralization potency of monoclonal antibodies targeting the SARS-CoV-2 S protein receptor binding domain.

(A and B) Vero cells were challenged with pVSV-SARS-CoV-2-S-mNeon pseudoparticles encoding either D614 (A) or D614G S protein variants, in the presence of serial dilutions of the indicated human monoclonal antibodies targeting the SARS-CoV-2 S protein receptor binding domain, or IgG1 isotype control. mNeon protein fluorescence was measured 24 hours post-infection as a read-out for virus infectivity. Data is graphed as percent neutralization relative to virus only infection control.

(C) Neutralization potency (IC_{50}) of individual monoclonals and of combinations of monoclonals, against the SARS-CoV-2 D614G and D614G S protein variants, as indicated.

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

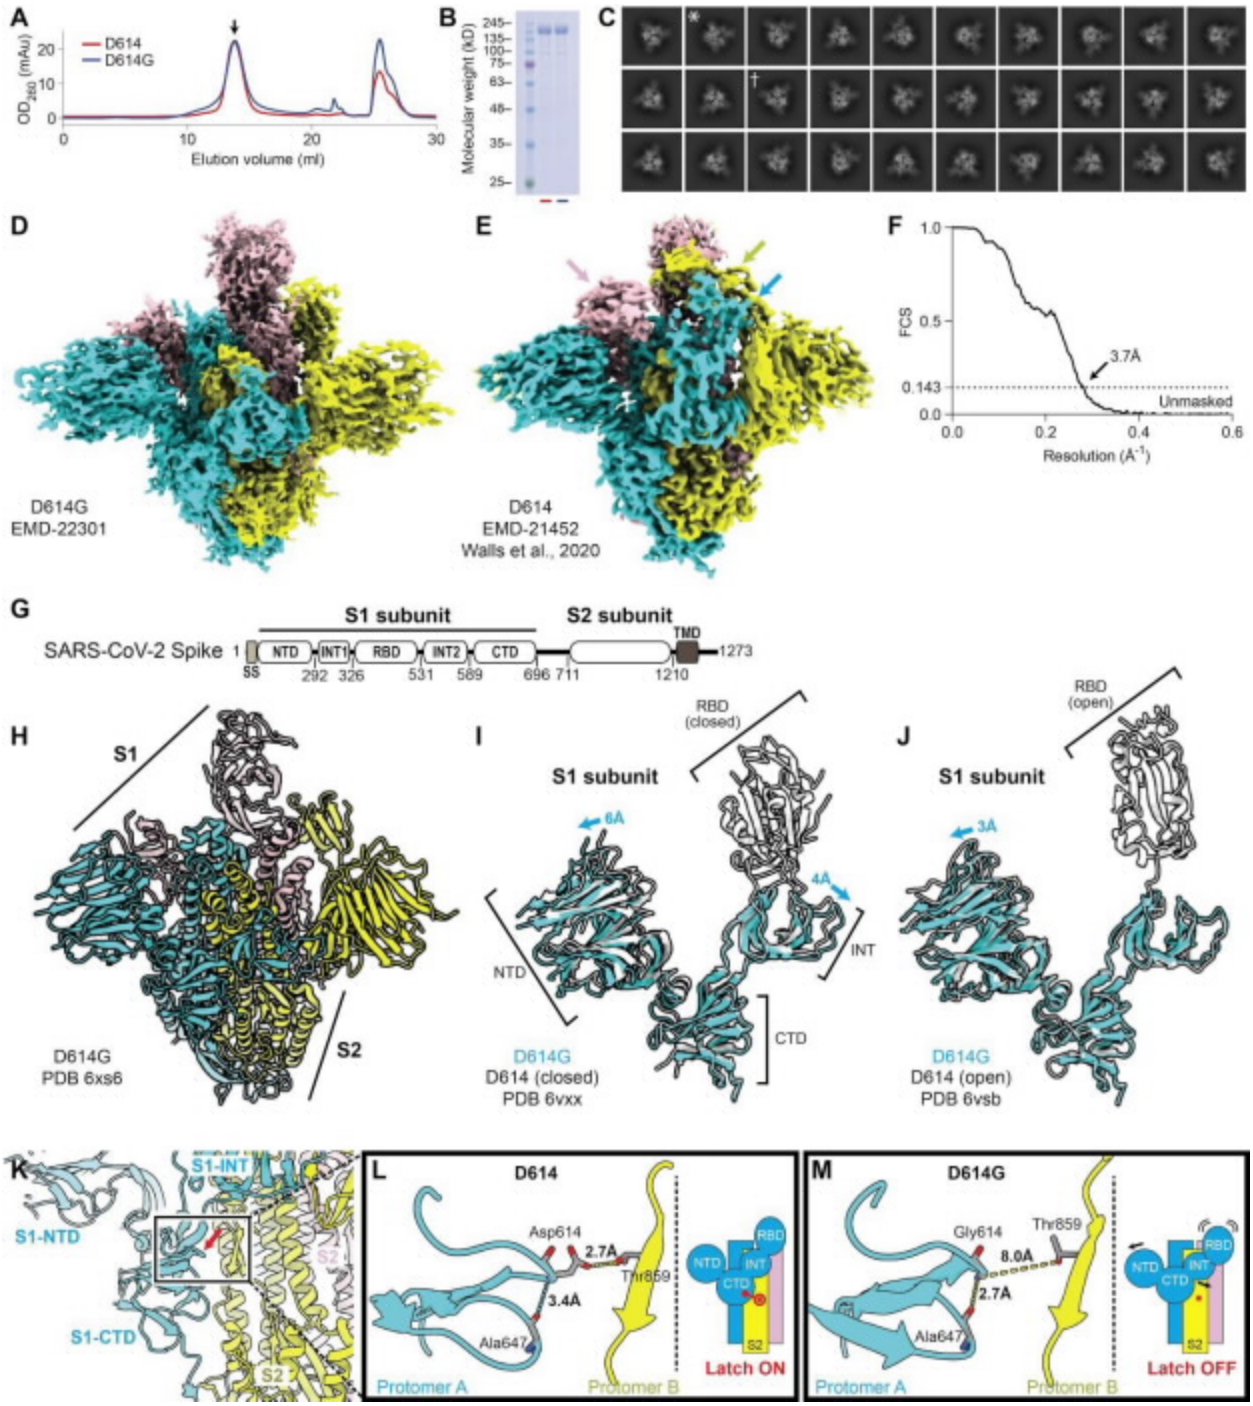

Figure 6. Structural determination of Spike D614G.

(A) Size exclusion column elution profiles of D614G (blue line) and D614 (red line).

(B) Coomassie-stained SDS-PAGE of the peaks collected in (A) shows equivalent, full-length monomeric S proteins at around 180 kD.

(C) 2D-clustering of trimeric D614G particles. Dagger denotes a top-view. Asterisk denotes a side-view.

(D) D614G envelope from the three-dimensional reconstruction. EMDB: EMD-22301.

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

(E) Published D614 envelope (EMD-21452). Arrows point to the density corresponding to the receptor binding domains, which is missing in the corresponding positions in (D).
(F) Gold-standard Fourier shell correlation of the density map in (D).
(G) Domain arrangement of the SARS-CoV-2 S protein.
(H) Atomic model for D614G without the receptor binding domain. PDB: 6XS6.
(I-J) Comparison of the D614G S1 subunit with the closed conformation (I) and open conformation (J) of the D614 S1 subunit. Arrows indicate the relative movement of the S1 subunit of D614G.
(K) Position of amino acid 614 on the S protein.
(L-M) Substitution of Asp614 with glycine changes hydrogen bonding around residue 614. In the case of D614 (L), an inter-protomer hydrogen bond is detected. For D614G (M), the Asp614-Thr859 hydrogen bond is eliminated, and interaction with intradomain Ala647 is strengthened.

bioRxiv preprint doi: https://doi.org/10.1101/2020.07.04.187757 . this version posted July 16, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder. It is made available under a CC-BY-NC-ND 4.0 International license.

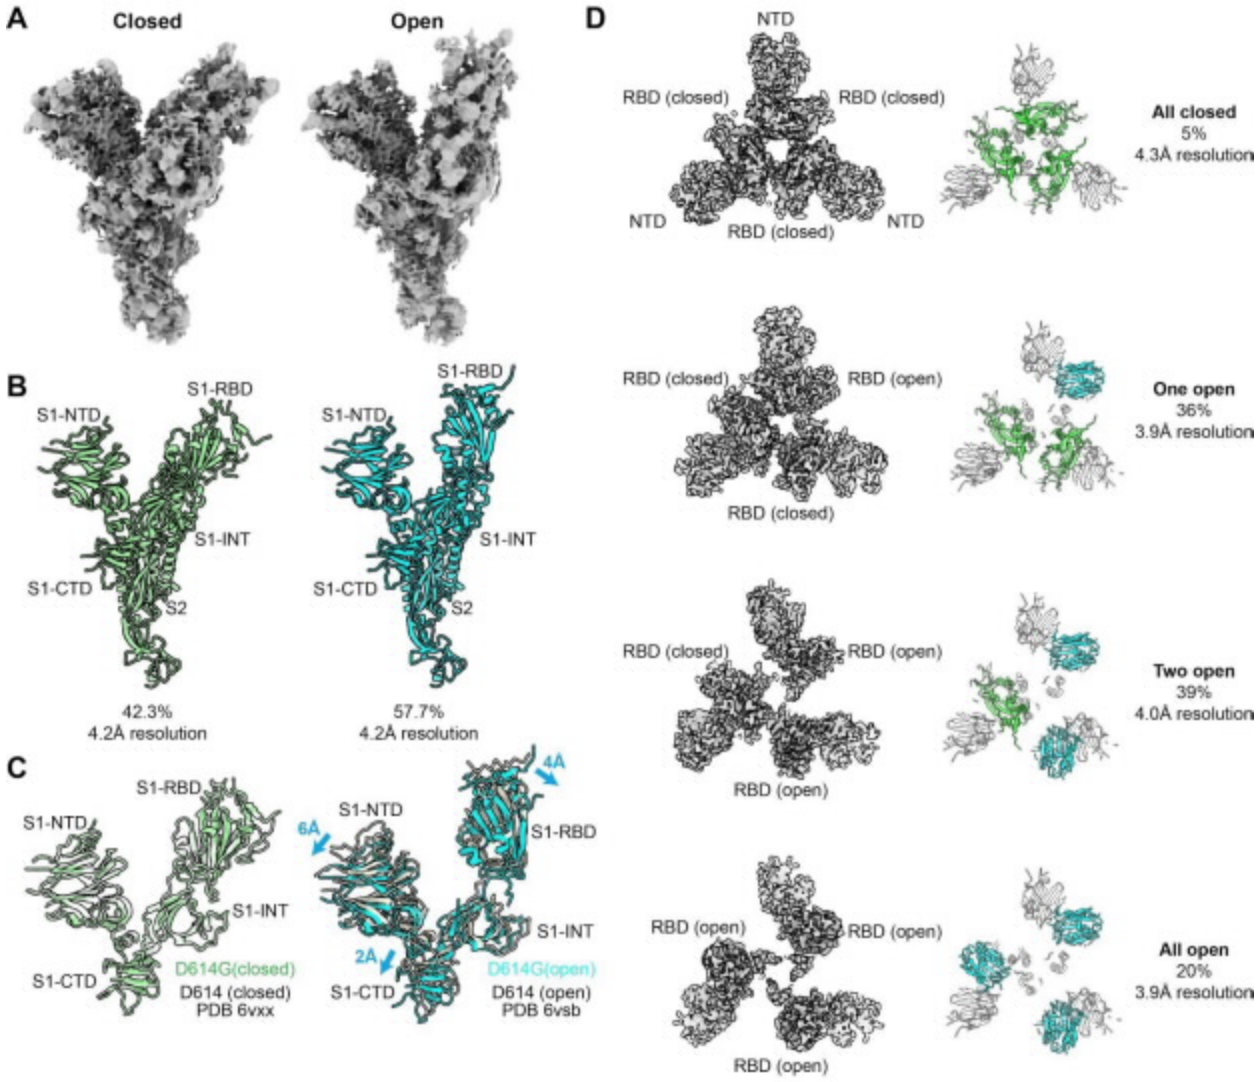

Figure 7. D614G populates more open conformations than does the ancestral S protein

(A) Cryo-EM density maps of the two conformations of D614G protomer. The first is a closed conformation with a buried RBD. The second is an open conformation with the RBD standing up.

(B) Atomic models for the closed (left) and open (right) conformations for the two D614G protomers shown in (A).

(C) Comparison of the two D614G protomer S1 subunit conformations with the corresponding conformations of the D614 protomer S1 subunit.

(D) The D614G S protein trimer adopts four conformations. In addition to the all closed and one open conformation detected with the D614 S protein trimer, the D614G S protein trimer adopts two-open and three-open conformations.

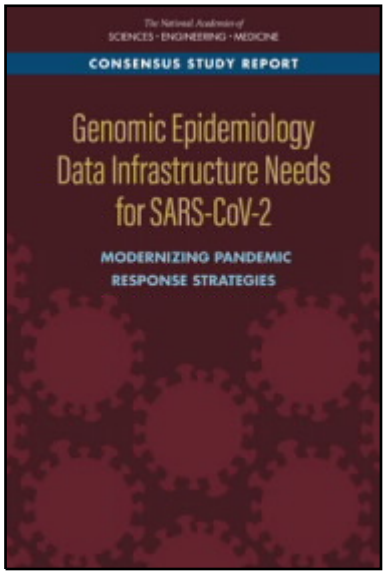
Consensus Study Report

JULY 2020

HIGHLIGHTS

Genomic Epidemiology Data Infrastructure Needs for SARS-CoV-2

Modernizing Pandemic Response Strategies



At the time of writing this report, the virus that causes COVID-19, SARS-CoV-2, has spread worldwide, infecting at least 10 million people and leading to an estimated 500,000 deaths. To best respond to this ongoing threat, policy makers and public health officials need access to cutting-edge pandemic, epidemic, and global preparedness and response strategies. Particularly, the ability to examine the genome of the virus may help public health officials more precisely understand transmission patterns, virus evolution, and potential treatment and prevention interventions. If policy makers and public health officials have access to these data, it may increase the possibility of breaking or delaying virus transmission and in turn reduce illness and deaths from COVID-19.

Recognizing the need to capitalize on these advances during the current COVID-19 pandemic, the Department of Health and Human Services' Office of the Assistant Secretary for Preparedness and Response (HHS/ASPR) and Office of Science and Technology Policy (OSTP) asked the National Academies of Sciences, Engineering, and Medicine to convene an ad hoc committee that would lay out a framework to help define and describe the data needs for a system that can track and correlate viral genome sequences with clinical and epidemiological data. The resulting system, outlined in this report, is designed to help integrate data sharing and data analysis on the evolution of SARS-CoV-2 into public health practice and decision making.

EXISTING DEFICIENCIES IN GENOMIC EPIDEMIOLOGY EFFORTS FOR SARS-COV-2

Several ongoing data projects are using genomic epidemiology to aid the public health response to COVID-19, including federal and nonprofit initiatives. In the United States, the Centers for Disease Control and Prevention's SARS-CoV-2 Sequencing for Public Health Emergency Response, Epidemiology, and Surveillance (SPHERES) consortium is coordinating a nationwide genomic sequencing effort. The National Institutes of Health is supporting two initiatives: the National COVID Cohort Collaborative (N3C), a secure portal for patient-level COVID-19 clinical data, and the National Center for Biotechnology Information's Reference Sequence (RefSeq) database. Several regional initiatives have emerged as well, integrating data sharing through existing global efforts like the Global Initiative on Sharing All Influenza Data (GISAID) and Nextstrain.

Due to a number of factors including poor funding, coordination, and capacity, the committee concluded that existing data sources and integration efforts for SARS-CoV-2 genome sequence data are patchy, typically passive, and reactive in the United States. As a result, available data do not represent key population features of individuals who are infected with SARS-CoV-2 and cannot adequately answer many pressing questions about the evolution and transmission of this virus.

To better collect necessary viral sequence data and other associated data, the committee recommended that HHS implement genome sequencing of SARS-CoV-2 on a national scale and ensure that this effort is fully representative of every segment of the population. Particularly, the committee highlighted the need to account for race and ethnicity, gender, age, geography, housing type, displayed symptoms, and transmissibility. To read the full text of this recommendation, see the Recommendations Insert.

BUILDING A FRAMEWORK TO TRACK AND CORRELATE VIRAL GENOME SEQUENCES WITH CLINICAL AND EPIDEMIOLOGICAL DATA

When combined with other types of data, researchers and public health officials may be able to use viral genome sequence data to inform questions related to transmission of a virus, virus evolution, and how the virus manifests as a disease.

However, in order to fully understand these issues, public officials need access to effectively integrated data. Currently, no central repository exists for the collection and curation of such infectious disease outbreak data from federal, state, and local health agencies, health care networks, and public health and clinical laboratories. To address this gap, the committee recommended that HHS develop and invest in a national data infrastructure system that can link genomic, clinical, and epidemiological data. This system should:

- Allow for linkage between these types of data without overburdening laboratories
- Create and foster safe data-sharing practices to protect personally identifying information
- Ensure shared data are standardized, interoperable, flexible, and practical
- Promote effective data collection
- Conduct annual reviews to identify gaps and potential improvements in data collection and sharing

To read the full text of this recommendation, see the Recommendations Insert.

DATA GOVERNANCE AND LEADERSHIP

In the United States, no current federal or state laws protect or mandate the sharing of sequence data from virus samples. Any such data sharing is done voluntarily and generally without concerns about possible regulatory barriers. In contrast, there are federal and state laws protecting clinical and epidemiological data, including the Health Insurance Portability and Accountability Act (HIPAA). Without funding to support the costs associated with gathering and preparing data to be shared with public health authorities and researchers, and without clear regulatory pathways and established infrastructure to support sharing, the sharing of virus sequencing data is suboptimal.

Given the national and interstate threat posed by a pandemic like COVID-19, data sharing needs to happen on a national scale through formalized agreements with federal authorities, rather than purely within state borders or with the federal government on an ad hoc basis. These data sharing and reporting processes should be clearly established and funded prior to any public health emergency. To standardize and encourage the practice of quality data sharing for public health practice during a pandemic, the committee recommended that HHS establish a national leadership structure to facilitate comprehensive data sharing. This structure should include science-driven leadership and governance for the use of SARS-CoV-2 genome sequences. Key components of this structure should also include

- leadership that has the authority and responsibility to identify and prioritize key issues related to data needs;
- a national strategy for using SARS-CoV-2 genome sequences that clearly articulates goals, priorities, and a path for achieving them; and
- a governing board with diverse, relevant expertise that has broad authority to oversee and advise the national strategy for SARS-CoV-2 genome sequencing and the delivery of actionable data for related investigations.

To read the full text of this recommendation, see the Recommendations Insert.

RECOMMENDATIONS

JULY 2020 • GENOMIC EPIDEMIOLOGY DATA INFRASTRUCTURE NEEDS FOR SARS-COV-2 MODERNIZING PANDEMIC RESPONSE STRATEGIES

RECOMMENDATION 1

The U.S. Department of Health and Human Services should ensure the generation of representative, high-quality full genome sequences of SARS-CoV-2 across the United States, and in the future, from emerging epidemic or pandemic pathogens, in order that these data can be used to meet key needs for genomic surveillance

- Pathogen samples must be obtained from individuals who represent broad diversity of factors such as race and ethnicity, gender, age, geography, and other demographic features such as housing type, clinical manifestations and outcomes, and transmissibility.
- Capacity for genomic sequencing should be developed and supported at many geographically distributed sites performing testing, including public health laboratories, academic and medical centers.
- Representative SARS-CoV-2 clinical samples from across the United States should be collected and sequenced on an ongoing basis to provide baseline data and facilitate near real-time transmission tracking.

Genome sequences should be shared openly on publicly accessible databases, such as the National Center for Biotechnology Information linked to the Global Initiative on Sharing All Influenza Data.

RECOMMENDATION 2

The U.S. Department of Health and Human Services should develop and invest in a national data infrastructure system that constructively builds upon existing programmatic infrastructure with the ability to accurately, efficiently, and safely link genomic data, clinical data, epidemiological data, and other relevant data across multiple sources critical to a public health response such as the current SARS-CoV-2 outbreak. Such a system should:

- Allow for the linkage of genomic data, clinical data, epidemiological data, and other relevant data in a way that is not overly burdensome to laboratories that collect data regularly.
- Create and foster safe data sharing practices to ensure that individuals' personal identifying information remains unexposed when data are being used and shared across the system.
- Be grounded in the pursuit of standardization, interoperability, flexibility, and the practical linkage of data, including consideration of a potential national patient identifier.
- Consider not only the data required to create such a system, but also investment in mechanisms supporting the collection and analysis of such data, including promoting formal education in "data wrangling" at the intersection of data science and infectious disease epidemiology.
- Conduct regular annual reviews—including scenario-based simulations—to identify capacity gaps, promote process improvement (based on existing U.S. infrastructure to assess the annual risk of seasonal influenza, work could improve usability and coverage of health information exchanges, and other initiatives) and ensure inclusion of entities with supporting functions across scales—including private health care systems that provide data or state and local public health laboratories that collect data—in ongoing system development and evaluation.

RECOMMENDATION 3

The U.S. Department of Health and Human Services should establish an effective and sustainable science-driven leadership and governance structure for the use of SARS-CoV-2 genome sequences in addressing critical national public health and basic science issues, develop a national strategy, and ensure the funding needed for successful execution of the strategy.

- Leaders of this effort must have sufficient authorities and responsibilities to ensure that key issues are identified and prioritized, representative data are generated, and barriers to data sharing are diminished.
- A national strategy for SARS-CoV-2 genome sequences linked to clinical and epidemiological data should be developed that articulates goals, priorities, and a path for achieving them.
- A board with diverse relevant expertise should be established with broad authority to oversee and advise the national strategy for SARS-CoV-2 genome sequences linked to clinical and epidemiological data, and the delivery of actionable data for related investigations.

Subject: Press release for EID SEARCH, our NIAID-funded CREID contract
Attachment: EID SEARCH CREID Grant Kickoff Press Release FINAL.docx

We got our press release approved by NIAID. Please see the attached.

We're expecting the NIAID CREID website (www.niaidcreid.org) to go live on Wednesday 12th August, and we've been told that the news will be released to the press next week (beginning 17th Aug). NIAID will confirm this and we'll be back in touch. Please don't speak to reporters until we get that date from NIAID.

One other thing, please make sure (as per our Notice of Award) that NIAID and the grant number are referenced in any press release, publication, or presentation. It's really important that we people recognize NIAID are funding this sort of international collaboration – I want to make sure the US Govt continues to support our global efforts to prevent pandemics!!!

Thanks everyone and speak to you all soon

Cheers,

Peter

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Rapid recovery of a SARS-CoV-2 e infected X-linked agammaglobulinemia patient after infusion of COVID-19 convalescent plasma

Estefanía Mira, MD[a], Oscar A. Yarce, MD[b], Consuelo Ortega, MD, PhD[c], Silvia Fernández, PhD[c], Natalia M. Pascual, MD[a], Cristina Gómez, MD[a], Miguel A. Alvarez, MD[d], Ignacio J. Molina, MD, PhD[e], Rafael Lama, MD, PhD[a], and Manuel Santamaria, MD, PhD[b,c]

Clinical Implications

A patient with X-linked agammaglobulinemia was infected with severe acute respiratory syndrome coronavirus 2 and presented a 40-day long and stagnant clinical evolution refractory to treatment. The patient received a single dose of coronavirus disease 2019 convalescent plasma and experienced a rapid clinical improvement within 1 week of infusion.

The high infectivity of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the lack of preexisting immunity among the population, and the complexity of the coronavirus disease 2019 (COVID-19) clinical presentation are some of the underlying reasons of the ongoing worldwide health crisis. Antibodies play relevant roles in antiviral responses,[1] and hence, patients with compromised specific humoral immunity may be at increased risk to suffer from severe forms of the disease. In fact, 3 recent studies described the clinical evolution of 6 patients with common variable immunodeficiency (CVID), 3 patients with x-linked agammaglobulinemia (XLA) (OMIM# 300755; Bruton's disease), and 1 patient with autosomal agammaglobulinemia.[2-4] However, the mild clinical presentation in agammaglobulinemic patients, as opposed to the former, prompted speculations that anti–SARS-CoV-2 antibodies may be dispensable in clearing the disease.[4] This would highlight the relevance of T-cell responses and the significance of anti–SARS-CoV-2 T-cell exhaustion in the ultimate progression of the disease.[5] However, administration of hyperimmune plasma was beneficial in some immunocompetent patients with COVID-19.[6]

We report the case of a 39-year-old male patient with XLA, receiving monthly immunoglobulin replacement therapy, admitted to our hospital with dyspnea, dry cough, and fever of 2-week duration. Chest X-rays showed unilateral alveolar condensation, and quantitative PCR (qPCR) amplification of SARS-CoV-2 from a nasopharyngeal exudate sample confirmed the diagnosis of COVID-19. The patient received hydroxychloroquine (400 mg/12 h, the first day; 200 mg/12 h, 4 days, orally), azithromycin (500 mg/24 h, 5 days, orally), and ceftriaxone (2 g/24 h, 7 days, intravenously [IV]) and a single dose (0.3 g/kg) of IV immunoglobulins. No supplemental oxygen was required.

In spite of a favorable initial clinical evolution, fever persisted and intense asthenia appeared. Therefore, empirical therapy against nosocomial germs was started with piperacillin/tazobactam (4 g/0.5 g/8 h, IV) and linezolid (600 mg/12 h, IV). SARS-CoV-2 qPCR test result remained positive on day 11 after admission. On day 15 computed tomography showed extensive bilateral pulmonary involvement in the form of nodular consolidations in ground glass with underlying interstitial pattern (Figure 1, upper panel). Blood, sputum, stool, and urine cultures were negative. Infections by other respiratory viruses (adenovirus, metapneumovirus, inovirus, and respiratory syncytial virus), as well as the presence of opportunistic germs such as Pneumocystis jiroveci, cytomegalovirus, EBV, Mycoplasma pneumoniae, aspergillus, leishmania, and brucella, were all excluded. A third SARS-CoV-2 qPCR was carried out on day 21 after admission and the result remained positive.

Stagnancy in the patient's evolution, as represented by the lack of response to any of the treatments dispensed (including a second pulse of nonspecific immunoglobulins at 0.8 g/kg/24 h and aggressive antibiotic therapy), together with persistent fever and bilateral pneumonia, prompted us to consider the possibility that natural killer (NK)-cell and T-cell exhaustion might be an underlying cause for immunologic failure, as shown elsewhere.[5] We assessed this possibility in lung lymphoid populations obtained by bronchoalveolar lavage on day 21 after admission, and they consisted of $CD3^b$ $CD8^b$ (86%) and $CD3^b$ $CD4^b$ T lymphocytes (11.5%) and $CD56^b$ $CD16^b$ NK cells (2.5%). Staining of intracellular cytokines in stimulated $CD8^b$ cells showed negligible production of TNF-α or IFN-γ (Figure 2, A, middle and bottom panels).

Because of the resulting lymphocyte phenotype, we reasoned that, in the absence of functional B cells, viral clearance would not be possible. Hence, we administered on day 23 after admission compassionate-use approved COVID-19 convalescent donor plasma (200 mL, single dose, IV). The plasma was analyzed by an ELISA (COVID-19 ELISA IgG, Vircell SL, Granada, Spain), which detected IgG antibodies against either the spike or nucleocapsid viral proteins with a titer greater than or equal to 1/320. After 24 hours of infusion, fever ceased without subsequent reappearance and with progressive improvement of asthenia. After 48 hours of infusion, qPCR from nasopharyngeal exudate failed to amplify SARS-CoV-2 sequences.

On day 30 after admission, that is, 1 week after administration of COVID-19 convalescent donor plasma, the patient remained asymptomatic and a chest tomography showed almost complete resolution of bilateral lung lesions (Figure 1, lower panel). Furthermore, a vigorous recovery in the peripheral T-lymphocyte subpopulations ($CD3^b$, $CD4^b$, and $CD8^b$) was observed, whereas NK-cell counts slightly increased (Figure 2, B). Hence, the patient was subsequently discharged and remains COVID-19 free.

Although cumulative cases of SARS-CoV-2–infected patients suffering from primary antibody immunodeficiencies are limited, it appears that individuals devoid of B cells (agammaglobulinemia) have a milder presentation and course than those with a partial B-cell repertoire (CVID).[2-4] This observation is

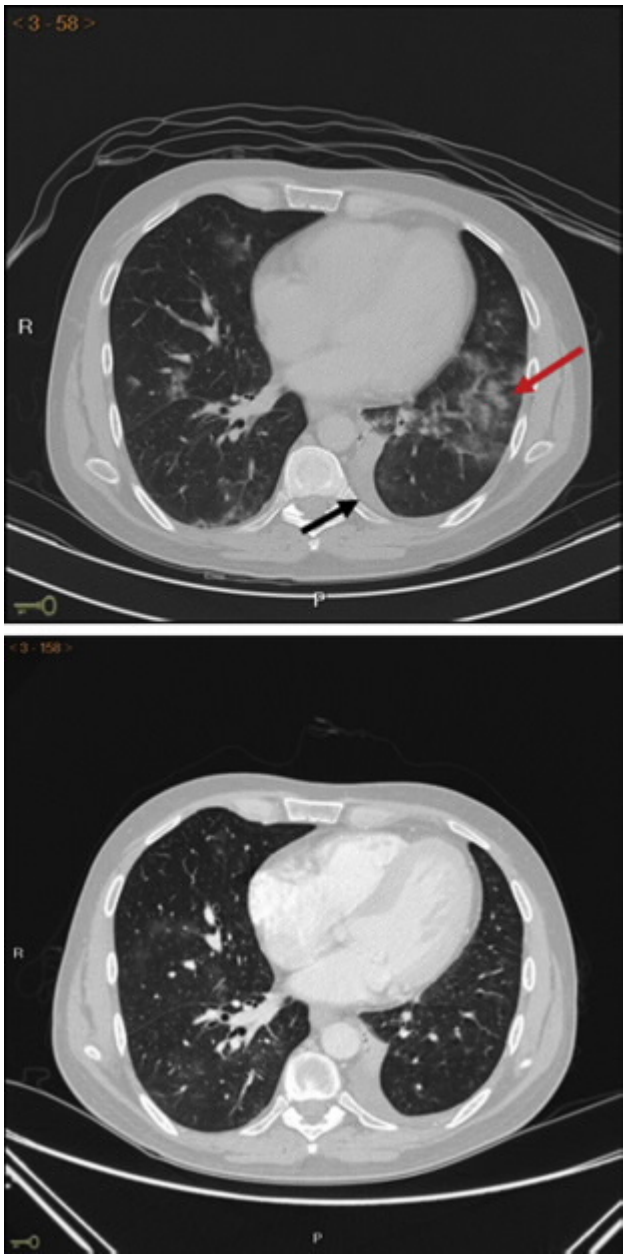

FIGURE 1. Upper panel: CT displaying bilateral pulmonary involvement in the form of nodular consolidations and ground-glass opacities primarily in the left lower lobe (red arrow) and small-size left pleural effusion (black arrow). Lower panel: CT of the chest 6 days after COVID-19 convalescent donor plasma transfusion showing almost complete resolution of bilateral lung lesions pattern. CT, Computed tomography.

strengthened by the finding that pharmacological blockade of Bruton tyrosine kinase results in diminished lung inflammatory response by inhibiting overproduction of macrophage-mediated cytokines.[7] The evolution of our patient was consistent with those observations until day 15 of admission, when he suffered a rapid deterioration in his condition accompanied by a lack of cytokine production by lung T and NK cells. If this lack of functional response was the consequence of cell exhaustion, we should bear in mind that T-cell response involve triggering of multiple epitope-specific clones, and not all may be equally prone to functional blockade.[8] Therefore, local silencing of immunodominant clones may hamper the overall immune response.

The remarkable and prompt recovery observed after infusion of convalescent plasma suggests that certain patients may have stringent dependency on specific antibodies to achieve viral clearance. Although this is a single case and therefore the observation could be coincidental and we have not formally established a cause-effect relationship, we nevertheless propose that administration of COVID-19 hyperimmune plasma should be further explored as first line of treatment for patients with congenital agammaglobulinemia, especially while SARS-CoV-2–specific antiviral drugs remain unavailable. Previous clinical cases suggest that B cells may have a prominent role in triggering lung inflammation[3]; in this scenario, defective germinal center formation due to the primary immunodeficiency would divert IL-6 intended for that process toward lung inflammation, thus raising the possibility of a B-cell interference as therapeutic intervention.[3] However, our data suggest a critical role of B cells in clearing the disease when certain immunologic conditions are present.

In summary, even though administration of passive immunity for patients with primary immunodeficiency has just been proposed,[9] this is the first report showing a rapid recovery of a patient with a primary antibody immunodeficiency after administration of hyperimmune plasma. Although it should be kept in mind whether the patient reported here was idiosyncratic and might not represent a prototypical patient with XLA (despite carrying a common Bruton tyrosine kinase gene mutation), our data merit further investigations to determine the precise clinical benefit of hyperimmune plasma in other antibody-deficient patients, as well as optimal dose and timing of its administration.

four pediatric patients with acute respiratory distress syndrome. We measured donor antibody levels and recipient antibody response prior to and following CP infusion. Infusion of CP was not associated with antibody-dependent enhancement (ADE) and did not suppress endogenous antibody response. We found CP was safe and possibly efficacious. Randomized pediatric trials are needed.

KEYWORDS
convalescent plasma, COVID-19, pediatrics, SARS-CoV-2

1 | INTRODUCTION

Early reports from the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) global pandemic suggested that children were less severely affected by coronavirus disease 2019 (COVID-19) compared to older adults.[1–3] Nevertheless, some children with COVID-19 are critically ill.[4,5] Currently, no therapies have been proven effective in the treatment of COVID-19 in children.

Convalescent plasma (CP) derived from patients that have recovered from SARS-CoV-2 can be infused into currently ill patients. The proposed mechanism of action is via neutralizing antibodies binding to virus, rendering it inert.[6] Specific to SARS-CoV-2, antibodies against the receptor-binding domain (RBD) have been identified as surrogates for neutralization.[7–11] CP also contains antibodies against the immunogenic nucleocapsid (N) protein, which are nonneutralizing and present in both actively infected and recovered patients.[7] The protective function of N antibodies remains unclear.[7,12] Antibodies against the full-length SARS-CoV-2 spike (S) protein include both nonneutralizing antibodies and neutralizing antibodies.[13]

Initial series of CP in adults with COVID-19 demonstrated potential benefits without apparent side effects.[14–17] In a recent clinical trial of adults with COVID-19, there was a nonstatistically significant trend toward clinical improvement in CP-treated patients versus controls, without improvement in time to discharge or mortality.[18] This trial was halted early due to poor accrual.[18] To date, there have been no reports on the use of CP in children.

CP infusion is associated with the side effects of any blood product: allergic reaction, transfusion-associated circulatory overload, and infection with blood-borne pathogens. There is a theoretical risk that infusion of donor antibodies may impede the recipient's endogenous production of antibodies, and of antibody-dependent enhancement (ADE), where antibodies developed during a previous infection cause a worsened clinical response with subsequent infection. ADE has been described in dengue fever, and in preclinical models of other coronaviruses.[19–21] ADE has not been reported in adult patients receiving CP for SARS-CoV-2.[6,17,18]

We present the first report of pediatric patients receiving CP for life-threatening COVID-19-associated respiratory disease with correlative measurements of the associated pre- and posttransfusion antibody response.

2 | METHODS

We treated four critically ill children actively infected with SARS-CoV-2 with CP at the Children's Hospital of Philadelphia (CHOP) under emergency Investigational New Drug applications (eINDs) through the Food and Drug Administration (FDA). Patients were considered for CP if they met FDA guidance for life-threatening disease (Appendix S1). Per the American Red Cross Guidelines, donors were eligible to provide CP if they met the following criteria: (a) they were initially proven positive for SARS-CoV-2 by a laboratory test; and either (b1) at least 14 days from symptom resolution with a repeat documented negative test for SARS-CoV-2, or (b2) at least 28 days from symptom resolution without a documented repeat test results at the time of plasma collection.

We prospectively screened and enrolled these patients into a larger SARS-CoV-2 biobanking protocol. The objective of the SARS-CoV-2 biorepository protocol is to collect samples on patients with confirmed SARS-CoV-2 infection or multisystem inflammatory syndrome in children (MIS-C). An initial report from this biorepository has been published.[22] Patients were enrolled on the biobank protocol if they had evidence of SARS-CoV-2 infection on reverse-transcriptase polymerase chain reaction (RT-PCR) testing from respiratory tract mucosa. This protocol was approved by the CHOP Institutional Review Board (IRB). Consent was obtained for both protocols from a legal authorized representative per the Declaration of Helsinki (written informed consent for CP; verbal consent for biobanking).

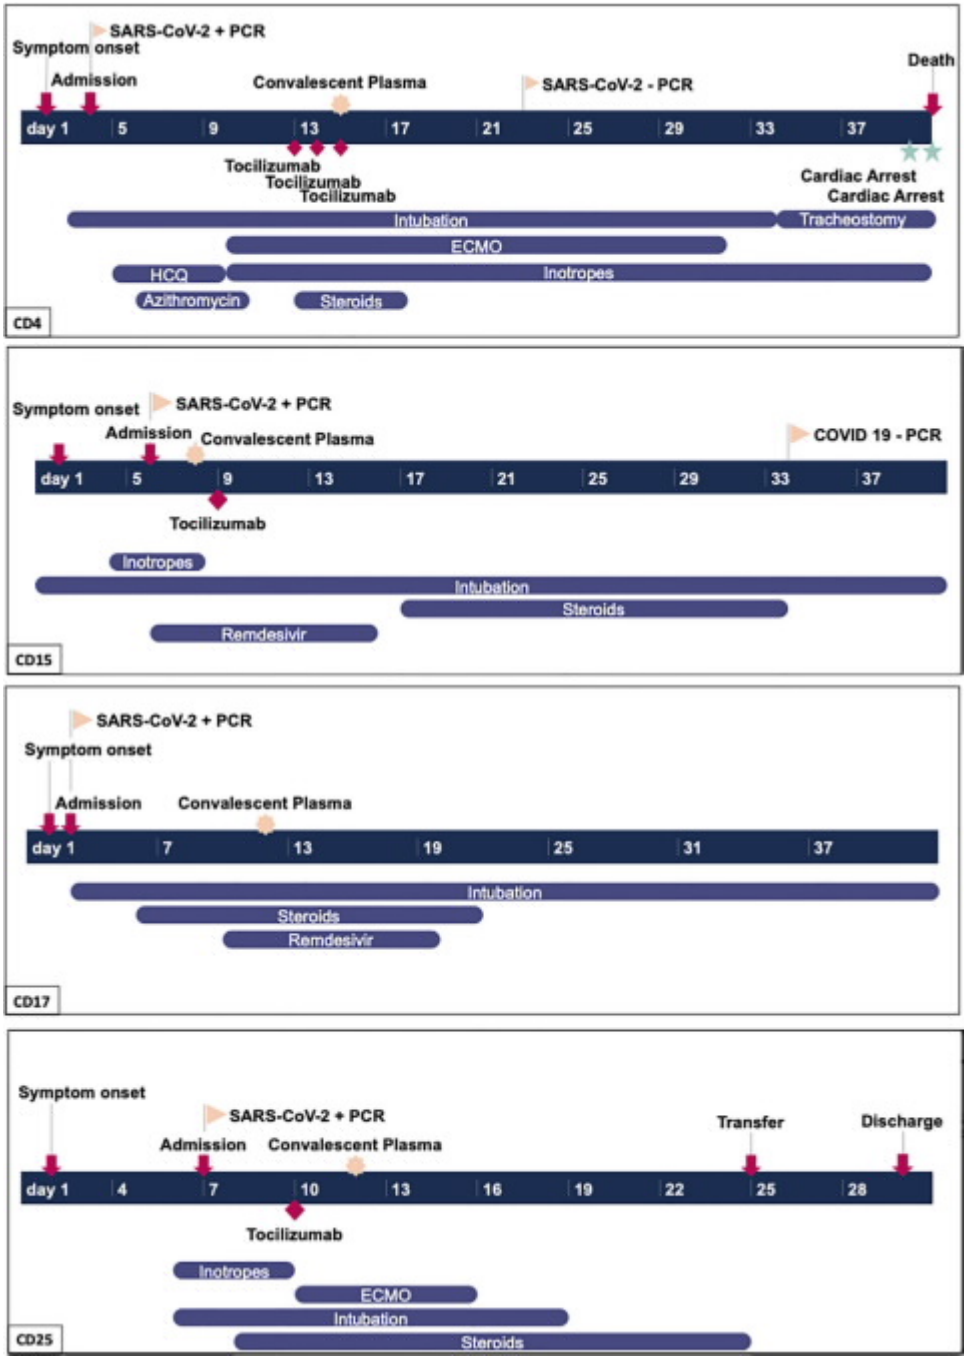

FIGURE 1 Graphical representation of clinical course of four patients included in the caseseries. Timeline includes up to day 40 of illness, or until death or discharge, whatever occurred first. ECMO, extracorporeal membrane oxygenation; HCQ, hydroxychloroquine; PCR, polymerase chain reaction

Verbal consent for biobanking was obtained based on IRB recommendations to prevent exposure to research staff and to avoid unintentional transmission of SARS-CoV-2via fomites such as consent forms.

Clinical data were abstracted from patient charts to standardized forms by a research assistant using a REDCap database, and verified by a physician. Blood sampleswere obtained from participants prior to CP infusion, following CP infusion, and weekly thereafter until death or discharge. Remnant donor CP was retained, per institutional protocol in case of transfusion reaction. Remnant donor CP was then collected and stored.

SARS-CoV-2-specificantibodies were measured by enzyme-linked immunosorbent assay (ELISA) as previously described.[8] Antibodies in serially diluted plasma (starting at 1:50) were measured against RBD of the SARS-CoV-2S protein,[9] full-length S protein, and the N protein (Sino Biological, Wayne, PA). Reciprocal plasma dilutions were calculated from an optical density threshold from a set concentration. Standard curves were generated by diluting an RBD-specific monoclonal

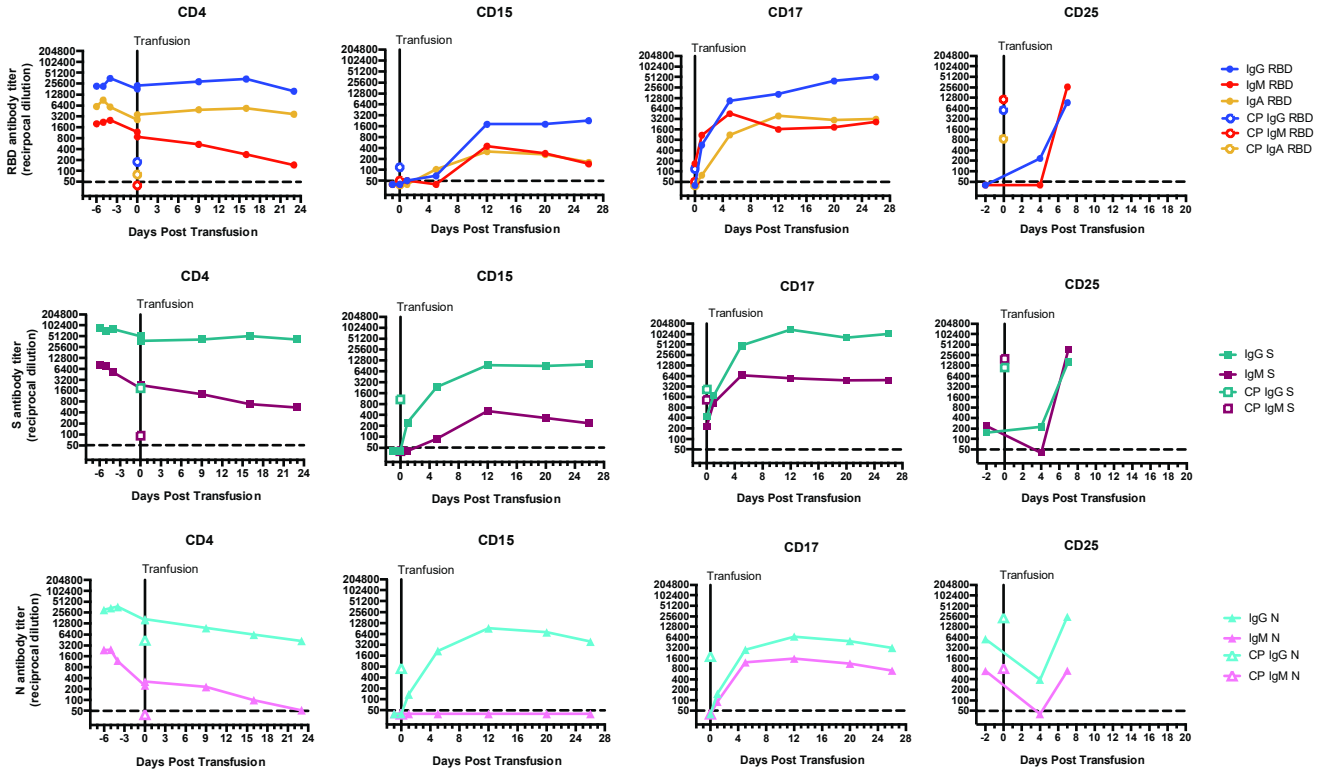

FIGURE 2 Longitudinal serum SARS-CoV-2 antibody titers in pediatric patients receiving convalescent plasma (CP) transfusion therapy. Antibody titers expressed as reciprocal serum dilution against SARS-CoV-2 antigens in four pediatric patients (CD4, CD15, CD17, and CD25), and corresponding CP donors (open symbols) before and after plasma transfusion. Antibody titers against (A-D) the SARS-CoV-2 receptor-binding domain of the spike (S) protein, (E-H) the full-length SARS-CoV-2 S protein (FL), and (I-L) the nucleoprotein of SARS-CoV-2 (N). Dashed lines denote the lower limit of detection (LLOD) of the assay (1:50 serum dilution)

antibody (CR3022) starting at 0.5 μg/mL (RBD and S ELISAs), or serially diluted pooled serum from actively SARS-CoV-2-infected adults (N ELISAs). See Appendix S2 for detailed methods.

3 | RESULTS AND DISCUSSION

Four patients, 14–18 years, were treated with CP during the study period. Patients received all available plasma from the donors, in the range of 200–220 mL. Patient CD4 received 2 mL/kg, and patients CD15, CD17, and CD25 received 4 mL/kg. All patients were critically ill with COVID-19-associated acute respiratory distress syndrome. All patients required intubation and ventilation; two required extracorporeal membrane oxygenation (ECMO). None of the patients had MIS-C. All patients received other SARS-CoV-2-directed therapies in addition to CP. Graphical case summaries are presented in Figure 1. Further details are presented in Appendix S3. No patients experienced any treatment-emergent adverse events (TEAE) related to CP infusion.

Longitudinal antibody titers are presented in Figure 2. Corresponding antibody titers for CP donors are displayed. At the time of CP infusion, patient CD4 had extremely high endogenous antibody titers (against SARS-CoV-2 RBD, S, and N). Antibody titers in this participant were sustained post transfusion. This individual showed transient clinical improvement, decannulating from ECMO; however, died from cardiac causes by day 25 post transfusion. An autopsy was performed, which demonstrated diffuse alveolar damage and hypertrophic cardiomyopathy with associated myocardial fibrosis. Spleen and lung cultures were positive for *Candida glabrata*. There was no evidence of myocarditis.

Patients CD15, CD17, and CD25 had low or undetectable RBD-specific antibody titers at the time of infusion. Serum antibodies against the SARS-CoV-2 RBD correlate with neutralizing activity, likely due to inhibition of the virus' ability to bind and enter target cells.[8–10] Of note, the donor plasma infused into patients CD15 and CD17 had relatively low RBD-specific antibody titer levels (< 1:160). Both CP donors for CD15 and CD17 had substantial full-length IgG S titers (> 1:1000), and these may have conferred some neutralizing activity. It is unclear if CP with low RBD-specific and high full-length IgG S antibody titers would provide benefit. CD15 and CD17 both remain in intensive care and did not have significant clinical improvement following CP infusion, although CD15 did wean off inotropic support shortly after receiving CP. CD17 did not require inotropic support. Both patients continued to require intubation and ventilatory support despite CP. As of August 22, 2020 both CD15 and CD17 remain in hospital and have had the placement of tracheostomies. They both remain on ventilatory support, although at a lower level than required during

acute illness. The donor for patient CD25 had higher SARS-CoV-2 RBD antibody titers (> 1:6000) than the donor for any of the other patients, making it more likely that this donor plasma could be beneficial. CD25 had the shortest period of admission and has been discharged from the hospital after being critically ill and on ECMO.

Prior to transfusion, three of the four recipients (CD15, CD17, and CD25) had undetectable IgG RBD antibody levels (< 1:50 serum dilution). Upon transfusion, all three participants eventually experienced a boost in IgG, IgM, and IgA antibodies against RBD that was sustained for 7-26 days post transfusion. In one participant (CD15), we detected antibodies against the full-length S protein before we detected antibodies against the RBD of the S protein. The boost in antibodies against N post transfusion was similar to that of RBD and S-specific serum antibodies for patients CD15, CD17, and CD25. In all three patients, the serum levels of SARS-CoV-2-specific antibodies eventually surpassed the amount transfused, indicating that these patients mounted a post transfusion de novo response and that CP did not eliminate the endogenous serological response.

In summary, CP was safely administered to four pediatric patients with severe COVID-19. There were no CP-related TEAE. The theoretical risks of ADE or elimination of endogenous antibody response did not occur. CP may be of greatest benefit for patients who are early in their illness and have not yet generated endogenous antibodies, and when the infused plasma has a high antibody titer. The patient who received CP with the highest antibody titer had the best clinical response, although the total antibody response mounted did not differ markedly from the other patients. The small sample size of our study precludes definitive conclusions about efficacy, however, the excellent clinical response in this patient is encouraging. The other patients had significant comorbidities that may have contributed to their clinical status. It is difficult to determine if CD15 and CD17 benefited, as it is possible without CP they could have continued to worsen. Future research should include randomized controlled trials to definitively examine the efficacy of CP in children.

Key Points

- ü COVID-19 convalescent plasma (CP) may be a safe and effective treatment option in SARS-CoV-2 infection refractory to remdesivir.
- ü Infants may benefit from CP despite developing immune systems and donor variability emphasizes the need for characterization prior to use.

Introduction

Although , 2% of coronavirus disease 2019 (COVID-19) infections are reported in the pediatric population, children with comorbidities such as congenital heart disease and those at a young age are more likely to become critically ill.[1-3] Remdesivir has been reported to be efficacious in adults with COVID-19[4]; however, there are no studies in children. Convalescent plasma (CP) can contain neutralizing antibodies to viruses,[5] and has been used during previous viral epidemics with clinical improvement.[6-11] COVID-19 CP (C19-CP) may be useful in critically ill adults, resulting in improvement in inflammatory markers, pulmonary lesions, and mortality.[12] However, the impact of C19-CP in pediatric patients, particularly infants with developing immune systems and significant comorbidities, is completely unknown.

We present an infant with cardiopulmonary failure secondary to unrepaired congenital heart disease exacerbated by COVID-19. Given postsurgical complications of children with viral respiratory infection,[13-17] the patient required clearance of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) for surgical candidacy. We hypothesized that C19-CP administration may clear SARS-CoV-2 following failure of remdesivir.

Case description

A 3.1-kg term 9-week-old female with trisomy 21 and unrepaired balanced complete atrioventricular canal defect with baseline mild to moderate common atrioventricular valve regurgitation (AVVR) presented in acute hypoxemic respiratory failure secondary to progressive decompensated heart failure. Notable findings included lymphopenia, b-natriuretic peptide of 530 pg/mL (reference range , 100 pg/mL), worsened AVVR (moderate to severe), and cardiomegaly and pulmonary edema on chest X-ray. Initial treatment, including bilevel noninvasive positive pressure ventilation, milrinone infusion, and IV diuretics, resulted in restoration of organ function. By hospital day 8, her common AVVR returned to baseline; she transitioned from milrinone to captopril, carvedilol, and IV diuretics and had weaned to high-flow nasal cannula; and she was transferred to the general cardiology floor.

On hospital day 12, she developed acute hypoxemic respiratory failure and decompensated heart failure, with atelectasis on chest X-ray and new rhinorrhea requiring bilevel noninvasive positive pressure ventilation. The result of SARS-CoV-2 nucleic acid testing (NAT) (DiaSorin Molecular Simplexa direct real-time PCR of viral RNA, Cypress, CA) on a nasopharyngeal (NP) swab was positive; a residual sample from a respiratory viral panel performed on hospital day 5 for intermittent desaturations was retested for SARS-CoV-2 and likewise had a positive result (Figure 1A). The source of the infection remains unclear. While the mother and siblings were asymptomatic, they were quarantined for 14 days after infection was identified in the patient but never tested. Nosocomial infection is certainly possible

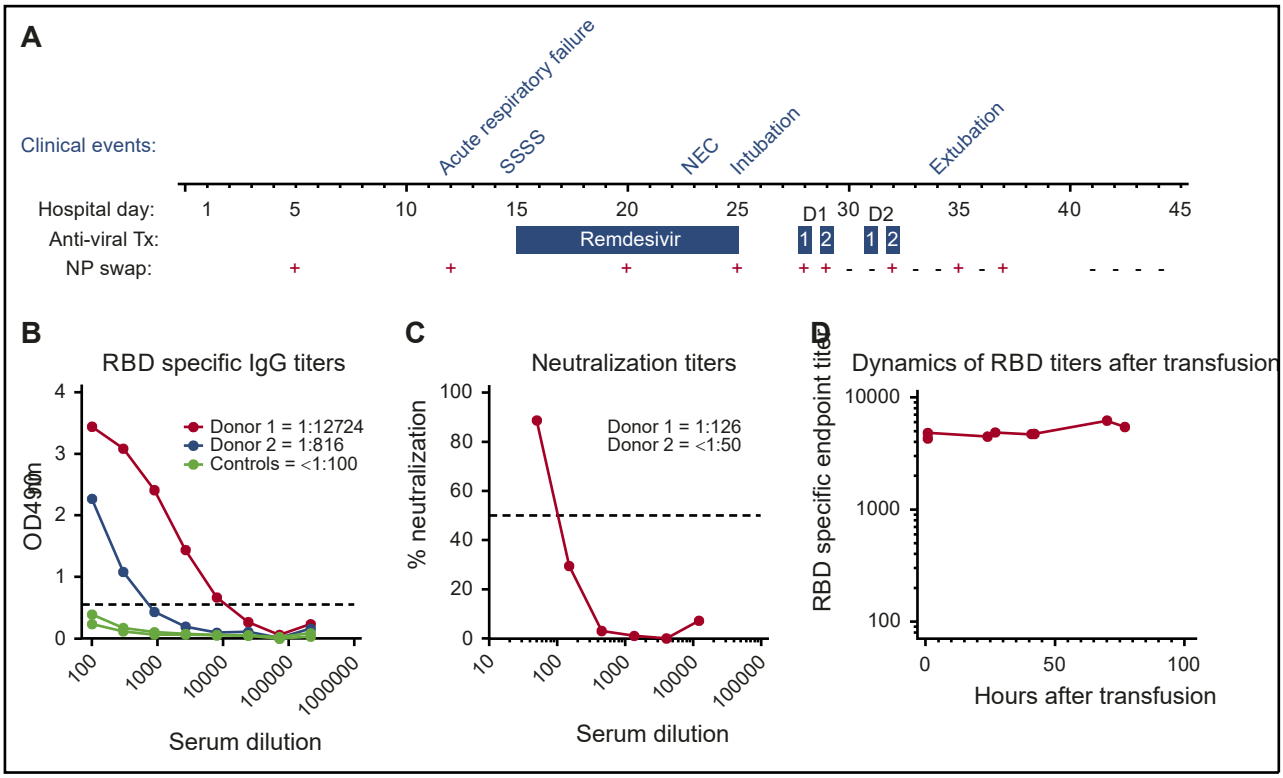

Figure 1. Hospital course summary and donor and patient plasma characterization. (A) Hospital course by clinical event, antiviral therapy (Tx), and C19-CP transfusion in relation to NP swab SARS-CoV-2 RNA results. Clinical events are as follows: acute respiratory failure on hospital day 12, staphylococcal scalded skin syndrome (SSSS) on hospital day 14, necrotizing enterococcus (NEC) on hospital day 23, intubation on hospital day 25, and extubation on hospital day 34. Dosages of antiviral therapy are as follows: remdesivir: 5 mg/kg per day on hospital day 15 and 2.5 mg/kg/day on hospital days 16 to 25; C19-CP donor 1: 10 mL/kg per day over 4 hours; 20 hours apart on hospital days 28 and 29; and C19-CP donor 2: 10 mL/kg per day over 4 hours; 20 hours apart on hospital days 31 and 32. (B) Enzyme-linked immunosorbent assays showing titration of samples from the 2 C19-CP donors and 3 negative controls collected before 2019, against SARS-CoV-2 spike RBD. End point titers were calculated using a cutoff of the average of the control samples, plus 3 times standard deviation value, marked with a dotted line. End points were calculated as the intersection of samples with this cutoff. Titers are shown numerically in the legend. (C) Neutralization activity of C19-CP donor samples against SARS-CoV-2. The focus reduction neutralization test $(FRNT)_{50}$ titers of the C19-CP donor samples were determined by an FRNT assay using an immunostain to detect infected foci. The dotted line represents the maximum concentrations of the serum tested (1/50). (D) Dynamics of RBD-specific end-point titers in the recipient after transfusion.

but less likely, as the hospital had very few infected patients, none of those infected were in the cardiac intensive care unit, and there was no shortage of personal protective gear at the hospital prior or following the patient's infection. Additional investigation did not reveal macrophage activation syndrome or new bacterial or viral infection. As her prolonged QTc prohibited use of hydroxychloroquine, remdesivir (5 mg/kg per day on hospital day 15 and 2.5 mg/kg per day on hospital days 16-25) was given. Her hospital course was complicated by staphylococcal scalded skin syndrome, treated with nafcillin, and stage II necrotizing enterocolitis (Bell criteria), treated with piperacillin-tazobactam (Figure 1A). Throughout this time, she continued to have persistent lymphopenia, a C-reactive protein (CRP) level of 5 mg/dL (reference range, , 1.0 mg/dL) with normal fibrinogen, and a common AVVR that remained unchanged with preserved biventricular function managed with IV diuretics.

Despite completion of remdesivir, on hospital day 25, she required endotracheal intubation for worsening respiratory failure. Repeat investigation was notable for persistent lymphopenia, persistent SARS-CoV-2, CRP 7.7 mg/dL, but no evidence of new secondary infection or macrophage activation syndrome was found. Milrinone was reinitiated in addition to IV diuretics. Given her lack of response to remdesivir and deteriorating clinical status, 2 aliquots of CP (10 mL/kg per aliquot) from 2 COVID-19 recovered donors (C19-CP) were transfused in accordance with the World Health Organization guidelines for Ebola CP treatment in children[9] (Figure 1A). She received increased IV diuretics, daily monitoring of serum chemistries, and intermittent monitoring of coagulopathy. Daily surveillance of SARS-CoV-2 NAT by NP swab was performed, and the results were negative following the second aliquot from donor 1 (Figure 1A) with concurrent reduced ventilator support. She was extubated on hospital day 34. The infant tolerated all transfusions without anaphylaxis, transfusion-related circulatory overload, transfusion-related acute lung injury, or hypercoagulability. The results of daily NP swabs were intermittently positive before becoming persistently negative (Figure 1A). Other notable findings post–C19-CP transfusion include CRP of 1.3 mg/dL and intermittent normalization of absolute lymphocyte count. The patient had an uneventful complete repair 47 days (hospital day 91) after SARS-CoV-2 infection resolution and is doing well.

Methods

The patient is blood group O RhD negative. Donor 1 is a 63-year-old male who donated 35 days following COVID-19 symptom resolution and is blood type A RhD positive. Donor 2 is a 56-year-old male who donated 55 days following COVID-19 symptom resolution and is blood type O RhD negative. Both had mild COVID-19 infection, and neither was hospitalized. The plasma donor units were transfused without prior characterization per emergency use. To understand the impact of C19-CP treatment, both donor units were tested for titers of IgG against the receptor-binding domain (RBD) of the SARS-CoV-2 spike protein (Emory University and Children's Healthcare of Atlanta, Atlanta, GA), which has been shown to correlate with neutralizing titers,[18] and subsequent microneutralization assays were performed in a biosafety level 3 laboratory.[19] Donor 1 had an immunoglobulin G (IgG) titer of 1:12 724 and neutralizing titer of 1:126. Donor 2 had an IgG titer of 1:816 and a neutralizing titer of , 1:50 (Figure 1B-C, respectively). Following the first aliquot from donor 1, the recipient showed robust IgG anti-SARS-CoV-2 antibody levels of ; 1:5000, which was sustained after all subsequent transfusions (Figure 1D).

Results and discussion

Young age, unrepaired congenital heart disease, trisomy 21, persistent lymphopenia, and naive immune system likely increased this patient's SARS-CoV-2 vulnerability. While this represents only 1 case, her improved respiratory status, increase in lymphocytes, and decrease in CRP after C19-CP transfusion suggest a positive clinical correlation, especially in the setting of subsequent SARS-CoV-2 clearance.

Logistical constraints prevented anti-SARS-CoV-2 antibody characterization of C19-CP prior to transfusion, which likely reflects common current approaches to emergent C19-CP administration. C19-CP from donor 1 likely provided the most significant impact on SARS-CoV-2 eradication given the higher neutralizing titer (Figure 1C), which is comparable to US Food and Drug Administration recommendations[20] and may be sufficient when treating COVID-19 in adults.[10-21] This case suggests that such titers may likewise be sufficient in infants. The delay in viral clearance may reflect the time required for C19-CP therapy to effectively eliminate the virus and is consistent with reports in adults with persistent SARS-CoV-2 NAT by NP samples beyond symptom resolution.[22,23]

Factors influencing high anti-SARS-CoV-2 titers with effective characteristics remain incompletely understood. Severe illness would be presumed to correlate with higher anti-SARS-CoV-2 antibodies. However, even though neither C19-CP donor was hospitalized, donor 1 possessed higher titers than donor 2, whose titers were below the limit of detection. This variability illustrates the challenge of current C19-CP transfusion practice, making it difficult to determine the potential benefit without adequate testing prior to C19-CP transfusion in place.

While neutralizing antibodies are critical for antibody-mediated protection against viral infection, the impact of CP on resolution of active infection remains incompletely understood. However, beyond direct neutralization of the virus, other mechanisms, such as antibody-dependent cellular cytotoxicity, may also play a role in the ability of C19-CP to aid in the clearance of an active infection. Such considerations may be especially important in infants with developing or suppressed immune systems that may attenuate the ability of other antibody effector systems to effectively clear COVID-19 following C19-CP therapy. While we were unfortunately unable to acquire neutralizing titer data from the patient prior to C19-CP administration to determine potential changes in antibody levels prior to and following administration of the first dose of C19-CP, data obtained following serial SARS-CoV-2 NAT evaluation provides uncommon insight into the temporal relationship between C19-CP and its potential impact on SARS-CoV-2 infection. However, this is a single case, and understandable uncertainties remain. Future studies will certainly be needed to fully define the efficacy of C19-CP in this vulnerable patient population.

Acknowledgments

The authors thank their colleagues at LifeSouth for collection of donor plasma. Parental consent was obtained for treatment with C19-CP. Review of medical records, publication of results, and research use of biospecimens per the Declaration of Helsinki under the protocols were approved by the Institutional Review Board of Emory University School of Medicine and the Department of Health and Human Services.

Authorship

Contribution: Z.R., S.R.S., and C.D.J. conceived of and wrote the manuscript; S.R.S., C.D.J., Z.R., M.S., and J.W. prepared the figures; A.L.S., H.V., C.L., M.G.Z., M.S., J.W., H.M., M.W., S.C., J.D.R.C., M.A., S.R.S., and C.D.J. critically reviewed, analyzed, and interpreted the data; M.G.Z., J.W., M.S., H.M., C.M.A., and S.R.S. performed the immunologic assays; and C.L. collected the donor units and information on blood donors.

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Rapid recovery of a SARS-CoV-2 e infected X-linked agammaglobulinemia patient after infusion of COVID-19 convalescent plasma

Estefanía Mira, MD[a], Oscar A. Yarce, MD[b], Consuelo Ortega, MD, PhD[c], Silvia Fernández, PhD[c], Natalia M. Pascual, MD[a], Cristina Gómez, MD[a], Miguel A. Alvarez, MD[d], Ignacio J. Molina, MD, PhD[e], Rafael Lama, MD, PhD[a], and Manuel Santamaria, MD, PhD[b,c]

Clinical Implications

A patient with X-linked agammaglobulinemia was infected with severe acute respiratory syndrome coronavirus 2 and presented a 40-day long and stagnant clinical evolution refractory to treatment. The patient received a single dose of coronavirus disease 2019 convalescent plasma and experienced a rapid clinical improvement within 1 week of infusion.

The high infectivity of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the lack of preexisting immunity among the population, and the complexity of the coronavirus disease 2019 (COVID-19) clinical presentation are some of the underlying reasons of the ongoing worldwide health crisis. Antibodies play relevant roles in antiviral responses,[1] and hence, patients with compromised specific humoral immunity may be at increased risk to suffer from severe forms of the disease. In fact, 3 recent studies described the clinical evolution of 6 patients with common variable immunodeficiency (CVID), 3 patients with x-linked agammaglobulinemia (XLA) (OMIM# 300755; Bruton's disease), and 1 patient with autosomal agammaglobulinemia.[2-4] However, the mild clinical presentation in agammaglobulinemic patients, as opposed to the former, prompted speculations that anti–SARS-CoV-2 antibodies may be dispensable in clearing the disease.[4] This would highlight the relevance of T-cell responses and the significance of anti–SARS-CoV-2 T-cell exhaustion in the ultimate progression of the disease.[5] However, administration of hyperimmune plasma was beneficial in some immunocompetent patients with COVID-19.[6]

We report the case of a 39-year-old male patient with XLA, receiving monthly immunoglobulin replacement therapy, admitted to our hospital with dyspnea, dry cough, and fever of 2-week duration. Chest X-rays showed unilateral alveolar condensation, and quantitative PCR (qPCR) amplification of SARS-CoV-2 from a nasopharyngeal exudate sample confirmed the diagnosis of COVID-19. The patient received hydroxychloroquine (400 mg/12 h, the first day; 200 mg/12 h, 4 days, orally), azithromycin (500 mg/24 h, 5 days, orally), and ceftriaxone (2 g/24 h, 7 days, intravenously [IV]) and a single dose (0.3 g/kg) of IV immunoglobulins. No supplemental oxygen was required.

In spite of a favorable initial clinical evolution, fever persisted and intense asthenia appeared. Therefore, empirical therapy against nosocomial germs was started with piperacillin/tazobactam (4 g/0.5 g/8 h, IV) and linezolid (600 mg/12 h, IV). SARS-CoV-2 qPCR test result remained positive on day 11 after admission. On day 15 computed tomography showed extensive bilateral pulmonary involvement in the form of nodular consolidations in ground glass with underlying interstitial pattern (Figure 1, upper panel). Blood, sputum, stool, and urine cultures were negative. Infections by other respiratory viruses (adenovirus, metapneumovirus, inovirus, and respiratory syncytial virus), as well as the presence of opportunistic germs such as Pneumocystis jiroveci, cytomegalovirus, EBV, Mycoplasma pneumoniae, aspergillus, leishmania, and brucella, were all excluded. A third SARS-CoV-2 qPCR was carried out on day 21 after admission and the result remained positive.

Stagnancy in the patient's evolution, as represented by the lack of response to any of the treatments dispensed (including a second pulse of nonspecific immunoglobulins at 0.8 g/kg/24 h and aggressive antibiotic therapy), together with persistent fever and bilateral pneumonia, prompted us to consider the possibility that natural killer (NK)-cell and T-cell exhaustion might be an underlying cause for immunologic failure, as shown elsewhere.[5] We assessed this possibility in lung lymphoid populations obtained by bronchoalveolar lavage on day 21 after admission, and they consisted of $CD3^b$ $CD8^b$ (86%) and $CD3^b$ $CD4^b$ T lymphocytes (11.5%) and $CD56^b$ $CD16^b$ NK cells (2.5%). Staining of intracellular cytokines in stimulated $CD8^b$ cells showed negligible production of TNF-α or IFN-γ (Figure 2, A, middle and bottom panels).

Because of the resulting lymphocyte phenotype, we reasoned that, in the absence of functional B cells, viral clearance would not be possible. Hence, we administered on day 23 after admission compassionate-use approved COVID-19 convalescent donor plasma (200 mL, single dose, IV). The plasma was analyzed by an ELISA (COVID-19 ELISA IgG, Vircell SL, Granada, Spain), which detected IgG antibodies against either the spike or nucleocapsid viral proteins with a titer greater than or equal to 1/320. After 24 hours of infusion, fever ceased without subsequent reappearance and with progressive improvement of asthenia. After 48 hours of infusion, qPCR from nasopharyngeal exudate failed to amplify SARS-CoV-2 sequences.

On day 30 after admission, that is, 1 week after administration of COVID-19 convalescent donor plasma, the patient remained asymptomatic and a chest tomography showed almost complete resolution of bilateral lung lesions (Figure 1, lower panel). Furthermore, a vigorous recovery in the peripheral T-lymphocyte subpopulations ($CD3^b$, $CD4^b$, and $CD8^b$) was observed, whereas NK-cell counts slightly increased (Figure 2, B). Hence, the patient was subsequently discharged and remains COVID-19 free.

Although cumulative cases of SARS-CoV-2–infected patients suffering from primary antibody immunodeficiencies are limited, it appears that individuals devoid of B cells (agammaglobulinemia) have a milder presentation and course than those with a partial B-cell repertoire (CVID).[2-4] This observation is

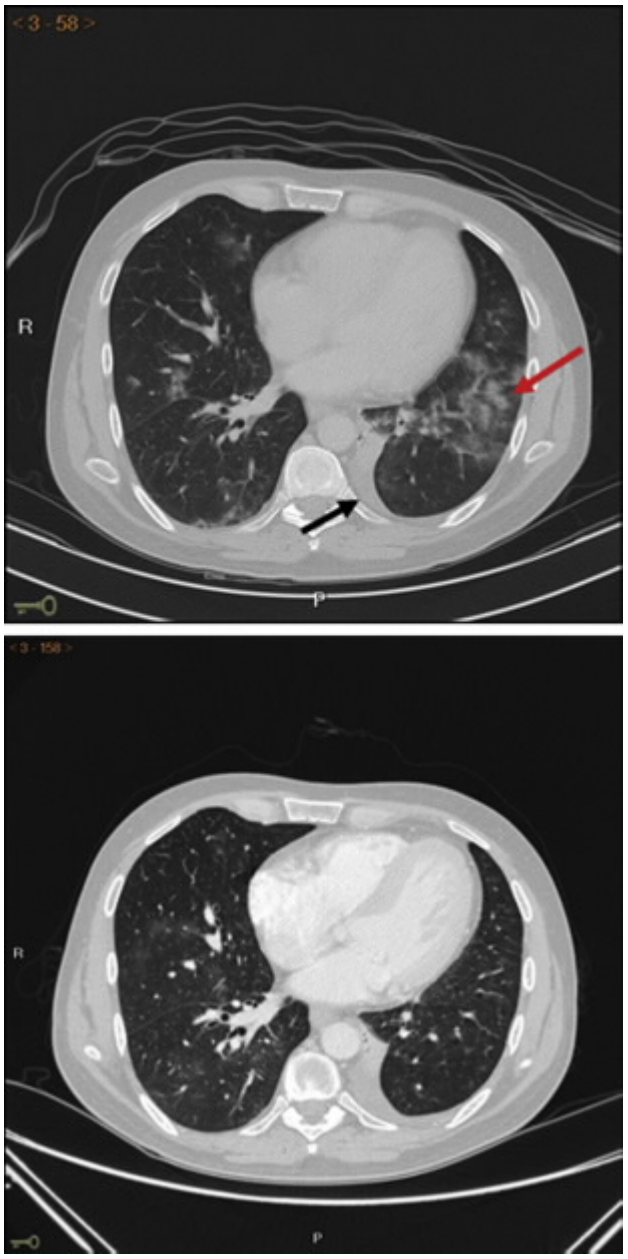

FIGURE 1. Upper panel: CT displaying bilateral pulmonary involvement in the form of nodular consolidations and ground-glass opacities primarily in the left lower lobe (red arrow) and small-size left pleural effusion (black arrow). Lower panel: CT of the chest 6 days after COVID-19 convalescent donor plasma transfusion showing almost complete resolution of bilateral lung lesions pattern. CT, Computed tomography.

strengthened by the finding that pharmacological blockade of Bruton tyrosine kinase results in diminished lung inflammatory response by inhibiting overproduction of macrophage-mediated cytokines.[7] The evolution of our patient was consistent with those observations until day 15 of admission, when he suffered a rapid deterioration in his condition accompanied by a lack of cytokine production by lung T and NK cells. If this lack of functional response was the consequence of cell exhaustion, we should bear in mind that T-cell response involve triggering of multiple epitope-specific clones, and not all may be equally prone to functional blockade.[8] Therefore, local silencing of immunodominant clones may hamper the overall immune response.

The remarkable and prompt recovery observed after infusion of convalescent plasma suggests that certain patients may have stringent dependency on specific antibodies to achieve viral clearance. Although this is a single case and therefore the observation could be coincidental and we have not formally established a cause-effect relationship, we nevertheless propose that administration of COVID-19 hyperimmune plasma should be further explored as first line of treatment for patients with congenital agammaglobulinemia, especially while SARS-CoV-2–specific antiviral drugs remain unavailable. Previous clinical cases suggest that B cells may have a prominent role in triggering lung inflammation[3]; in this scenario, defective germinal center formation due to the primary immunodeficiency would divert IL-6 intended for that process toward lung inflammation, thus raising the possibility of a B-cell interference as therapeutic intervention.[3] However, our data suggest a critical role of B cells in clearing the disease when certain immunologic conditions are present.

In summary, even though administration of passive immunity for patients with primary immunodeficiency has just been proposed,[9] this is the first report showing a rapid recovery of a patient with a primary antibody immunodeficiency after administration of hyperimmune plasma. Although it should be kept in mind whether the patient reported here was idiosyncratic and might not represent a prototypical patient with XLA (despite carrying a common Bruton tyrosine kinase gene mutation), our data merit further investigations to determine the precise clinical benefit of hyperimmune plasma in other antibody-deficient patients, as well as optimal dose and timing of its administration.

four pediatric patients with acute respiratory distress syndrome. We measured donor antibody levels and recipient antibody response prior to and following CP infusion. Infusion of CP was not associated with antibody-dependent enhancement (ADE) and did not suppress endogenous antibody response. We found CP was safe and possibly efficacious. Randomized pediatric trials are needed.

1 | INTRODUCTION

Early reports from the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) global pandemic suggested that children were less severely affected by coronavirus disease 2019 (COVID-19) compared to older adults.[1–3] Nevertheless, some children with COVID-19 are critically ill.[4,5] Currently, no therapies have been proven effective in the treatment of COVID-19 in children.

Convalescent plasma (CP) derived from patients that have recovered from SARS-CoV-2 can be infused into currently ill patients. The proposed mechanism of action is via neutralizing antibodies binding to virus, rendering it inert.[6] Specific to SARS-CoV-2, antibodies against the receptor-binding domain (RBD) have been identified as surrogates for neutralization.[7–11] CP also contains antibodies against the immunogenic nucleocapsid (N) protein, which are nonneutralizing and present in both actively infected and recovered patients.[7] The protective function of N antibodies remains unclear.[7,12] Antibodies against the full-length SARS-CoV-2 spike (S) protein include both nonneutralizing antibodies and neutralizing antibodies.[13]

Initial series of CP in adults with COVID-19 demonstrated potential benefits without apparent side effects.[14–17] In a recent clinical trial of adults with COVID-19, there was a nonstatistically significant trend toward clinical improvement in CP-treated patients versus controls, without improvement in time to discharge or mortality.[18] This trial was halted early due to poor accrual.[18] To date, there have been no reports on the use of CP in children.

CP infusion is associated with the side effects of any blood product: allergic reaction, transfusion-associated circulatory overload, and infection with blood-borne pathogens. There is a theoretical risk that infusion of donor antibodies may impede the recipient's endogenous production of antibodies, and of antibody-dependent enhancement (ADE), where antibodies developed during a previous infection cause a worsened clinical response with subsequent infection. ADE has been described in dengue fever, and in preclinical models of other coronaviruses.[19–21] ADE has not been reported in adult patients receiving CP for SARS-CoV-2.[6,17,18]

We present the first report of pediatric patients receiving CP for life-threatening COVID-19-associated respiratory disease with correlative measurements of the associated pre- and posttransfusion antibody response.

2 | METHODS

We treated four critically ill children actively infected with SARS-CoV-2 with CP at the Children's Hospital of Philadelphia (CHOP) under emergency Investigational New Drug applications (eINDs) through the Food and Drug Administration (FDA). Patients were considered for CP if they met FDA guidance for life-threatening disease (Appendix S1). Per the American Red Cross Guidelines, donors were eligible to provide CP if they met the following criteria: (a) they were initially proven positive for SARS-CoV-2 by a laboratory test; and either (b1) at least 14 days from symptom resolution with a repeat documented negative test for SARS-CoV-2, or (b2) at least 28 days from symptom resolution without a documented repeat test results at the time of plasma collection.

We prospectively screened and enrolled these patients into a larger SARS-CoV-2 biobanking protocol. The objective of the SARS-CoV-2 biorepository protocol is to collect samples on patients with confirmed SARS-CoV-2 infection or multisystem inflammatory syndrome in children (MIS-C). An initial report from this biorepository has been published.[22] Patients were enrolled on the biobank protocol if they had evidence of SARS-CoV-2 infection on reverse-transcriptase polymerase chain reaction (RT-PCR) testing from respiratory tract mucosa. This protocol was approved by the CHOP Institutional Review Board (IRB). Consent was obtained for both protocols from a legal authorized representative per the Declaration of Helsinki (written informed consent for CP; verbal consent for biobanking).

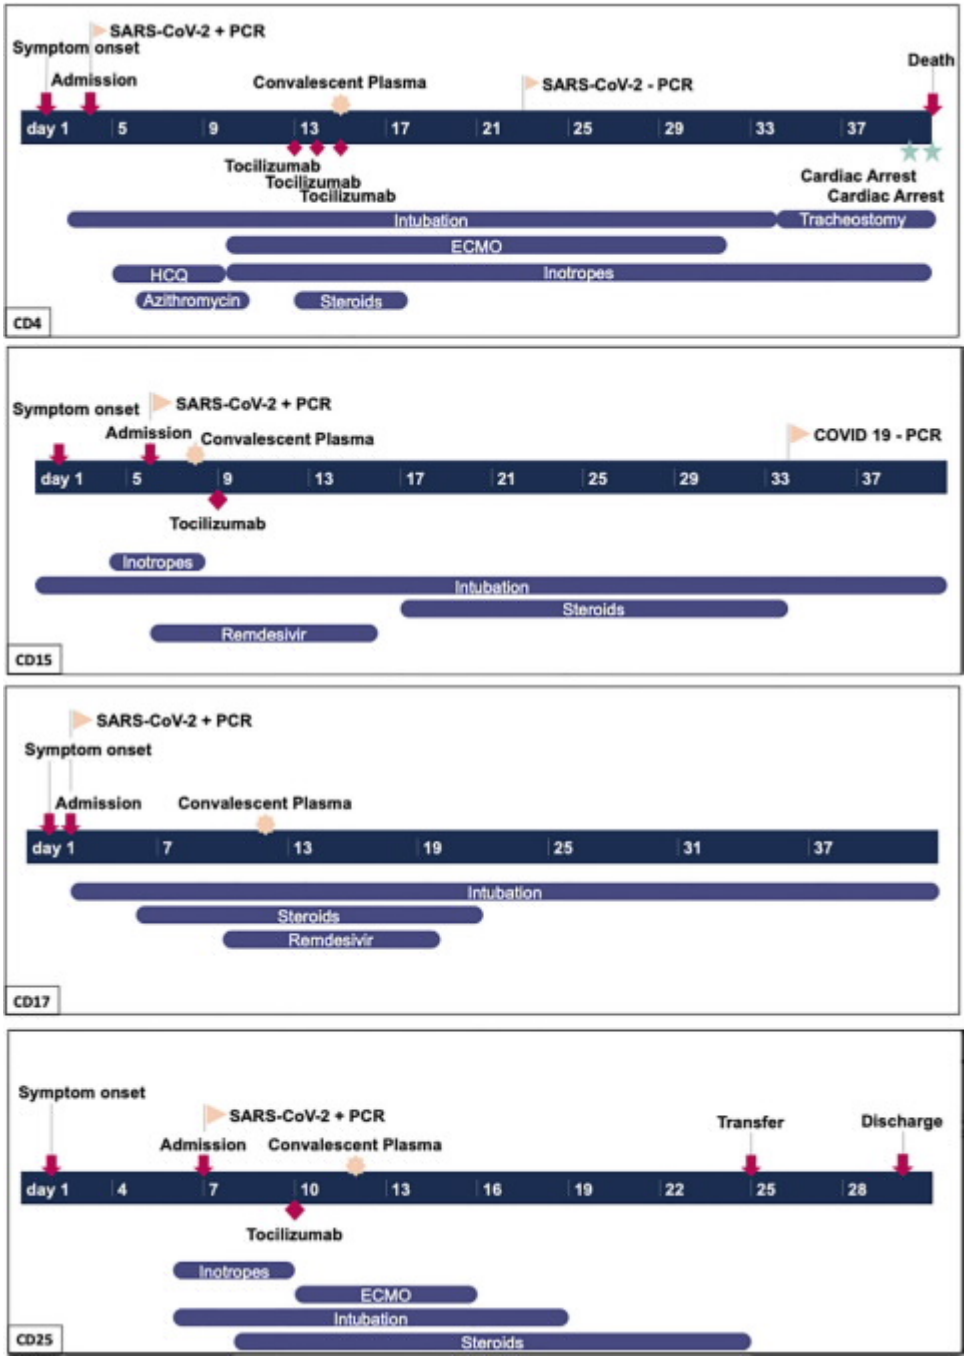

FIGURE 1 Graphical representation of clinical course of four patients included in the caseseries. Timeline includes up to day 40 of illness, or until death or discharge, whatever occurred first. ECMO, extracorporeal membrane oxygenation; HCQ, hydroxychloroquine; PCR, polymerase chain reaction

Verbal consent for biobanking was obtained based on IRB recommendations to prevent exposure to research staff and to avoid unintentional transmission of SARS-CoV-2via fomites such as consent forms.

Clinical data were abstracted from patient charts to standardized forms by a research assistant using a REDCap database, and verified by a physician. Blood sampleswere obtained from participants prior to CP infusion, following CP infusion, and weekly thereafter until death or discharge. Remnant donor CP was retained, per institutional protocol in case of transfusion reaction. Remnant donor CP was then collected and stored.

SARS-CoV-2-specificantibodies were measured by enzyme-linked immunosorbent assay (ELISA) as previously described.[8] Antibodies in serially diluted plasma (starting at 1:50) were measured against RBD of the SARS-CoV-2S protein,[9] full-length S protein, and the N protein (Sino Biological, Wayne, PA). Reciprocal plasma dilutions were calculated from an optical density threshold from a set concentration. Standard curves were generated by diluting an RBD-specific monoclonal

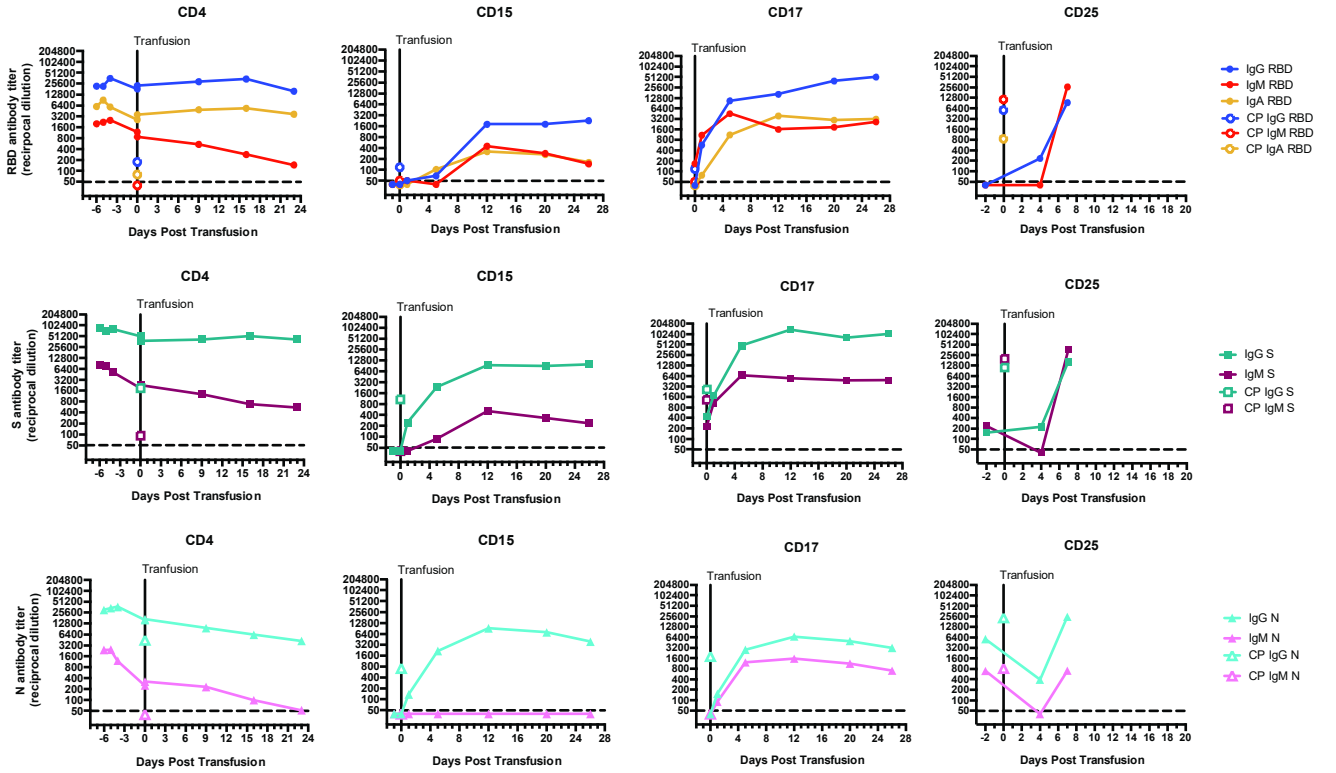

FIGURE 2 Longitudinal serum SARS-CoV-2 antibody titers in pediatric patients receiving convalescent plasma (CP) transfusion therapy. Antibody titers expressed as reciprocal serum dilution against SARS-CoV-2 antigens in four pediatric patients (CD4, CD15, CD17, and CD25), and corresponding CP donors (open symbols) before and after plasma transfusion. Antibody titers against (A-D) the SARS-CoV-2 receptor-binding domain of the spike (S) protein, (E-H) the full-length SARS-CoV-2 S protein (FL), and (I-L) the nucleoprotein of SARS-CoV-2 (N). Dashed lines denote the lower limit of detection (LLOD) of the assay (1:50 serum dilution)

antibody (CR3022) starting at 0.5 μg/mL (RBD and S ELISAs), or serially diluted pooled serum from actively SARS-CoV-2-infected adults (N ELISAs). See Appendix S2 for detailed methods.

3 | RESULTS AND DISCUSSION

Four patients, 14–18 years, were treated with CP during the study period. Patients received all available plasma from the donors, in the range of 200–220 mL. Patient CD4 received 2 mL/kg, and patients CD15, CD17, and CD25 received 4 mL/kg. All patients were critically ill with COVID-19-associated acute respiratory distress syndrome. All patients required intubation and ventilation; two required extracorporeal membrane oxygenation (ECMO). None of the patients had MIS-C. All patients received other SARS-CoV-2-directed therapies in addition to CP. Graphical case summaries are presented in Figure 1. Further details are presented in Appendix S3. No patients experienced any treatment-emergent adverse events (TEAE) related to CP infusion.

Longitudinal antibody titers are presented in Figure 2. Corresponding antibody titers for CP donors are displayed. At the time of CP infusion, patient CD4 had extremely high endogenous antibody titers (against SARS-CoV-2 RBD, S, and N). Antibody titers in this participant were sustained post transfusion. This individual showed transient clinical improvement, decannulating from ECMO; however, died from cardiac causes by day 25 post transfusion. An autopsy was performed, which demonstrated diffuse alveolar damage and hypertrophic cardiomyopathy with associated myocardial fibrosis. Spleen and lung cultures were positive for *Candida glabrata*. There was no evidence of myocarditis.

Patients CD15, CD17, and CD25 had low or undetectable RBD-specific antibody titers at the time of infusion. Serum antibodies against the SARS-CoV-2 RBD correlate with neutralizing activity, likely due to inhibition of the virus' ability to bind and enter target cells.[8–10] Of note, the donor plasma infused into patients CD15 and CD17 had relatively low RBD-specific antibody titer levels (< 1:160). Both CP donors for CD15 and CD17 had substantial full-length IgG S titers (> 1:1000), and these may have conferred some neutralizing activity. It is unclear if CP with low RBD-specific and high full-length IgG S antibody titers would provide benefit. CD15 and CD17 both remain in intensive care and did not have significant clinical improvement following CP infusion, although CD15 did wean off inotropic support shortly after receiving CP. CD17 did not require inotropic support. Both patients continued to require intubation and ventilatory support despite CP. As of August 22, 2020 both CD15 and CD17 remain in hospital and have had the placement of tracheostomies. They both remain on ventilatory support, although at a lower level than required during

acute illness. The donor for patient CD25 had higher SARS-CoV-2 RBD antibody titers (> 1:6000) than the donor for any of the other patients, making it more likely that this donor plasma could be beneficial. CD25 had the shortest period of admission and has been discharged from the hospital after being critically ill and on ECMO.

Prior to transfusion, three of the four recipients (CD15, CD17, and CD25) had undetectable IgG RBD antibody levels (< 1:50 serum dilution). Upon transfusion, all three participants eventually experienced a boost in IgG, IgM, and IgA antibodies against RBD that was sustained for 7-26 days post transfusion. In one participant (CD15), we detected antibodies against the full-length S protein before we detected antibodies against the RBD of the S protein. The boost in antibodies against N post transfusion was similar to that of RBD and S-specific serum antibodies for patients CD15, CD17, and CD25. In all three patients, the serum levels of SARS-CoV-2-specific antibodies eventually surpassed the amount transfused, indicating that these patients mounted a post transfusion de novo response and that CP did not eliminate the endogenous serological response.

In summary, CP was safely administered to four pediatric patients with severe COVID-19. There were no CP-related TEAE. The theoretical risks of ADE or elimination of endogenous antibody response did not occur. CP may be of greatest benefit for patients who are early in their illness and have not yet generated endogenous antibodies, and when the infused plasma has a high antibody titer. The patient who received CP with the highest antibody titer had the best clinical response, although the total antibody response mounted did not differ markedly from the other patients. The small sample size of our study precludes definitive conclusions about efficacy, however, the excellent clinical response in this patient is encouraging. The other patients had significant comorbidities that may have contributed to their clinical status. It is difficult to determine if CD15 and CD17 benefited, as it is possible without CP they could have continued to worsen. Future research should include randomized controlled trials to definitively examine the efficacy of CP in children.

Key Points

- ü COVID-19 convalescent plasma (CP) may be a safe and effective treatment option in SARS-CoV-2 infection refractory to remdesivir.
- ü Infants may benefit from CP despite developing immune systems and donor variability emphasizes the need for characterization prior to use.

Introduction

Although , 2% of coronavirus disease 2019 (COVID-19) infections are reported in the pediatric population, children with comorbidities such as congenital heart disease and those at a young age are more likely to become critically ill.[1-3] Remdesivir has been reported to be efficacious in adults with COVID-19[4]; however, there are no studies in children. Convalescent plasma (CP) can contain neutralizing antibodies to viruses,[5] and has been used during previous viral epidemics with clinical improvement.[6-11] COVID-19 CP (C19-CP) may be useful in critically ill adults, resulting in improvement in inflammatory markers, pulmonary lesions, and mortality.[12] However, the impact of C19-CP in pediatric patients, particularly infants with developing immune systems and significant comorbidities, is completely unknown.

We present an infant with cardiopulmonary failure secondary to unrepaired congenital heart disease exacerbated by COVID-19. Given postsurgical complications of children with viral respiratory infection,[13-17] the patient required clearance of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) for surgical candidacy. We hypothesized that C19-CP administration may clear SARS-CoV-2 following failure of remdesivir.

Case description

A 3.1-kg term 9-week-old female with trisomy 21 and unrepaired balanced complete atrioventricular canal defect with baseline mild to moderate common atrioventricular valve regurgitation (AVVR) presented in acute hypoxemic respiratory failure secondary to progressive decompensated heart failure. Notable findings included lymphopenia, b-natriuretic peptide of 530 pg/mL (reference range , 100 pg/mL), worsened AVVR (moderate to severe), and cardiomegaly and pulmonary edema on chest X-ray. Initial treatment, including bilevel noninvasive positive pressure ventilation, milrinone infusion, and IV diuretics, resulted in restoration of organ function. By hospital day 8, her common AVVR returned to baseline; she transitioned from milrinone to captopril, carvedilol, and IV diuretics and had weaned to high-flow nasal cannula; and she was transferred to the general cardiology floor.

On hospital day 12, she developed acute hypoxemic respiratory failure and decompensated heart failure, with atelectasis on chest X-ray and new rhinorrhea requiring bilevel noninvasive positive pressure ventilation. The result of SARS-CoV-2 nucleic acid testing (NAT) (DiaSorin Molecular Simplexa direct real-time PCR of viral RNA, Cypress, CA) on a nasopharyngeal (NP) swab was positive; a residual sample from a respiratory viral panel performed on hospital day 5 for intermittent desaturations was retested for SARS-CoV-2 and likewise had a positive result (Figure 1A). The source of the infection remains unclear. While the mother and siblings were asymptomatic, they were quarantined for 14 days after infection was identified in the patient but never tested. Nosocomial infection is certainly possible

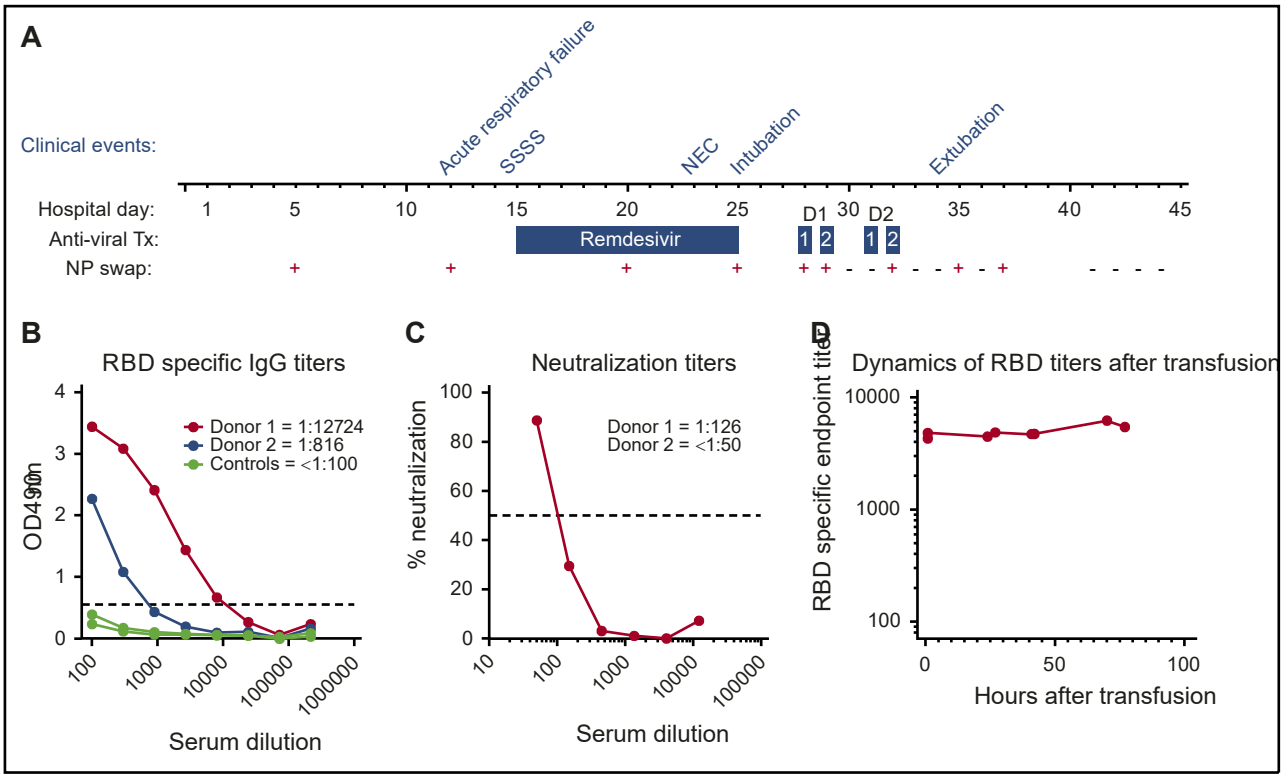

Figure 1. Hospital course summary and donor and patient plasma characterization. (A) Hospital course by clinical event, antiviral therapy (Tx), and C19-CP transfusion in relation to NP swab SARS-CoV-2 RNA results. Clinical events are as follows: acute respiratory failure on hospital day 12, staphylococcal scalded skin syndrome (SSSS) on hospital day 14, necrotizing enterococcus (NEC) on hospital day 23, intubation on hospital day 25, and extubation on hospital day 34. Dosages of antiviral therapy are as follows: remdesivir: 5 mg/kg per day on hospital day 15 and 2.5 mg/kg/day on hospital days 16 to 25; C19-CP donor 1: 10 mL/kg per day over 4 hours; 20 hours apart on hospital days 28 and 29; and C19-CP donor 2: 10 mL/kg per day over 4 hours; 20 hours apart on hospital days 31 and 32. (B) Enzyme-linked immunosorbent assays showing titration of samples from the 2 C19-CP donors and 3 negative controls collected before 2019, against SARS-CoV-2 spike RBD. End point titers were calculated using a cutoff of the average of the control samples, plus 3 times standard deviation value, marked with a dotted line. End points were calculated as the intersection of samples with this cutoff. Titers are shown numerically in the legend. (C) Neutralization activity of C19-CP donor samples against SARS-CoV-2. The focus reduction neutralization test $(FRNT)_{50}$ titers of the C19-CP donor samples were determined by an FRNT assay using an immunostain to detect infected foci. The dotted line represents the maximum concentrations of the serum tested (1/50). (D) Dynamics of RBD-specific end-point titers in the recipient after transfusion.

but less likely, as the hospital had very few infected patients, none of those infected were in the cardiac intensive care unit, and there was no shortage of personal protective gear at the hospital prior or following the patient's infection. Additional investigation did not reveal macrophage activation syndrome or new bacterial or viral infection. As her prolonged QTc prohibited use of hydroxychloroquine, remdesivir (5 mg/kg per day on hospital day 15 and 2.5 mg/kg per day on hospital days 16-25) was given. Her hospital course was complicated by staphylococcal scalded skin syndrome, treated with nafcillin, and stage II necrotizing enterocolitis (Bell criteria), treated with piperacillin-tazobactam (Figure 1A). Throughout this time, she continued to have persistent lymphopenia, a C-reactive protein (CRP) level of 5 mg/dL (reference range, , 1.0 mg/dL) with normal fibrinogen, and a common AVVR that remained unchanged with preserved biventricular function managed with IV diuretics.

Despite completion of remdesivir, on hospital day 25, she required endotracheal intubation for worsening respiratory failure. Repeat investigation was notable for persistent lymphopenia, persistent SARS-CoV-2, CRP 7.7 mg/dL, but no evidence of new secondary infection or macrophage activation syndrome was found. Milrinone was reinitiated in addition to IV diuretics. Given her lack of response to remdesivir and deteriorating clinical status, 2 aliquots of CP (10 mL/kg per aliquot) from 2 COVID-19 recovered donors (C19-CP) were transfused in accordance with the World Health Organization guidelines for Ebola CP treatment in children[9] (Figure 1A). She received increased IV diuretics, daily monitoring of serum chemistries, and intermittent monitoring of coagulopathy. Daily surveillance of SARS-CoV-2 NAT by NP swab was performed, and the results were negative following the second aliquot from donor 1 (Figure 1A) with concurrent reduced ventilator support. She was extubated on hospital day 34. The infant tolerated all transfusions without anaphylaxis, transfusion-related circulatory overload, transfusion-related acute lung injury, or hypercoagulability. The results of daily NP swabs were intermittently positive before becoming persistently negative (Figure 1A). Other notable findings post–C19-CP transfusion include CRP of 1.3 mg/dL and intermittent normalization of absolute lymphocyte count. The patient had an uneventful complete repair 47 days (hospital day 91) after SARS-CoV-2 infection resolution and is doing well.

Methods

The patient is blood group O RhD negative. Donor 1 is a 63-year-old male who donated 35 days following COVID-19 symptom resolution and is blood type A RhD positive. Donor 2 is a 56-year-old male who donated 55 days following COVID-19 symptom resolution and is blood type O RhD negative. Both had mild COVID-19 infection, and neither was hospitalized. The plasma donor units were transfused without prior characterization per emergency use. To understand the impact of C19-CP treatment, both donor units were tested for titers of IgG against the receptor-binding domain (RBD) of the SARS-CoV-2 spike protein (Emory University and Children's Healthcare of Atlanta, Atlanta, GA), which has been shown to correlate with neutralizing titers,[18] and subsequent microneutralization assays were performed in a biosafety level 3 laboratory.[19] Donor 1 had an immunoglobulin G (IgG) titer of 1:12 724 and neutralizing titer of 1:126. Donor 2 had an IgG titer of 1:816 and a neutralizing titer of , 1:50 (Figure 1B-C, respectively). Following the first aliquot from donor 1, the recipient showed robust IgG anti-SARS-CoV-2 antibody levels of ; 1:5000, which was sustained after all subsequent transfusions (Figure 1D).

Results and discussion

Young age, unrepaired congenital heart disease, trisomy 21, persistent lymphopenia, and naive immune system likely increased this patient's SARS-CoV-2 vulnerability. While this represents only 1 case, her improved respiratory status, increase in lymphocytes, and decrease in CRP after C19-CP transfusion suggest a positive clinical correlation, especially in the setting of subsequent SARS-CoV-2 clearance.

Logistical constraints prevented anti-SARS-CoV-2 antibody characterization of C19-CP prior to transfusion, which likely reflects common current approaches to emergent C19-CP administration. C19-CP from donor 1 likely provided the most significant impact on SARS-CoV-2 eradication given the higher neutralizing titer (Figure 1C), which is comparable to US Food and Drug Administration recommendations[20] and may be sufficient when treating COVID-19 in adults.[10-21] This case suggests that such titers may likewise be sufficient in infants. The delay in viral clearance may reflect the time required for C19-CP therapy to effectively eliminate the virus and is consistent with reports in adults with persistent SARS-CoV-2 NAT by NP samples beyond symptom resolution.[22,23]

Factors influencing high anti-SARS-CoV-2 titers with effective characteristics remain incompletely understood. Severe illness would be presumed to correlate with higher anti-SARS-CoV-2 antibodies. However, even though neither C19-CP donor was hospitalized, donor 1 possessed higher titers than donor 2, whose titers were below the limit of detection. This variability illustrates the challenge of current C19-CP transfusion practice, making it difficult to determine the potential benefit without adequate testing prior to C19-CP transfusion in place.

While neutralizing antibodies are critical for antibody-mediated protection against viral infection, the impact of CP on resolution of active infection remains incompletely understood. However, beyond direct neutralization of the virus, other mechanisms, such as antibody-dependent cellular cytotoxicity, may also play a role in the ability of C19-CP to aid in the clearance of an active infection. Such considerations may be especially important in infants with developing or suppressed immune systems that may attenuate the ability of other antibody effector systems to effectively clear COVID-19 following C19-CP therapy. While we were unfortunately unable to acquire neutralizing titer data from the patient prior to C19-CP administration to determine potential changes in antibody levels prior to and following administration of the first dose of C19-CP, data obtained following serial SARS-CoV-2 NAT evaluation provides uncommon insight into the temporal relationship between C19-CP and its potential impact on SARS-CoV-2 infection. However, this is a single case, and understandable uncertainties remain. Future studies will certainly be needed to fully define the efficacy of C19-CP in this vulnerable patient population.

Acknowledgments

The authors thank their colleagues at LifeSouth for collection of donor plasma. Parental consent was obtained for treatment with C19-CP. Review of medical records, publication of results, and research use of biospecimens per the Declaration of Helsinki under the protocols were approved by the Institutional Review Board of Emory University School of Medicine and the Department of Health and Human Services.

Authorship

Contribution: Z.R., S.R.S., and C.D.J. conceived of and wrote the manuscript; S.R.S., C.D.J., Z.R., M.S., and J.W. prepared the figures; A.L.S., H.V., C.L., M.G.Z., M.S., J.W., H.M., M.W., S.C., J.D.R.C., M.A., S.R.S., and C.D.J. critically reviewed, analyzed, and interpreted the data; M.G.Z., J.W., M.S., H.M., C.M.A., and S.R.S. performed the immunologic assays; and C.L. collected the donor units and information on blood donors.

A. Personal Statement

I have the expertise, leadership, training, expertise and motivation necessary to successfully carry out the proposed research project. I have a broad background in psychology, with specific training and expertise in ethnographic and survey research and secondary data analysis on psychological aspects of drug addiction. My research includes neuropsychological changes associated with addiction. As PI or co-Investigator on several university- and NIH-funded grants, I laid the groundwork for the proposed research by developing effective measures of disability, depression, and other psychosocial factors relevant to the aging substance abuser, and by establishing strong ties with community providers that will make it possible to recruit and track participants over time as documented in the following publications. In addition, I successfully administered the projects (e.g. staffing, research protections, budget), collaborated with other researchers, and produced several peer-reviewed publications from each project. As a result of these previous experiences, I am aware of the importance of frequent communication among project members and of constructing a realistic research plan, timeline, and budget. The current application builds logically on my prior work. During 2005-2006 my career was disrupted due to family obligations. However, upon returning to the field I immediately resumed my research projects and collaborations and successfully competed for NIH support.

B. Positions and Honors

Positions and Employment

1998-2000	Fellow, Division of Intramural Research, National Institute of Drug Abuse, Bethesda, MD
2000-2002	Lecturer, Department of Psychology, Middlebury College, Middlebury, VT
2001-	Consultant, Coastal Psychological Services, San Francisco, CA
2002-2005	Assistant Professor, Department of Psychology, Washington University, St. Louis, MO
2007-	Associate Professor, Department of Psychology, Washington University, St. Louis, MO

Other Experience and Professional Memberships

1995-	Member, American Psychological Association
1998-	Member, Gerontological Society of America
1998-	Member, American Geriatrics Society
2000-	Associate Editor, Psychology and Aging
2003-	Board of Advisors, Senior Services of Eastern Missouri
2003-05	NIH Peer Review Committee: Psychobiology of Aging, ad hoc reviewer
2007-11	NIH Risk, Adult Addictions Study Section, members

Honors

2003	Outstanding Young Faculty Award, Washington University, St. Louis, MO
2004	Excellence in Teaching, Washington University, St. Louis, MO
2009	Award for Best in Interdisciplinary Ethnography, International Ethnographic Society

C. Contribution to Science

1. My early publications directly addressed the fact that substance abuse is often overlooked in older adults. However, because many older adults were raised during an era of increased drug and alcohol use, there are reasons to believe that this will become an increasing issue as the population ages. These publications found that older adults appear in a variety of primary care settings or seek mental health providers to deal with emerging addiction problems. These publications document this emerging problem but guide primary care providers and geriatric mental health providers to recognize symptoms, assess the nature of the problem and apply the necessary interventions. By providing evidence and simple clinical approaches, this body of work has changed the standards of care for addicted older adults and will continue to provide assistance in relevant medical settings well into the future. I served as the primary investigator or co-investigator in all of these studies.

2. In addition to the contributions described above, with a team of collaborators, I directly documented the effectiveness of various intervention models for older substance abusers and demonstrated the importance of social support networks. These studies emphasized contextual factors in the etiology and maintenance of addictive disorders and the disruptive potential of networks in substance abuse treatment. This body of work also discusses the prevalence of alcohol, amphetamine, and opioid abuse in older adults and how networking approaches can be used to mitigate the effects of these disorders.

3. Methadone maintenance has been used to treat narcotics addicts for many years but I led research that has shown that over the long-term, those in methadone treatment view themselves negatively and they gradually begin to view treatment as an intrusion into normal life. Elderly narcotics users were shown in carefully constructed ethnographic studies to be especially responsive to tailored social support networks that allow them to eventually reduce their maintenance doses and move into other forms of therapy. These studies also demonstrate the policy and commercial implications associated with these findings.

XX September 2020

Dr. Peter Daszak
President
EcoHealth Alliance
520 Eighth Avenue, Ste. 1200
New York, NY 10018

Dear Dr. Daszak,

This letter expresses the high interest that staff at [insert name of institution] has in collaborative research with EcoHealth Alliance and other partners on the proposed NIAID R01 research entitled "Analyzing the potential for future bat coronavirus emergence in Southeast Asia".

The [insert name of institution] recognizes the mutual benefits to be gained through research cooperation. The successful partnership on the proposed research will advance our understanding of the ability of bat-origin coronaviruses to spillover into high-risk human populations and cause illnesses that may have been previously unreported, or undiagnosed. We believe the results will be scientifically important, and have great public health value for [Insert country name] and the region by identifying key pandemic threats.

We at [insert name of institution] look forward to working with EcoHealth Alliance on this important research. Our work will include managing [Insert sentence on key roles in project, e.g. "human surveillance, wildlife surveillance, sample collection, testing, and development of laboratory diagnostics"]. We will also actively take part in knowledge sharing and research cross-training with other partners, and are willing to work together with other partner to strengthen the ability of [Insert country name] and other countries in the region to respond to epidemic disease outbreaks.

Sincerely,

[Insert signature]

Key Points

- A severely immunocompromised patient with MM and COVID19 who received a convalescent plasma product showed SARS-CoV-2 clearance.
- The convalescent plasma showed humoral immunity against all structural SARS-CoV-2 proteins, which was successfully transferred to the patient.

Introduction

Coronavirus disease 2019 (COVID-19) has become the greatest global health challenge.[1] Importantly, patients at an advanced age and with preexisting medical conditions,[2-5] in particular cancer patients on immunosuppressive treatment, show a more severe disease and increased mortality.[6-8] COVID-19 infection is caused by a novel coronavirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2).[9] The virus consists of various nonstructural proteins and 4 major structural proteins: the surface-exposed spike (S), membrane (M), and envelope (E) proteins and the internal nucleocapsid (N) protein.[9,10] The SARS-CoV-2 virus enters cells, such as pneumocytes in the lung,[11] via binding of the receptor-binding domain (RBD) within its S1 protein[12] to the angiotensin-converting enzyme-2 receptor.[10,13]

Recent findings indicate that infected patients develop spontaneous antibody-mediated immune responses against viral particles,[10,14,15] and an apparent improvement in the clinical status was observed upon treatment with convalescent plasma containing anti–SARS-CoV-2 antibodies.[16] Indeed, it was recently shown that patient-derived antibodies directed against the viral S protein are able to neutralize the SARS-CoV-2 virus.[12] However, the exact targets of the clinically relevant antibodies within the polyclonal plasma remain unclear, the potential immunogenicity and clinical relevance of other viral proteins has not been investigated, and individual epitopes of the antibodies present in convalescent plasma and in the blood of COVID-19 patients have not been identified. In addition, it has never been demonstrated whether the complete antiviral immunity can be transferred and detected in the recipient after transfusing a convalescent plasma product.

Case description

Our patient ID359 is a 72-year-old female who was diagnosed with immunoglobulin G (IgG) k multiple myeloma (MM) 10 years prior to her admission for COVID-19. She had received 4 prior lines of treatment, including 3 autologous stem cell transplants, steroids, cytotoxic chemotherapy, proteasome inhibitors, immunomodulatory drugs, and the anti-CD38 monoclonal antibody daratumumab. She was in partial remission after 8 cycles of carfilzomib/pomalidomide/dexamethasone and had received her most recent dose of carfilzomib; 3 weeks prior to this admission; she still had active disease with a serum IgG k monoclonal protein measuring 0.36 g/dL (Figure 1A), serum free k light chains of 30.6 mg/L, and an elevated k/l ratio.

The patient underwent testing of a nasopharyngeal sample by SARS-CoV-2 polymerase chain reaction (PCR), following continuous exposure to an individual with known COVID-19 for ; 1 week, and was diagnosed with the infection. At the time of testing (day 2 3), she was asymptomatic; however, on the following day (day 2 2), she developed diarrhea and nausea. One day later (day 2 1), she developed substantial dyspnea, cough, wheezing, and, from home, she reported hypoxia with an oxygen saturation of 75% to 85%. The patient was admitted to the emergency room at the University of Utah. On

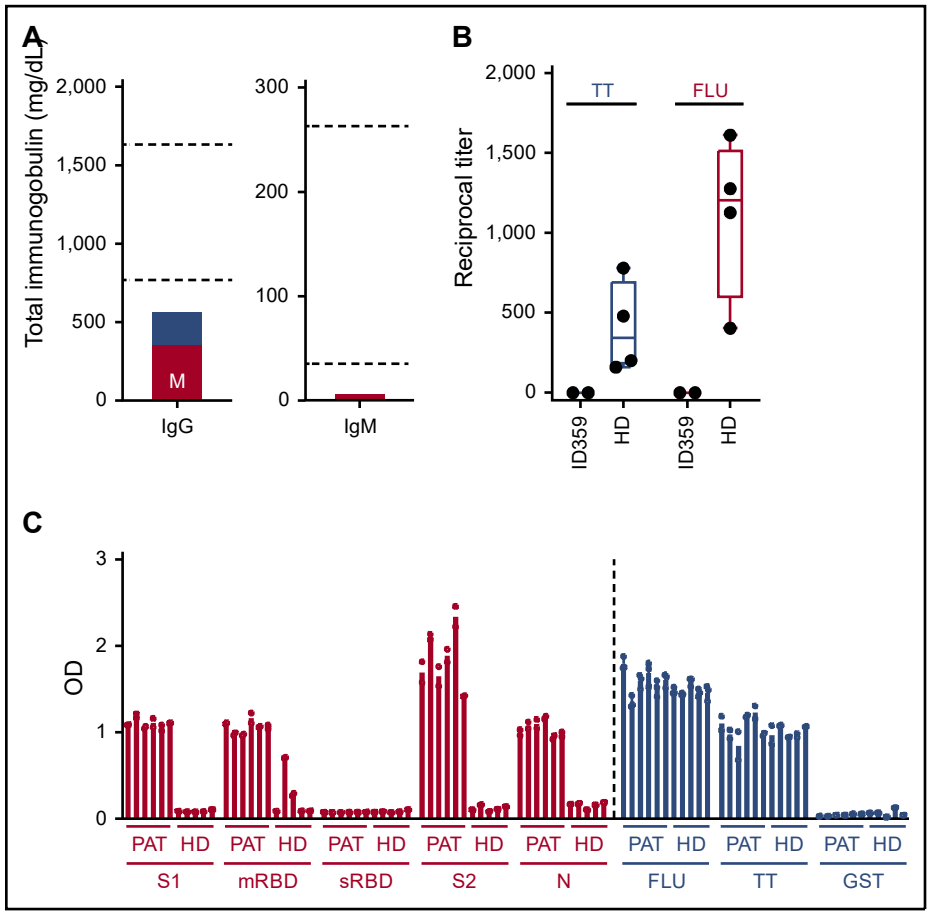

Figure 1. Compromised antiviral immunity in an MM patient with hypogammaglobulinemia. (A) Total IgG and IgM levels of patient ID359 on the day of COVID-19 diagnosis, as determined by immunoelectrophoresis. M indicates the level of total monoclonal protein in the g region, and dotted lines indicate the reference range. (B) Reciprocal IgG titers against tetanus toxoid (TT; Millipore-Sigma, cat. no. 582231) and influenza H1N1 nucleoprotein (FLU; Sino Biological, cat. no. 11675-V08B) in patient ID359 plasma at COVID-19 diagnosis, as well as in 4 healthy donors (HD), as determined by ELISA. (C) IgG responses, expressed as optical density (OD) readings, of 6 COVID-19 patients (PAT) and 5 healthy donors (HD) against SARS-CoV-2 proteins S1 (ACRO Biosystems; cat. no. S1N-C52H3), S2 (expressed in Expi293 cells), and N (BioVision; cat. no. P1523-50), the S1 RBD expressed in mammalian cells (mRBD; RayBiotech; cat. no. 230-30162) or produced synthetically (sRBD; LifeTein), positive-control proteins TT and FLU, and negative-control glutathione S-transferase (GST; expressed in Expi293 cells), as determined by ELISA. Data represent the mean, and circles indicate technical replicates.

admission, she was found to be in respiratory distress and was hypoxic and disoriented. Venous blood gas analysis showed hypoxia and hypercapnia. She was placed on oxygen via nasal cannula, and a chest radiograph showed streaky left basilar opacities pointing to viral pneumonia. Other abnormal laboratory results included leukopenia and lymphopenia and worsening of her chronic renal disease. The patient was diagnosed with acute hypoxic respiratory failure due to COVID-19 infection, without any clinical signs of cytokine storm, and viral pneumonia. She was admitted to the medical COVID unit where she received 2 to 3 L of oxygen via nasal cannula for the next 24 hours.

Evaluating her humoral immune system, the patient was found to have severe hypogammaglobulinemia with very low absolute levels of normal IgG and IgM (Figure 1A), consistent with her long-standing MM and several lines of immunosuppressive treatments, including a monoclonal antibody targeting CD38-expressing plasma cells. Remarkably, the low amount of total IgG that she did have consisted largely of myeloma-related monoclonal M protein (Figure 1A). Accordingly, she showed nonexistent antibody titers against influenza A virus and tetanus toxoid (Figure 1B). A routine ELISA screening for anti–COVID-19 antibodies demonstrated a complete absence of antiviral serological reactivity.

On day 0, based on the lack of clinical improvement, the US Food and Drug Administration clinical criteria for convalescent plasma administration under the expanded access program, and her severe immunosuppression, we transfused 1 200-mL unit of convalescent plasma from a donor who had recovered from COVID-19. Importantly, the patient did not receive any other treatment potentially having an effect on the course of COVID-19, such as steroids or antivirals. After transfusion of the convalescent plasma, the patient showed a dramatic clinical improvement, became asymptomatic, and was discharged home only 2 days later (day 1 3). The patient continued to be asymptomatic; a SARS-CoV-2 PCR performed on a nasopharyngeal sample on day 1 19 was negative, indicating complete viral clearance.

Methods

Serum samples

Patient and healthy donor samples were collected under protocol #45880, which was approved by the Institutional Review Board at the University of Utah. Written informed consent was obtained from participants prior to inclusion in the study.

Serum ELISA and titration

Ninety-six-well plates were coated with 5 mg/mL recombinant protein or peptides. ELISAs were performed as described previously.[17]

Pseudotyped virus-neutralization assay

Assays were performed as described, using plasmid HIV-1-d-env-luc with pSARS-Cov-2-S for patient samples and MLV-C (2)Env(-), L-luc-SN and pSARS-Cov-2-S for donor plasma.[18]

Downloaded from http://ashpublications.org/bloodadvances/article-pdf/4/19/4864/1760926/advancesadv2020002595.pdf by guest on 11 October 2020

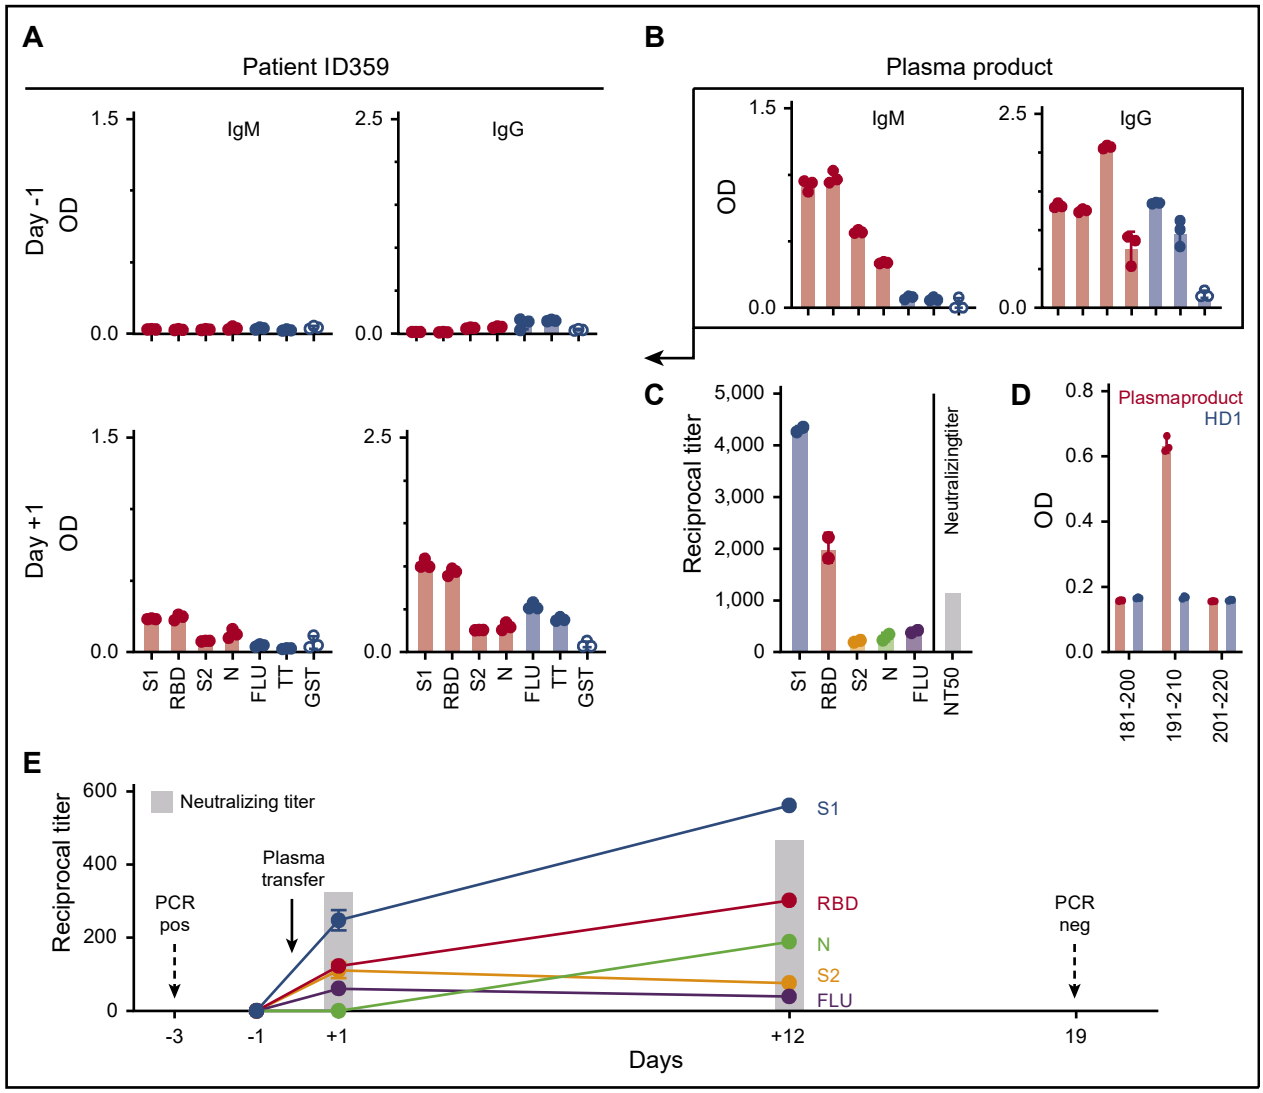

Figure 2. Transfer of SARS-CoV-2–specific immunity to MM patient by convalescent plasma infusion and subsequent viral clearance. (A) IgM and IgG antibody responses in patient ID359 plasma against SARS-CoV-2 proteins and control proteins at 1:20 serum dilution before and after convalescent plasma infusion, as determined by ELISA. (B) IgM and IgG responses at 1:20 plasma dilution against SARS-CoV-2 and control proteins in convalescent plasma product, as determined by ELISA. (C) Reciprocal IgG antibody titers against SARS-CoV-2 and control proteins and neutralizing antibody titers in the convalescent plasma product. (D) Epitope mapping of convalescent plasma product and plasma from a healthy donor (HD1) using synthetic S1 peptides, as determined by ELISA. 20mer peptides overlapping by 10 aa for SARS-CoV-2 S1, S2, M, and E sequences were synthetized (peptides & elephants, Hennigsdorf, Germany). Data represent the mean, and circles indicate technical replicates. (E) Reciprocal IgG titers against SARS-CoV-2 proteins and FLU, as well as neutralizing antibody activity in patient ID359 plasma, before and after convalescent plasma infusion. Antibody titers represent mean 6 standard deviation from 2 technical replicates. GST, glutathione S-transferase; neg, negative.

Results and discussion

To perform the first detailed analysis of convalescent plasma product and its effect on the anti–SARS-CoV-2 immunity in the recipient, we established an ELISA measuring antibody titers against the SARS-CoV-2 structural proteins. We obtained full-length recombinant proteins for the S1 protein, the RBD within the S1 protein, and the S2 and nucleocapsid (N) proteins. S1, S2, and RBD used in this study were expressed in human 293 cells to preserve structure and glycosylation patterns. Peptide libraries consisting of 20mers overlapping by 10 aa were synthesized for these SARS-CoV-2 proteins and for the M and E proteins. In addition, we obtained a 69-aa synthetic peptide comprising a highly conserved cryptic epitope in the RBDs of SARS-CoV-2 and severe acute respiratory syndrome coronavirus.[19]

We performed assay validation assessing sera from 6 patients with PCR-confirmed and symptomatic COVID-19 and from 5 healthy donors for antibodies against the different SARS-CoV-2 proteins and peptides, positive-control antigens influenza H1N1 nucleoprotein (FLU) and tetanus toxoid (TT), and the negative-control protein glutathione S-transferase. We found that all patients showed strong antibody responses against S1 and the RBD (Figure 1C). In addition, all 5 patients showed antibody responses against the S2 and N proteins. Interestingly, the RBD produced synthetically was not recognized by any of the patient-derived antibodies,

Downloaded from http://ashpublications.org/bloodadvances/article-pdf/4/19/4864/1760926/advancesadv2020002595.pdf by guest on 11 October 2020

pointing to glycosylation-dependent and/or conformational epitopes as targets for the antiviral immune responses. Accordingly, we did not observe antibody responses against pooled M and E peptides (data not shown). With the exception of the mammalian cell–expressed RBD, which was recognized by serum from 1 healthy donor, none of the other SARS-CoV-2 proteins were recognized by sera from non–COVID-19 individuals (Figure 1C).

As expected, when screening the patient's blood on the day of admission, we did not detect antibodies against any of the viral proteins (Figure 2A) or any neutralizing antibody activity (Figure 2E). It has previously been shown that, at least in the case of severe acute respiratory syndrome coronavirus, lung injury is associated with neutralizing antibody development[20] and, it may be noteworthy that, in our patient, respiratory distress occurred despite a severely suppressed humoral immune system and the absence of anti–SARS-CoV-2 antibodies. In contrast, a , 1-mL leftover from the frozen and thawed convalescent plasma product administered to the patient contained IgM and IgG antibodies (Figure 2B) and a low level of IgA antibodies (data not shown) against S1, RBD, S2, and N proteins, as well as IgG antibodies against positive-control proteins FLU and TT (Figure 2B-C). Importantly, the donor plasma also contained significant neutralizing activity (reciprocal 50% neutralizing titer [NT_{50}]; Figure 2C). Analyzing the convalescent plasma product using overlapping synthetic peptide libraries we were able to identify 1 linear epitope within the S1 protein, N-terminal from the RBD, at aa position 191 to 210 (Figure 2D).

On the morning after treatment with convalescent plasma (day 1 1), we were able to detect IgM and IgG antibody responses (Figure 2A), but no IgA antibodies (data not shown), against all tested viral proteins in the patient's blood, albeit at a lower level compared with the plasma product. The plasma product evidenced the highest IgG antibody titers against SARS-CoV-2 proteins S1 and RBD and lower antibody titers against S2 and N (Figure 2D). Following plasma transfer, the patient showed a similar distribution pattern (Figure 2E), confirming that the humoral immunity had indeed been passively transferred to the recipient. Importantly, the transfer of the donor-derived antiviral immunity also resulted in neutralizing antibody activity in the patient's blood (Figure 2E). The antibodies against the different viral proteins were still detectable in the patient 12 days after transfusion of the convalescent plasma, at titers even higher than on the day after treatment, with a higher neutralizing activity (Figure 2E) and new low-level antiviral IgA antibodies (data not shown), indicating the development of at least some autologous SARS-CoV-2–specific immunity.

In summary, our data indicate that transfer of convalescent plasma is safe, even in severely immunocompromised patients with hematologic malignancies who are under treatment for their malignancy. We also show here for the first time that the complete humoral immunity against the different viral target proteins can successfully be transferred and detected in the recipient and that antibody levels are maintained over time. Finally, our observations indicate that these patients may derive clinical benefit from such a treatment, although this will need to be confirmed by randomized clinical trials.

To: NSF Ecology and Evolution of Infectious Diseases (EEID) Program (NSF-19-592)

From:
Ralph S Baric, PhD
William R. Kenan, Jr. Distinguished Professor. Department of Epidemiology
Professor, Department of Microbiology and Immunology

By signing below, I acknowledge that I am listed as a collaborator on this proposal, entitled "**US-China Collab: Spillover, co-infection, and control of bat-origin livestock coronaviruses**" with Peter Daszak as the Principal Investigator. I agree to undertake the tasks assigned to me or my organization, as described in the project description of the proposal, and I commit to provide or make available the resources specified therein.

Sincerely,

Organization:
University of North Carolina at Chapel Hill
Chapel Hill, NC 27599

Date: 29 October, 2020

REGN-COV2 INDEPENDENT DATA MONITORING COMMITTEE RECOMMENDS HOLDING ENROLLMENT IN HOSPITALIZED PATIENTS WITH HIGH OXYGEN REQUIREMENTS AND CONTINUING ENROLLMENT IN PATIENTS WITH LOW OR NO OXYGEN REQUIREMENTS

TARRYTOWN, N.Y., Oct. 30, 2020 /PRNewswire/ --

The IDMC also recommends continuation of enrollment in the REGN-COV2 outpatient trial

Regeneron Pharmaceuticals, Inc. (NASDAQ: REGN) received today a recommendation from the independent data monitoring committee (IDMC) for the REGN-COV2 antibody cocktail treatment trials for COVID-19 that the current hospitalized patient trial be modified. Specifically, based on a potential safety signal and an unfavorable risk/benefit profile at this time, the IDMC recommends further enrollment of patients requiring high-flow oxygen or mechanical ventilation be placed on hold pending collection and analysis of further data on patients already enrolled. The IDMC also recommends continuing enrollment of hospitalized patients requiring either no or low-flow oxygen as the risk/benefit remains acceptable in these cohorts. Finally, the IDMC recommends continuation of the outpatient trial without modification.

Regeneron remains blinded to the data and is implementing the IDMC recommendations. Regeneron is also informing the U.S. Food and Drug Administration, which is currently evaluating REGN-COV2 for a potential Emergency Use Authorization in mild-to-moderate outpatients at high risk for poor outcomes. Regeneron is also sharing the recommendation with the independent committee monitoring the RECOVERY trial in the UK, which is evaluating REGN-COV2 in hospitalized patients.

About the REGN-COV2 Trial in Hospitalized Patients

The trial is designed to enroll patients in four independently randomized cohorts:

- Cohort 1: patients on low-flow oxygen
- Cohort 1A: patients not requiring oxygen
- Cohort 2: patients on high-flow oxygen
- Cohort 3: patients on mechanical ventilation

About REGN-COV2
REGN-COV2 is a combination of two monoclonal antibodies (REGN10933 and REGN10987) and was designed specifically to block infectivity of SARS-CoV-2, the virus that causes COVID-19.

To develop REGN-COV2, Regeneron scientists evaluated thousands of fully-human antibodies produced by the company's *VelocImmune®* mice, which have been genetically modified to have a human immune system, as well as antibodies identified from humans who have recovered from COVID-19. The two potent, virus-neutralizing antibodies that form REGN-COV2 bind non-competitively to the critical receptor binding domain of the virus's spike protein, which diminishes the ability of mutant viruses to escape treatment and protects against spike variants that have arisen in the human population, as detailed in *Science*.

REGN-COV2's development and manufacturing has been funded in part with federal funds from the Biomedical Advanced Research and Development Authority (BARDA), part of the Office of the Assistant Secretary for Preparedness and Response at the U.S. Department of Health and Human Services under OT number: HHSO100201700020C. Regeneron has partnered with Roche to increase the global supply of REGN-COV2 beginning in 2021. If REGN-COV2 proves safe and effective in clinical trials and regulatory approvals are granted, Regeneron will manufacture and distribute it in the U.S. and Roche will develop, manufacture and distribute it outside the U.S.

About Regeneron

Regeneron (NASDAQ: REGN) is a leading biotechnology company that invents life-transforming medicines for people with serious diseases. Founded and led for over 30 years by physician-scientists, our unique ability to repeatedly and consistently translate science into medicine has led to eight FDA-approved treatments and numerous product candidates in development, all of which were homegrown in our laboratories. Our medicines and pipeline are designed to help patients with eye diseases, allergic and inflammatory diseases, cancer, cardiovascular and metabolic diseases, pain, infectious diseases and rare diseases.

Regeneron is accelerating and improving the traditional drug development process through our proprietary *VelociSuite* technologies, such as *VelocImmune®*, which uses unique genetically-humanized mice to produce optimized fully-human antibodies and bispecific antibodies, and through ambitious research initiatives such as the Regeneron Genetics Center, which is conducting one of the largest genetics sequencing efforts in the world.

For additional information about the company, please visit www.regeneron.com or follow @Regeneron on Twitter.

Forward-Looking Statements and Use of Digital Media

This press release includes forward-looking statements that involve risks and uncertainties relating to future events and the future performance of Regeneron Pharmaceuticals, Inc. ("Regeneron" or the "Company"), and actual events or results may differ materially from these forward-looking statements. Words such as "anticipate," "expect," "intend," "plan," "believe," "seek," "estimate," variations of such words, and similar expressions are intended to identify such forward-looking statements, although not all forward-looking statements contain these identifying words. These statements concern, and these risks and uncertainties include, among others, the impact of SARS-CoV-2 (the virus that has caused the COVID-19 pandemic) on Regeneron's business and its employees, collaborators, and suppliers and other third parties on which Regeneron relies, Regeneron's and its collaborators' ability to continue to conduct research and clinical programs (including those discussed in this press release), Regeneron's ability to manage its supply chain, net product sales of products marketed by Regeneron and/or its collaborators (collectively, "Regeneron's Products"), and the global economy; the nature, timing, and possible success and therapeutic applications of Regeneron's Products and product candidates and research and clinical programs now underway or planned, including without limitation the development program relating to REGN-COV2 (Regeneron's investigational dual antibody for the treatment and prevention of COVID-19); safety issues resulting from the administration of Regeneron's Products and product candidates (such as REGN-COV2) in patients, including serious complications or side effects in connection with the use of Regeneron's Products and product candidates in clinical trials; the impact of the recommendation of the independent data monitoring committee for the REGN-COV2 trials and the potential safety signal discussed in this press release on further clinical development of REGN-COV2, the decision by the U.S. Food and Drug Administration ("FDA") with respect to a potential Emergency Use Authorization ("EUA") for REGN-COV2, and possible regulatory approval of REGN-COV2; whether the FDA will grant an EUA for REGN-COV2 and, if an EUA is granted, the scope and terms of such EUA and how long such EUA would remain in effect for REGN-COV2; the likelihood, timing, and scope of possible regulatory approval and commercial launch of Regeneron's product candidates (such as REGN-COV2) and new indications for Regeneron's Products; the ability of

Regeneron to manufacture in anticipated quantities Regeneron's Products and product candidates, including REGN-COV2; the ability of Regeneron to manufacture and manage supply chains for multiple products and product candidates; the ability of Regeneron's collaborators, suppliers, or other third parties (as applicable) to perform manufacturing, filling, finishing, packaging, labeling, distribution, and other steps related to Regeneron's Products and product candidates; uncertainty of market acceptance and commercial success of Regeneron's Products and product candidates and the impact of studies (whether conducted by Regeneron or others and whether mandated or voluntary), including the studies evaluating REGN-COV2 discussed in this press release, on any potential regulatory approval (including with respect to REGN-COV2) and/or the commercial success of Regeneron's Products and product candidates; determinations by regulatory and administrative governmental authorities which may delay or restrict Regeneron's ability to continue to develop or commercialize Regeneron's Products and product candidates, including without limitation REGN-COV2; ongoing regulatory obligations and oversight impacting Regeneron's Products, research and clinical programs, and business, including those relating to patient privacy; the availability and extent of reimbursement of Regeneron's Products from third-party payers, including private payer healthcare and insurance programs, health maintenance organizations, pharmacy benefit management companies, and government programs such as Medicare and Medicaid; coverage and reimbursement determinations by such payers and new policies and procedures adopted by such payers; competing drugs and product candidates that may be superior to, or more cost effective than, Regeneron's Products and product candidates; the extent to which the results from the research and development programs conducted by Regeneron and/or its collaborators may be replicated in other studies and/or lead to advancement of product candidates to clinical trials, therapeutic applications, or regulatory approval; unanticipated expenses; the costs of developing, producing, and selling products; the ability of Regeneron to meet any of its financial projections or guidance and changes to the assumptions underlying those projections or guidance; the potential for any license or collaboration agreement, including Regeneron's agreements with Sanofi, Bayer, and Teva Pharmaceutical Industries Ltd. (or their respective affiliated companies, as applicable), as well as Regeneron's collaboration with Roche relating to REGN-COV2, to be cancelled or terminated; and risks associated with intellectual property of other parties and pending or future litigation relating thereto (including without limitation the patent litigation and other related proceedings relating to EYLEA® (aflibercept) Injection, Dupixent® (dupilumab), and Praluent® (alirocumab)), other litigation and other proceedings and government investigations relating to the Company and/or its operations, the ultimate outcome of any such proceedings and investigations, and the impact any of the foregoing may have on Regeneron's business, prospects, operating results, and financial condition. A more complete description of these and other material risks can be found in Regeneron's filings with the U.S. Securities and Exchange Commission, including its Form 10-K for the year ended December 31, 2019 and its Form 10-Q for the quarterly period ended June 30, 2020. Any forward-looking statements are made based on management's current beliefs and judgment, and the reader is cautioned not to rely on any forward-looking statements made by Regeneron. Regeneron does not undertake any obligation to update (publicly or otherwise) any forward-looking statement, including without limitation any financial projection or guidance, whether as a result of new information, future events, or otherwise.

Regeneron uses its media and investor relations website and social media outlets to publish important information about the Company, including information that may be deemed material to investors. Financial and other information about Regeneron is routinely posted and is accessible on Regeneron's media and investor relations website (http://newsroom.regeneron.com) and its Twitter feed (http://twitter.com/regeneron).

IMPORTANT INFORMATION AND REVISION NOTES

This revision includes new details about what needs to be included in the Data Management Plan.

Any proposal submitted in response to this solicitation should be submitted in accordance with the revised*NSF Proposal & Award Policies & Procedures Guide* (PAPPG) (NSF 20-1), which is effective for proposals submitted, or due, on or after June 1, 2020.

SUMMARY OF PROGRAM REQUIREMENTS

General Information

Program Title:

Ecology and Evolution of Infectious Diseases (EEID)

Synopsis of Program:

The multi-agency Ecology and Evolution of Infectious Diseases program supports research on the ecological, evolutionary, and social drivers that influence the transmission dynamics of infectious diseases. The central theme of submitted projects must be the quantitative or computational understanding of pathogen transmission dynamics. The intent is discovery of principles of infectious disease transmission and testing mathematical or computational models that elucidate infectious disease systems. Projects should be broad, interdisciplinary efforts that go beyond the scope of typical studies. They should focus on the determinants and interactions of transmission among any host species, including but not limited to humans, non-human animals, and/or plants. This includes, for example, the spread of pathogens; the influence of environmental factors such as climate; the population dynamics and genetics of reservoir species or hosts; the feedback between ecological transmission and evolutionary dynamics; and the cultural, social, behavioral, and economic dimensions of pathogen transmission. Research may be on zoonotic, environmentally-borne, vector-borne, or enteric pathogens of either terrestrial or aquatic systems and organisms, including diseases of animals and plants, at any scale from specific pathogens to inclusive environmental systems. Proposals for research on disease systems of public health concern to developing countries are strongly encouraged, as are disease systems of concern in agricultural systems. Investigators are encouraged to develop the appropriate multidisciplinary team, including for example, anthropologists, modelers, ecologists, bioinformaticians, genomics researchers, social scientists, economists, oceanographers, mathematical scientists, epidemiologists, evolutionary biologists, entomologists, parasitologists, microbiologists, bacteriologists, virologists, pathologists or veterinarians, with the goal of integrating knowledge across disciplines to enhance our ability to predict and control infectious diseases.

Award Information

Anticipated Type of Award: Standard Grant or Continuing Grant

Estimated Number of Awards: 12

Anticipated Funding Amount: $24,000,000

in FY 2021, pending the availability of funds. That amount includes approximately $11.0M from NSF for new standard or continuing awards, approximately $7.5M from NIH for new or continuing awards, and $5.5M from USDA for new awards. The expected funding from the UKRI for the UK component of the US-UK Collaborative Projects will be a maximum of £2M. The expected funding from the BSF for the Israeli component of the US-Israel Collaborative Projects will be a maximum of $720,000. The expected funding from the NSFC for the Chinese component of the US-China Collaborative Projects will be a maximum of ¥9M.

Eligibility Information

Who May Submit Proposals:

The categories of proposers eligible to submit proposals to the National Science Foundation are identified in the *NSF Proposal & Award Policies & Procedures Guide* (PAPPG), Chapter I.E. Unaffiliated individuals are not eligible to submit proposals in response to this solicitation.

Who May Serve as PI:

There are no restrictions or limits.

Limit on Number of Proposals per Organization:

There are no restrictions or limits.

Limit on Number of Proposals per PI or Co-PI: 2

In a given year, an individual may participate as a PI, co-PI, or subaward lead on no more than **two** proposals submitted in response to this solicitation. **This limit does not include Research Coordination Networks (RCN) proposals.** In addition, an individual from Israel may participate in no more than **one** US-BSF proposal and an individual from China may participate in no more than **one** US-China proposal. Proposals in excess of the limit for any person will be returned without review in the reverse order received. Participating in a proposal as other senior personnel does not count in this limit. Changes in investigator roles post-submission to meet the eligibility limits will not be allowed. **It is the responsibility of the submitters to confirm that the entire team is within the eligibility guidelines.**

Proposal Preparation and Submission Instructions

A. Proposal Preparation Instructions

- **Letters of Intent:** Not required
- **Preliminary Proposal Submission:** Not required

Full Proposals:

- Full Proposals submitted via FastLane: *NSF Proposal and Award Policies and Procedures Guide* (PAPPG) guidelines apply. The complete text of the PAPPG is available electronically on the NSF website at: https://www.nsf.gov/publications/pub_summ.jsp?ods_key=pappg
- Full Proposals submitted via Research.gov: *NSF Proposal and Award Policies and Procedures Guide* (PAPPG) guidelines apply. The complete text of the PAPPG is available electronically on the NSF website at: https://www.nsf.gov/publications/pub_summ.jsp?ods_key=pappg
- Full Proposals submitted via Grants.gov: *NSF Grants.gov Application Guide: A Guide for the Preparation and Submission of NSF Applications via Grants.gov* guidelines apply (Note: The *NSF Grants.gov Application Guide* is available on the Grants.gov website and on the NSF website at: https://www.nsf.gov/publications/pub_summ.jsp?ods_key=grantsgovguide).

B. Budgetary Information

- **Cost Sharing Requirements:**

  Inclusion of voluntary committed cost sharing is prohibited.

- **Indirect Cost (F&A) Limitations:**

  Not Applicable

- **Other Budgetary Limitations:**

  Other budgetary limitations apply. Please see the full text of this solicitation for further information.

C. Due Dates

Full Proposal Deadline(s) (due by 5 p.m. submitter's local time):

November 18, 2020

Third Wednesday in November, Annually Thereafter

Proposal Review Information Criteria

Merit Review Criteria:

National Science Board approved criteria. Additional merit review criteria apply. Please see the full text of this solicitation for further information.

Award Administration Information

Award Conditions:

Additional award conditions apply. Please see the full text of this solicitation for further information.

Reporting Requirements:

Additional reporting requirements apply. Please see the full text of this solicitation for further information.

I. INTRODUCTION

The past twenty-five years have seen a dramatic increase in our awareness of the need to understand the ecological and evolutionary drivers of disease emergence and transmission dynamics. While our knowledge has increased about specific systems and the basic principles of simple systems, understanding of complex systems and translation of those principles into ecosystem, public health, and agricultural health management tools remains challenging. System complexity includes such factors as multiple interacting species of hosts, pathogens and/or vectors; interactions among pathogenic and non-pathogenic microbes; interactions between biological, cultural and social factors; effects of spatial and temporal structure; and evolutionary dynamics.

The emergence and the re-emergence of numerous infectious diseases around the world have coincided with unprecedented rates of change in the structure and diversity of the environment and human social and economic systems. Nearly all of the world's terrestrial and aquatic ecosystems have undergone dramatic changes due to a variety of human activities such as habitat transformation, human displacement and relocation, urbanization, rapid long-distance transport and increased international trade, species invasions, deliberate introduction of infectious diseases for biological control, wildlife trafficking, chemical waste contamination, use of antimicrobial agents in agriculture and medicine, and climate change. The coincidence of broad scale environmental changes, the expansion of human social and economic networks, and the emergence and re-emergence of infectious diseases may point to underlying predictable ecological and eco-evolutionary relationships.

We have improved our ability to define the molecular identity and dynamics of pathogens and have greatly increased our understanding of host defense systems. We are able to apply genetic knowledge to understand the evolutionary dynamics of infectious diseases. These improvements have contributed significantly to our knowledge of the epidemiology and transmission patterns of diseases. However, the relationship of these factors to the biotic and structural complexity of ecological, agricultural, and social systems in which transmission occurs remains poorly understood. For example, little is known about the transmission dynamics of interacting pathogens and non-pathogens within a common host. In addition, although these dynamics take place over evolutionary time for pathogens and in the context of social systems, insufficient attention has been given to integrating ecological, epidemiological, evolutionary, and socio-economic dynamics.

At present, basic and applied research in infectious disease ecology and evolution are not well integrated. The potential benefits of an interdisciplinary research program in this area include:

- development of disease transmission theory,
- improved understanding of how diseases (re)emerge,
- improved understanding of host population and ecosystem effects on disease transmission,
- increased capacity to forecast and respond to outbreaks,
- improved understanding of unintended health effects of development projects affecting terrestrial, freshwater, and coastal marine systems,
- enhanced safety of food supplies, and
- improved strategies to control or prevent infectious diseases and enhance biosecurity.

An understudied aspect of disease transmission is the importance of socio-ecological factors and processes. Important new insights into the drivers and control of infectious diseases in humans and other species can only be achieved by integrated approaches that take into account the ways in which the natural and social environments affect the emergence and spread of infectious disease. This concept, often called "one health," links medical, veterinary, social and environmental sciences by drawing on a common pool of knowledge between the three sectors in order to exploit the potential of animal disease research to provide insights into ecosystem, agricultural, and human health.

This activity is a continuation of the previous joint National Science Foundation/National Institutes of Health/United States Department of Agriculture (NSF/NIH/USDA) Ecology of Infectious Disease competition. Information on past awards can be found atEEID Awards. Additional information for NIH can be found at http://www.fic.nih.gov/Programs/Pages/ecology-infectious-diseases.aspxand for USDA at https://nifa.usda.gov/funding-opportunity/ecology-and-evolution-infectious-diseases.

II. PROGRAM DESCRIPTION

The goal of the Ecology and Evolution of Infectious Diseases (EEID) program is to support important and innovative research on the ecological, evolutionary, and socio-ecological principles that influence the transmission dynamics of infectious diseases. The program's focus is on the discovery of general principles and processes and on building and testing models that elucidate these principles.**Projects must address the quantitative or computational understanding of pathogen transmission dynamics.** Research in EEID is expected to be an interdisciplinary effort that goes beyond the scope of typical studies funded by the standing programs of the partner agencies. Projects should bring together such areas as anthropology, bioinformatics, computational science, ecology, economics, epidemiology, evolution, food science, genomics, geography, global health, mathematics, medicine, microbiology, oceanography, plant science, population biology, sociology, physical environmental sciences, systems science, and veterinary medicine. Research within EEID is expected to generate rigorously characterized and tested models that are of value to the scientific community, but also may be useful in decision making.**The history of the EEID program has shown that the most competitive proposals are those that advance broad, conceptual knowledge that reaches beyond the specific system under study and that may be useful for understanding public, agricultural or ecosystem health, natural resource use and wildlife management, and/or economic development. Such proposals are typically interdisciplinary in their approach and/or the nature of the question(s) being addressed.**

Infectious disease transmission reflects complex, dynamic relationships that occur on varying spatial and temporal landscapes, are created by both ecological and evolutionary processes, and are revealed in genome architecture, physiological systems, population dynamics, and community structure, as well as behavioral and social dynamics. The interactions between disease-causing organisms, their vectors, and their host(s) are embedded within much larger networks of interacting systems, including other microorganisms that may or may not cause disease, one or more vector species, and multiple host species. Analysis of environmental influences (biological, geophysical, economic, and social) on individual and population susceptibility is fundamental to understanding these complex systems of infectious diseases. Research into the ecology (population, community, evolutionary, and social) of infectious diseases will contribute to a deeper understanding of these complex infectious disease systems, to the development of well characterized and tested models, and to the elucidation of general ecological and evolutionary principles.

Insights into the dynamics of infectious disease systems may require integration across several temporal, spatial, and functional scales including molecular, individual, population, societal, and ecosystem levels. Similarly, they may require integration across biological, socio-economic, and geophysical domains. The field of evolutionary ecology, which focuses on both the importance of ecological context in studies of evolution and the importance of evolutionary change for ecological systems, may also provide important insights into infectious disease systems. The interplay of evolution and ecology has implications for understanding how infectious agents emerge as pathogens, adapt to one or more hosts, interact with other microbial communities (e.g., microbiome), and are transmitted among hosts.

A critical goal of research supported by this program is the generation of principles and conceptual frameworks that organize and inform the research and that lead to mathematical, computational, and statistical models of infectious disease dynamics. Diverse modeling approaches are appropriate, including, but not limited to, mathematical equations, computational simulations, geospatial algorithms, and statistical models.**For the EEID program, the most competitive proposals are organized around an overarching conceptual framework that leads to such a model.** Models should aim to be explanatory beyond the specific system under study and must be well-characterized and rigorously tested. Proposals must describe how models will be developed, evaluated, and disseminated. Proposals must identify which individual(s) will oversee the quantitative approaches and provide evidence of demonstrated expertise in mathematical, computational, or statistical modeling and/or data analysis. Likewise, strategies for data collection must be well designed to contribute to and test model design. Proposals must include plans for dissemination of data, models, and tools developed by this program.

A variety of *topics, questions, systems and approaches*are appropriate. Among the areas of particular interest are: the role of social influences on the susceptibility of individuals or populations; multiway interactions between pathogenic and non-pathogenic organisms and their mutual hosts; the role of medical, agricultural or environmental practices on pathogen emergence and transmission; emergence of pathogens from non-pathogenic populations; host switching; evolutionary dynamics in an ecological context such as disease control interventions and drug resistance. These topics have significant ecological and evolutionary components that should be studied as a system, not in isolation. Depending on the hypotheses or research questions being addressed, investigations might entail some combination of laboratory experiments, field observations or manipulations, public health interventions (although clinical trials are beyond the scope of the EEID program), analysis of social and cultural processes, or ethnographic studies. Research may also focus on novel analyses of existing data and/or theoretical investigations of ecological and evolutionary dynamics. Investigations may focus on model infectious disease systems in natural (terrestrial, freshwater, or marine) or laboratory settings where those systems elucidate general principles.

Research may use a variety of study systems. The organism(s) or system(s) selected for study should be justified with respect to its suitability to study questions of ecology and/or evolutionary ecology. Research may involve a variety of infectious agents, individual diseases, or groups of diseases, and might involve one or more social systems, regions, habitats, or groups of organisms. Proposals may focus on terrestrial or aquatic systems and organisms and may include infectious diseases of humans, non-human animals, or plants.**Regardless of the system or approach taken, a proposal must have a significant focus on the ecology of pathogen transmission to be eligible for funding.**

Because of the complexity of studies on the ecology and evolutionary ecology of infectious diseases, multidisciplinary teams of domestic and international collaborators with expertise from diverse disciplines are likely to be most effective. Investigators are encouraged to develop collaborations with public health research communities where that is appropriate. Collaborative teams could include, for example: ecologists, epidemiologists, medical scientists, veterinary scientists, oceanographers, evolutionary biologists, social and behavioral scientists, entomologists, food scientists, microbiologists, pathologists, and parasitologists, geologists, hydrologists, geospatial analysts, and mathematical scientists. The research plan should indicate how multiple disciplines will be integrated and how new investigators in U.S. and collaborating foreign institutions will be prepared to further this research.

The EEID program is not intended to be the only avenue of support by the participating agencies for supporting research on infectious diseases. Specifically, proposals submitted in response to this solicitation must address ecological dynamics and among-host transmission, even when evolutionary studies are a substantive part of the proposal. Investigations that are outside the scope of this EEID announcement include:

- those limited solely to genetic patterns of evolutionary change (e.g., comparative genomics),
- those that focus solely on human diseases without considering the broader ecological context,
- those that focus solely on pathogen discovery,
- those that focus solely on within-host biological processes,
- those that focus solely on vector species ecology, and
- those that have not pre-identified at least one pathogenic organism that will be the focus of the study,
- those that focus on antimicrobial resistance without considering pathogen transmission dynamics.

The EEID competition broadly welcomes, but does not require, that projects include international collaborators. Three specific forms of collaboration (US-UK Collaborative Projects, US-Israel Collaborative Projects, and US-China Collaborative Projects) are described below. These specific activities do not preclude other international collaborations.

EEID Partner Interests

Fogarty International Center

The Fogarty International Center (FIC) is dedicated to advancing the mission of the National Institutes of Health (NIH) by supporting and facilitating global health research conducted by U.S. and international investigators, building partnerships between health research institutions in the U.S. and abroad, and training the next generation of scientists to address global health needs. The FIC is interested in EEID applications that include explicit plans for capacity building in Low- or Middle-Income Countries (LMICs), as defined by the World Bank and encourages applications that are focused on significant and/or emerging infectious disease threats, including zoonotic disease threats, to human health in LMICs. The FIC will consider supporting meritorious EEID research applications that address the above priorities and/or meritorious EEID Research Coordination Network (RCN) applications aimed at capacity building in LMICs.

National Institute of General Medical Sciences

The National Institute of General Medical Sciences (NIGMS) supports basic research that improves understanding of biological processes and lays the foundation for advances in disease diagnoses, prevention, and treatment. NIGMS also has a strong interest in training and support of the nation's scientific workforce. NIGMS is interested in EEID applications that address the evolution of hosts, pathogens and their interactions as well as basic biology and population genetics of hosts and pathogens as they relate to disease transmission and prevention. NIGMS will consider supporting meritorious EEID research applications as single-PI or multi-PI research program grants.

National Institute of Allergy and Infectious Diseases

The National Institute of Allergy and Infectious Diseases (NIAID) conducts and supports basic and applied research to better understand, treat, and ultimately prevent infectious, immunologic, and allergic diseases. NIAID supports research on nearly 300 infectious agents and investigates the biological properties of these pathogens and the immune system's responses to them. Findings from this research are vital to NIAID efforts to create vaccines, drugs, and diagnostic tools to better diagnose, prevent, and treat infectious diseases.

USDA/NIFA

The National Institute of Food and Agriculture (NIFA) supports research, education, and extension work that addresses key problems of national, regional, and multi-state importance in sustaining all components of food and agriculture, including farm efficiency and profitability, ranching, bioenergy, forestry (both urban and agroforestry), aquaculture, rural communities and entrepreneurship, human nutrition, food safety, physical and social sciences, home economics and rural human ecology, biotechnology, and conventional breeding, and including both conventional and organic food production systems.

Applicants may submit proposals that support one or more of the seven USDA's strategic goals for FY2018-2022 (https://www.usda.gov/our-agency/about-usda/strategic-goals). Any such activity proposed (e.g., partnerships, exchanges, training, and/or travel), must first and foremost support NIFA's domestic program goals. Applicants must clearly describe and demonstrate how international activities proposed in applications will contribute to and support advances in U.S. agriculture.

US-UK Collaborative Proposals

Recognizing the potential for international collaboration to advance EEID research and education objectives, NSF has partnered for this solicitation with the UK Research and Innovation. This partnership will facilitate coordinated funding of U.S. and U.K. research collaboration within the EEID program. UKRI encourages proposals with focus on animal and human Coronaviruses including SARS-CoV-2, although other topics are also eligible.

UK researchers applying under this heading must meet UKRI eligibility requirements for managed mode calls and must apply through an institution eligible to receive UKRI funding. Please see UKRI funding rules: http://www.bbsrc.ac.uk/funding/apply/grants-guide.aspx.

PIs are **strongly encouraged** to contact the relevant Cognizant Program Officer to confirm that the UK component fits UKRI requirements. Applications with non-eligible UK partners will not be considered for funding as a US-UK Collaborative Projects.

US-Israel Collaborative Proposals

Recognizing the potential for international collaboration to advance EEID research and education objectives, NSF has partnered for this solicitation with the U.S.-Israel Binational Science Foundation (BSF), which is an organization owned by the two governments with the aim of facilitating scientific relations between them. The Israeli component of the US-Israel Collaborative Projects will be funded by the BSF using special funds provided by the Israeli government.

Israeli researchers applying under this heading must meet BSF eligibility requirements and must apply through an institution eligible to receive BSF funding. Please see BSF eligibility rules: http://www.bsf.org.il/ElectronicSubmission/GatewayFormsAndGuidelines.aspx?PageId=7&innerTextID=0

US-UK-Israel Collaborative Proposals

Multinational collaborative research projects that involve researchers from the US, UK and Israel are also welcome. Any such projects must meet the requirements of each of the NSF, the UKRI, and the BSF.

US-China Collaborative Proposals

Recognizing the potential for international collaboration to advance EEID research and education objectives, NSF has partnered for this solicitation with the National Natural Science Foundation of China (NSFC). The Chinese component of the US-China Collaborative Projects will be funded by the NSFC using funds provided by the Chinese government.

Chinese researchers applying under this heading must meet NSFC eligibility requirements and must apply through an institution eligible to receive NSFC funding. Please see NSFC eligibility rules: http://www.nsfc.gov.cn/nsfc/cen/xmzn/2017xmzn/sqxz.html. Applications with non-eligible China partners will not be considered for funding as a US-China Collaborative Project.

US-China-UK Collaborative Proposals

Multinational collaborative research projects that involve researchers from the US, China and the UK are also welcome. Any such projects must meet the requirements of each of the NSF, the NSFC, and the UKRI.

US-China-Israel Collaborative Proposals

Multinational collaborative research projects that involve researchers from the US, China and Israel are also welcome. Any such projects must meet the requirements of each of the NSF, the NSFC, and the BSF.

Research Coordination Network (RCN) Proposals

The EEID program will accept proposals to establish Research Coordination Networks that focus on issues involving infectious disease ecology, socio-ecology, and evolution. RCN projects are also eligible to be submitted as US-UK, US-China, or US-UK-China Collaborative Projects. Information on the scope of RCN projects and the format of those proposals can be found at (https://www.nsf.gov/funding/pgm_summ.jsp?pims_id=11691&org=BIO&from=home). Such RCN proposals should be submitted under the EEID solicitation and deadline.

III. AWARD INFORMATION

Award size: Under this solicitation, the maximum award size for all years for the US component is $2.5 million, including indirect costs. The minimum award size is $1.5 million total project costs for all years, except for international collaborative proposals (US-UK, US-Israel, and US-China Collaborative Projects) that have a minimum award size of $1.0 million for the US component. Those collaborative projects can request additional funding for the international component of the project. For US-Israel Collaborative Projects, the maximum award size for the Israeli portion is $720,000. For US-China Collaborative Projects, the maximum award size for the Chinese portion is ¥4.5M total project costs for all years.

Award duration: The maximum award duration is five years.

RCN proposals: The maximum award size for RCN proposals is $500,000 as per the RCN solicitation. For international Collaborative RCN proposals, the maximum award size for the US component is $500,000.

Award number: Approximately 12 new awards are anticipated in FY 2021, depending on the quality of submissions and the availability of funds; the expected funding will be $24.0 million. That amount includes approximately $11.0M from the NSF for new standard or continuing awards, approximately $7.5M from the NIH for new or continuing awards, and $5.5M from the USDA for new awards. Of those 12 awards, up to 4 are anticipated to be US-UK Collaborative Projects, depending on the quality of submissions and the availability of funds; the expected funding from the UKRI for this call is up to £2M. This amount reflects 80% of the full economic costs in the U.K. Of those 12 awards, up to 1 is anticipated to be a US-Israel Collaborative Project, depending on the quality of submissions and the availability of funds; the expected funding from the BSF for the Israeli component of the US-Israel Collaborative Projects will be a maximum of $80,000/year. Of those 12 awards, up to 2 are anticipated to be US-China Collaborative Projects for a total of ¥9M, depending on the quality of the submissions and the availability of funds.

Upon conclusion of the review process, meritorious proposals may be recommended for funding by either NSF, NIH, or USDA, at the option of the agencies, not the proposing organizations. Proposals selected for funding by NIH or USDA will need to be reformatted and resubmitted to that agency. Subsequent submission and grant administration procedures will be in accordance with the individual policies of the awarding agency. Further information will be provided to these applicants after selection.

Proposals selected for funding consideration by the NIH will be invited to resubmit to the Division of Receipt and Referral (DRR) in NIH's Center for Scientific Review (CSR) (see Section VI.B). PIs submitting to the NIH must be registered in eRA Commons and the applicant's organization must be registered with SAM, Grants.gov and eRA Commons. PIs should therefore ensure that all registrations required for NIH submission are in place before the NIH receipt deadline.

USDA/NIFA Legislative Authority: The USDA authority for this RFA is contained in Section 7406 of the Food, Conservation, and Energy Act of 2008 (FCEA) (Pub. L. 110-246) which amends section 2(b) of the Competitive, Special, and Facilities Research Grant Act (7 U.S.C. 450i(b)) to authorize the Secretary of Agriculture to establish the Agriculture and Food Research Initiative (AFRI); a new competitive grant program to provide funding for fundamental and applied research, extension, and education to address food and agricultural sciences. AFRI is subject to the provision found at 7 CFR Part 3430.

For US-UK, US-UK-Israel, or US-UK-China Collaborative Projects, the UK component of the collaboration will be awarded through the UKRI in accordance with its policies. If the UKRI selects an application for funding, the applicant will be required to submit the costs for the UK element of the proposal via the Je-S application submission system before final sign-off. UK collaborators should therefore ensure they are registered Je-S users before the proposal is submitted.

For US-Israel, US-Israel-UK, or US-Israel-China Collaborative Projects, the Israeli component of the collaboration will be awarded through the BSF in accordance with its policies and regulations. The collaborative proposal must be submitted to the BSF by the Israeli scientist by the BSF-established deadline.

For US-China, US-China-UK, or US-China-Israel Collaborative Projects, the Chinese component of the collaboration will be awarded through the NSFC in accordance with its policies and regulations. The collaborative proposal must be submitted to the NSFC application submission system by the Chinese scientists by the NSFC-established deadline.

IV. ELIGIBILITY INFORMATION

Who May Submit Proposals:

The categories of proposers eligible to submit proposals to the National Science Foundation are identified in the *NSF Proposal & Award Policies & Procedures Guide* (PAPPG), Chapter I.E. Unaffiliated individuals are not eligible to submit proposals in response to this solicitation.

Who May Serve as PI:

There are no restrictions or limits.

Limit on Number of Proposals per Organization:

There are no restrictions or limits.

Limit on Number of Proposals per PI or Co-PI: 2

In a given year, an individual may participate as a PI, co-PI, or subaward lead on no more than **two** proposals submitted in response to this solicitation. **This limit does not include Research Coordination Networks (RCN) proposals.** In addition, an individual from Israel may participate in no more than **one** US-BSF proposal and an individual from China may participate in no more than **one** US-China proposal. Proposals in excess of the limit for any person will be returned without review in the reverse order received. Participating in a proposal as other senior personnel does not count in this limit. Changes in investigator roles post-submission to meet the eligibility limits will not be allowed. **It is the responsibility of the submitters to confirm that the entire team is within the eligibility guidelines.**

Additional Eligibility Info:

NIH Eligibility: Clinical trials are not allowed. The NIH will only consider applications that do not propose clinical trials. Individuals who are considering submitting a proposal in response to this solicitation should review https://grants.nih.gov/ct-decision/ in determining whether the project meets the NIH definition of a Clinical Trial. Institutions eligible for awards by the NIH's Fogarty International Center (FIC) include foreign institutions in low- and middle-income countries (LMICs), as defined by the World Bank (foreign institutions in high-income countries are not eligible for FIC awards).

USDA/NIFA Eligibility: Eligible entities for award include, (1) State agricultural experiment stations; (2) colleges and universities (including junior colleges offering associate degrees or higher); (3) university research foundations; (4) other research institutions and organizations; (5) Federal agencies, (6) national laboratories; (7) private organizations or corporations; (8) individuals who are U.S. citizens, nations, or permanent residents; and (9) any group consisting of 2 or more entities identified in (1) through (8). Eligible institutions do not include foreign and international organizations.

V. PROPOSAL PREPARATION AND SUBMISSION INSTRUCTIONS

A. Proposal Preparation Instructions

Full Proposal Preparation Instructions: Proposers may opt to submit proposals in response to this Program Solicitation via FastLane, Research.gov, or Grants.gov.

- Full proposals submitted via FastLane: Proposals submitted in response to this program solicitation should be prepared and submitted in accordance with the general guidelines contained in the *NSF Proposal & Award Policies & Procedures Guide* (PAPPG). The complete text of the PAPPG is available electronically on the NSF website at: https://www.nsf.gov/publications/pub_summ.jsp?ods_key=pappg. Paper copies of the PAPPG may be obtained from the NSF Publications Clearinghouse, telephone (703) 292-8134 or by e-mail from nsfpubs@nsf.gov. Proposers are reminded to identify this program solicitation number in the program solicitation block on the NSF Cover Sheet For Proposal to the National Science Foundation. Compliance with this requirement is critical to determining the relevant proposal processing guidelines. Failure to submit this information may delay processing.
- Full Proposals submitted via Research.gov: Proposals submitted in response to this program solicitation should be prepared and submitted in accordance with the general guidelines contained in the *NSF Proposal and Award Policies and Procedures Guide* (PAPPG). The complete text of the PAPPG is available electronically on the NSF website at: https://www.nsf.gov/publications/pub_summ.jsp?ods_key=pappg. Paper copies of the PAPPG may be obtained from the NSF Publications Clearinghouse, telephone (703) 292-8134 or by e-mail from nsfpubs@nsf.gov. The Prepare New Proposal setup will prompt you for the program solicitation number.
- Full proposals submitted via Grants.gov: Proposals submitted in response to this program solicitation via Grants.gov should be prepared and submitted in accordance with the *NSF Grants.gov Application Guide: A Guide for the Preparation and Submission of NSF Applications via Grants.gov*. The complete text of the *NSF Grants.gov Application Guide* is available on the Grants.gov website and on the NSF website at: (https://www.nsf.gov/publications/pub_summ.jsp?ods_key=grantsgovguide). To obtain copies of the Application Guide and Application Forms Package, click on the Apply tab on the Grants.gov site, then click on the Apply Step 1: Download a Grant Application Package and Application Instructions link and enter the funding opportunity number, (the program solicitation number without the NSF prefix) and press the Download Package button. Paper copies of the Grants.gov Application Guide also may be obtained from the NSF Publications Clearinghouse, telephone (703) 292-8134 or by e-mail from nsfpubs@nsf.gov.

See PAPPG Chapter II.C.2 for guidance on the required sections of a full research proposal submitted to NSF. Please note that the proposal preparation instructions provided in this program solicitation may deviate from the PAPPG instructions.

Special Information and Supplementary Documentation:

Proposals Involving Multiple Institutions. Of the two types of collaborative proposal formats described in the Proposal & Award Policies & Procedures Guide, this solicitation allows only a single proposal submission with subawards administered by that lead organization. In the case of proposals involving multiple organizations, a single organization **must** be identified as the lead, and **a single proposal** describing the entire project must be submitted by that organization. Funds may be distributed among partner organizations via subawards from the lead organization. A budget utilizing the standard NSF budget format should be submitted for each subawardee. The requirement for a single organization to submit the sole proposal for a project is designed to facilitate effective coordination among participating organizations and to avoid difficulties that ensue in funded projects when individuals change organizations and/or cease to fulfill project responsibilities.

- **Research Experiences for Undergraduates**. Funds to support Research Experiences for Undergraduates (REUs) should be included in the original proposal. A limited number of post-award supplements may be available if such activities were unforeseen at the time of submission and the request broadens participation in STEM fields. Eligibility for post-award educational supplements for REU, RET, RAHSS, and ROA projects is described on the DEB supplement request website: https://www.nsf.gov/bio/deb/suppopp.jsp. **Submission Guidance:** The descriptions of proposed REU activities should be included in the Supplementary Documents. For REUs, follow the guidelines for "REU supplement requests as part of a proposal" in the REU solicitation. REU projects must involve students in meaningful ways in ongoing research programs or in research projects specifically designed for the REU student. If the intent is to engage students as technicians, then an REU is not the appropriate support mechanism; instead, salary support should be entered on the Undergraduate Students line of the proposal budget. The description of these activities is limited to 3 pages. If multiple institutions on a collaborative proposal are requesting funds for REUs, all REU activities should be included in one supplementary document, limited to 3 pages. All person related costs, including stipends and/or travel should be placed in Participant Support Costs on the budget. A detailed breakdown of the budget must be included in the budget justification. Budgets for REUs are generally $6,000-8,000 per student.

- **Senior Personnel List Spreadsheet.** An additional spreadsheet listing all senior personnel involved in the project **must** be submitted. This spreadsheet is separate from the spreadsheet that lists collaborators and other affiliations (COA) information. The spreadsheet template can be found at https://www.nsf.gov/bio/deb/debpersonnellist.xlsx. Please read the instructions carefully. Using the template, compile an Excel file that provides information for all persons identified in the proposal as: "PI or co-PI" (i.e., those listed on the Cover Sheet); "Other Senior Personnel/Subawardee"; or "Other Personnel" who have a biographical sketch included in the proposal, including all international collaborators. Only one spreadsheet should be submitted per project. The file **must** include the FastLane proposal ID assigned after submission of your proposal (i.e., not the Temporary ID # or Grants.gov ID #). Once completed, the file should be submitted by email to debtemplate@nsf.gov within one business day of proposal submission.

- **Data Management Plan.** The PAPPG (II.C.2.j) requires the inclusion of a Data Management Plan (DMP) with all full proposal submissions. The DMP can be no longer than two pages and must be inclusive of the entire project. It must include two sections: (1) *Data Plans*, and (2) *Intellectual Property Plans*. Those sections should address the following points:

    1. *Data Plans*. All projects must ensure that data and biological materials are collected, archived, digitized, and made available using methods that allow current and future investigators to access data and material. Funded projects must disseminate project data broadly in a timely and responsible manner, using widely accepted electronic data standards, a named community-accepted, publicly-accessible data repository and with as few restrictions as possible. Data and digital products should be identified, and the following described for *each* of them:
        - Format and standard of primary data;
        - Metadata to be collected and disseminated with the primary data;
        - Timetable of release of ALL data, consistent with privacy and other concerns regarding sensitive information;
        - Public repository to be used;
        - License for use, with an emphasis on open source licenses such as MIT and GPL;
        - Any constraints on release, which must be clearly justified; and
        - Person(s) responsible for the release.

        All software and code must be in a versioned code repository (e.g., GitHub, BitBucket). We strongly encourage release of ready-to-use software and code through integration with computing resources (e.g., Galaxy, CyVerse), in Virtual Machines (e.g., AWS, JetStream), and/or in Containers (e.g., Docker/DockerHub). Published results should always include information on how to access the supporting data.

        Additional guidance about the development of Data Management plans, including domain-specific guidance, is provided by the Directorate for Biological Sciences, the Directorate for Social, Behavioral and Economic Sciences, the Division of Ocean Sciences, and the UKRI.

    2. *Intellectual Property Plans*. The DMP MUST provide a protocol and timeline for the development of intellectual property agreements. The agreement should indicate:
        - Who are the owners of any data or other intellectual property;
        - How financial benefits of the intellectual property will be allocated;
        - How authorship of publications will be determined; and
        - How IP disputes will be adjudicated.

    A reasonable charge for community resources is permissible, but the fee structure must be outlined clearly in the IP plan. If a Material Transfer Agreement is required, the terms must be described in detail. No reach-through rights are allowed. Data or materials resulting from NSF-funded research obtained with proprietary materials must be readily available without any restrictions to the users. For this reason, the terms of any usage agreements should be stated clearly in the IP plan.

    For multi-institutional projects, the lead institution is responsible for coordinating and managing the intellectual property resulting from the award. A complete IP agreement MUST be included with the first annual report of the project.

    - **Letters of Collaboration.** Supplementary Documents may include letters of collaboration from individuals or organizations that are integral parts of the proposed project but are not listed as PI, co-PI, or other senior personnel on the main proposal or any subaward. Such involvement may include subsidiary involvement in some aspect of the project, cooperation on outreach efforts, or documentation of permission to access materials or data. Letters of collaboration should focus solely on affirming that the individual or organization is willing to collaborate on the project as specified in the project description. No additional text, especially elaboration of the nature of activities to be undertaken by the collaborator and endorsements of the potential value or significance of the project for the collaborator, may be included. The template that **must** be used for the preparation of letters of collaboration is provided below.

    Letters of collaboration should not be provided from any individual designated as a principal investigator or a senior personnel, nor are letters of collaboration required from any organization that will be a subawardee in the proposal budget.

    Each letter of collaboration **must** be signed by the designated collaborator. Requests to collaborators for letters of collaboration should be made by the PI well in advance of the proposal submission deadline, because they **must** be included at the time of proposal submission. **Letters deviating from**

this template will not be accepted and may be grounds for returning the proposal without review.

Template to be used for letters of collaboration

To: NSF _____(*Program Title*)_____ Program

From: _____

(*Printed name of the individual collaborator or name of the organization and name and position of the official submitting this memo*)

By signing below (or transmitting electronically), I acknowledge that I am listed as a collaborator on this proposal, entitled "_____(*proposal title*)_____," with _____(*PI name*)_____ as the Principal Investigator. I agree to undertake the tasks assigned to me or my organization, as described in the project description of the proposal, and I commit to provide or make available the resources specified therein.

Signed: _____

Organization: _____

Date: _____

Research Coordination Network proposals

These proposals should begin the title with "**RCN:**" and follow the proposal preparation instructions in the RCN solicitation (https://www.nsf.gov/funding/pgm_summ.jsp?pims_id=11691&org=BIO&from=home).

US-UK Collaborative proposals

For full application: These proposals should begin the title with "**US-UK Collab:**". Collaborative RCN proposals should begin the title with "**US-UK Collab: RCN**:" Information for the UK portion of US-UK Collaborative Proposals should be included as Supplementary Documents or as a single copy document as specified below. That information should include the following, and only the following:

1. Biographical sketches of UK senior personnel: Those biographical sketches must conform to NSF format and limitations.

2. UK budget: Costs for the UK component of the project should be entered onto the Je-S system but the completed form **SHOULD NOT** be submitted electronically to the UKRI at this stage. Instead, a PDF version of the form should be saved and sent to the US lead PI for inclusion as a supplementary document in the proposal. Also, an electronic copy of this document should be sent to UKRI Cognizant Programme Officer no later than the NSF submission deadline. Full details on what is required can be obtained at (http://www.bbsrc.ac.uk/eeid). Applicants should ensure that they contact the main UK Cognizant Programme Officer at UKRI to discuss the remit of their proposal and to confirm whether they should complete a Je-S form. The researchers will be asked to attend a meeting to be held at either the National Science Foundation or an alternate location. Include the necessary travel costs for attendance at the meeting in the proposed budget.

3. Letters of collaboration: Letters of collaboration from UK scientists are required. These letters must be restricted to a statement of intent to collaborate only as described above. Additional information on the nature of the collaboration and the roles of the investigators should be included in the Project Description.

4. Institutional endorsement: An institutional certification of the submission must be a signed letter from an authorized U.K. institutional representative and included in supplemental documents with the following text:

"I confirm on behalf of [*insert name of institution*] that the U.S.-U.K.Collaborative proposal between [*insert name of US PI and institution*] and [*insert name of UK PI*] is endorsed and has been submitted by [*name of Research Office*]."

5. Sharing of unattributed reviews: Unattributed reviews will be shared with UKRI. The following text must be included in a **Single Copy Document** and signed by the lead US investigator, confirming that the investigators involved in the proposal acknowledge and confirm this fact.

On behalf of the proposal investigators, I, _____ (*insert US Lead PI Name*), consent that the proposal as well as its unattributed reviews will be shared with the EEID partner-funding agencies.

Signed: _____

Organization: _____

Date: _____

6. Collaborators and other affiliations. A COA document must be submitted for each senior personnel for whom a biographical sketch is included.

US-Israel Collaborative proposals

These proposals should begin the title with "**US-Israel Collab**:". Information for the Israel portion of the US-Israel Collaborative Proposals should be included as Supplementary Documents or as a single copy document as specified below. That information should include the following, and only the following:

1. Biographical sketches of Israeli PIs: Those biographical sketches must conform to NSF format and limitations.

2. Israeli budget: Costs for the Israeli component should be copied from the BSF submission of the proposal using the BSF format: http://www.bsf.org.il/data/FormsToDownload/BSF-NSF_EEID_Program_Call_for_Proposal.pdf

3. Letters of collaboration: Letters of collaboration from scientists on the Israeli component are required. These letters must be restricted to a statement of intent to collaborate only as described above. Additional information on the nature of the collaboration and the roles of the investigators should be included in the Project Description.

4. Institutional endorsement: An institutional certification of the submission must be a signed letter from an authorized Israeli institutional

representative and included in supplemental documents with the following text:

"I confirm on behalf of [*insert name of institution*] that the U.S.-Israel Collaborative proposal between [*insert name of US PI and institution*] and [*insert name of Israeli PI*] is endorsed and has been submitted by [*name of Research Office*]."

5. Sharing of unattributed reviews: Unattributed reviews will be shared with the BSF. The following text must be included in a**Single Copy Document** and signed by the lead US investigator, confirming that the investigators involved in the proposal acknowledge and confirm this fact.

On behalf of the proposal investigators, I, _____ (*insert US Lead PI Name)*, consent that the proposal as well as its unattributed reviews will be shared with the EEID partner-funding agencies.

Signed: _____

Organization: _____

Date: _____

6. Collaborators and other affiliations. A COA document must be submitted for each senior personnel for whom a biographical sketch is included.

Full proposals that include an Israeli collaboration must be also submitted to the BSF by the Israeli partner, using the BSF submission system: http://www.bsf.org.il/ElectronicSubmission/GatewayFormsAndGuidelines.aspx?PageId=7&innerTextID=0 Additional information can be found at: http://www.bsf.org.il/data/FormsToDownload/BSF-NSF_Ecology_and_Evolution_Infectious_Diseases_Program_Call_for_Proposal.pdf

US-UK-Israel Collaborative proposals

These proposals should begin the title with '**US-UK-Israel Collab:**". Information for the UK and Israel portion should be included as Supplementary Documents as described above.

US-China Collaborative proposals

These proposals should begin the title with '**US-China Collab**:". Collaborative RCN proposals should begin the title with '**US-China Collab: RCN**:" Information for the China portion of the US-China Collaborative Proposals should be included as Supplementary Documents or as a single copy document as specified below. That information should include the following, and only the following:

1. Biographical sketches of Chinese PIs: Those biographical sketches must conform to NSF format and limitations.

2. Chinese budget: Costs for the Chinese component should be copied from the Chinese submission of the proposal using the NSFC format.

3. Letters of collaboration: Letters of collaboration from scientists on the Chinese component are required. These letters must be restricted to a statement of intent to collaborate only as described above. Additional information on the nature of the collaboration and the roles of the investigators should be included in the Project Description.

4. Sharing of unattributed reviews: Unattributed reviews will be shared with the NSFC. The following text must be included in a**Single Copy Document** and signed by the lead US investigator, confirming that the investigators involved in the proposal acknowledge and confirm this fact.

On behalf of the proposal investigators, I, (*insert US Lead PI Name*), consent that the proposal as well as its unattributed reviews will be shared with the EEID partner-funding agencies.

Signed: _____

Organization: _____

Date: _____

5. Collaborators and other affiliations. A COA document must be submitted for each senior personnel for whom a biographical sketch is included.

Full proposals that include an Chinese collaboration must be also submitted to the NSFC by the Chinese partner as supplementary documents, including the Letters of Collaboration, to their online applications, using the NSFC application submission system: http://isisn.nsfc.gov.cn/egrantweb/

US-UK-China Collaborative proposals

These proposals should begin the title with '**US-UK-China Collab:**". Collaborative RCN proposals should begin the title with '**US-UK-China Collab: RCN**:" Information for the UK and China portion should be included as Supplementary Documents as described above.

US-China-Israel Collaborative proposals

These proposals should begin the title with '**US-China-Israel Collab:**". Information for the China and Israel portion should be included as Supplementary Documents as described above.

B. Budgetary Information

Cost Sharing:

Inclusion of voluntary committed cost sharing is prohibited.

Other Budgetary Limitations:

EEID projects must have a minimum budget of $1,500,000 in total project costs for all years, except that US-UK Collaborative, US-Israel, and US-China Collaborative projects must have a minimum budget of $1,000,000 in total project costs for all years. Research that falls within the scope of the EEID initiative

but with project aims that do not require budgets of this magnitude should be directed to the appropriate core program.

Budget Preparation Instructions:

Subawards

In accordance with the applicable award terms and conditions, proposers are reminded of their responsibilities with regard to subawardees. Should an award be made, the primary awardee is responsible for ensuring compliance with the appropriate terms and conditions to, as well as the management and oversight of, any subawardees on the project, including any foreign subawardees.

C. Due Dates

- **Full Proposal Deadline(s)** (due by 5 p.m. submitter's local time):

  November 18, 2020

  Third Wednesday in November, Annually Thereafter

D. FastLane/Research.gov/Grants.gov Requirements

For Proposals Submitted Via FastLane or Research.gov:

To prepare and submit a proposal via FastLane, see detailed technical instructions available at: https://www.fastlane.nsf.gov/a1/newstan.htm. To prepare and submit a proposal via Research.gov, see detailed technical instructions available at: https://www.research.gov/research-portal/appmanager/base/desktop?_nfpb=true&_pageLabel=research_node_display&_nodePath=/researchGov/Service/Desktop/ProposalPreparationandSubmission.html. For FastLane or Research.gov user support, call the FastLane and Research.gov Help Desk at 1-800-673-6188 or e-mail fastlane@nsf.gov or rgov@nsf.gov. The FastLane and Research.gov Help Desk answers general technical questions related to the use of the FastLane and Research.gov systems. Specific questions related to this program solicitation should be referred to the NSF program staff contact(s) listed in Section VIII of this funding opportunity.

For Proposals Submitted Via Grants.gov:

Before using Grants.gov for the first time, each organization must register to create an institutional profile. Once registered, the applicant's organization can then apply for any federal grant on the Grants.gov website. Comprehensive information about using Grants.gov is available on the Grants.gov Applicant Resources webpage: https://www.grants.gov/web/grants/applicants.html. In addition, the NSF Grants.gov Application Guide (see link in Section V.A) provides instructions regarding the technical preparation of proposals via Grants.gov. For Grants.gov user support, contact the Grants.gov Contact Center at 1-800-518-4726 or by email: support@grants.gov. The Grants.gov Contact Center answers general technical questions related to the use of Grants.gov. Specific questions related to this program solicitation should be referred to the NSF program staff contact(s) listed in Section VIII of this solicitation.

Submitting the Proposal: Once all documents have been completed, the Authorized Organizational Representative (AOR) must submit the application to Grants.gov and verify the desired funding opportunity and agency to which the application is submitted. The AOR must then sign and submit the application to Grants.gov. The completed application will be transferred to the NSF FastLane system for further processing.

Proposers that submitted via FastLane or Research.gov may use Research.gov to verify the status of their submission to NSF. For proposers that submitted via Grants.gov, until an application has been received and validated by NSF, the Authorized Organizational Representative may check the status of an application on Grants.gov. After proposers have received an e-mail notification from NSF, Research.gov should be used to check the status of an application.

VI. NSF PROPOSAL PROCESSING AND REVIEW PROCEDURES

Proposals received by NSF are assigned to the appropriate NSF program for acknowledgement and, if they meet NSF requirements, for review. All proposals are carefully reviewed by a scientist, engineer, or educator serving as an NSF Program Officer, and usually by three to ten other persons outside NSF either as *ad hoc* reviewers, panelists, or both, who are experts in the particular fields represented by the proposal. These reviewers are selected by Program Officers charged with oversight of the review process. Proposers are invited to suggest names of persons they believe are especially well qualified to review the proposal and/or persons they would prefer not review the proposal. These suggestions may serve as one source in the reviewer selection process at the Program Officer's discretion. Submission of such names, however, is optional. Care is taken to ensure that reviewers have no conflicts of interest with the proposal. In addition, Program Officers may obtain comments from site visits before recommending final action on proposals. Senior NSF staff further review recommendations for awards. A flowchart that depicts the entire NSF proposal and award process (and associated timeline) is included in PAPPG Exhibit III-1.

A comprehensive description of the Foundation's merit review process is available on the NSF website at: https://www.nsf.gov/bfa/dias/policy/merit_review/.

Proposers should also be aware of core strategies that are essential to the fulfillment of NSF's mission, as articulated in *Building the Future: Investing in Discovery and Innovation - NSF Strategic Plan for Fiscal Years (FY) 2018 – 2022* These strategies are integrated in the program planning and implementation process, of which proposal review is one part. NSF's mission is particularly well-implemented through the integration of research and education and broadening participation in NSF programs, projects, and activities.

One of the strategic objectives in support of NSF's mission is to foster integration of research and education through the programs, projects, and activities it supports at academic and research institutions. These institutions must recruit, train, and prepare a diverse STEM workforce to advance the frontiers of science and participate in the U.S. technology-based economy. NSF's contribution to the national innovation ecosystem is to provide cutting-edge research under the guidance of the Nation's most creative scientists and engineers. NSF also supports development of a strong science, technology, engineering, and mathematics (STEM) workforce by investing in building the knowledge that informs improvements in STEM teaching and learning.

NSF's mission calls for the broadening of opportunities and expanding participation of groups, institutions, and geographic regions that are underrepresented in STEM disciplines, which is essential to the health and vitality of science and engineering. NSF is committed to this principle of diversity and deems it central to the programs, projects, and activities it considers and supports.

A. Merit Review Principles and Criteria

The National Science Foundation strives to invest in a robust and diverse portfolio of projects that creates new knowledge and enables breakthroughs in understanding across all areas of science and engineering research and education. To identify which projects to support, NSF relies on a merit review process that incorporates consideration of both the technical aspects of a proposed project and its potential to contribute more broadly to advancing NSF's mission "to promote the progress of science; to advance the national health, prosperity, and welfare; to secure the national defense; and for other purposes." NSF makes every effort to conduct a fair, competitive, transparent merit review process for the selection of projects.

1. Merit Review Principles

These principles are to be given due diligence by PIs and organizations when preparing proposals and managing projects, by reviewers when reading and evaluating proposals, and by NSF program staff when determining whether or not to recommend proposals for funding and while overseeing awards. Given that NSF is the primary federal agency charged with nurturing and supporting excellence in basic research and education, the following three principles apply:

- All NSF projects should be of the highest quality and have the potential to advance, if not transform, the frontiers of knowledge.
- NSF projects, in the aggregate, should contribute more broadly to achieving societal goals. These "Broader Impacts" may be accomplished through the research itself, through activities that are directly related to specific research projects, or through activities that are supported by, but are complementary to, the project. The project activities may be based on previously established and/or innovative methods and approaches, but in either case must be well justified.
- Meaningful assessment and evaluation of NSF funded projects should be based on appropriate metrics, keeping in mind the likely correlation between the effect of broader impacts and the resources provided to implement projects. If the size of the activity is limited, evaluation of that activity in isolation is not likely to be meaningful. Thus, assessing the effectiveness of these activities may best be done at a higher, more aggregated, level than the individual project.

With respect to the third principle, even if assessment of Broader Impacts outcomes for particular projects is done at an aggregated level, PIs are expected to be accountable for carrying out the activities described in the funded project. Thus, individual projects should include clearly stated goals, specific descriptions of the activities that the PI intends to do, and a plan in place to document the outputs of those activities.

These three merit review principles provide the basis for the merit review criteria, as well as a context within which the users of the criteria can better understand their intent.

2. Merit Review Criteria

All NSF proposals are evaluated through use of the two National Science Board approved merit review criteria. In some instances, however, NSF will employ additional criteria as required to highlight the specific objectives of certain programs and activities.

The two merit review criteria are listed below. **Both** criteria are to be given **full consideration** during the review and decision-making processes; each criterion is necessary but neither, by itself, is sufficient. Therefore, proposers must fully address both criteria. (PAPPG Chapter II.C.2.d(i). contains additional information for use by proposers in development of the Project Description section of the proposal). Reviewers are strongly encouraged to review the criteria, including PAPPG Chapter II.C.2.d(i), prior to the review of a proposal.

When evaluating NSF proposals, reviewers will be asked to consider what the proposers want to do, why they want to do it, how they plan to do it, how they will know if they succeed, and what benefits could accrue if the project is successful. These issues apply both to the technical aspects of the proposal and the way in which the project may make broader contributions. To that end, reviewers will be asked to evaluate all proposals against two criteria:

- **Intellectual Merit:** The Intellectual Merit criterion encompasses the potential to advance knowledge; and
- **Broader Impacts:** The Broader Impacts criterion encompasses the potential to benefit society and contribute to the achievement of specific, desired societal outcomes.

The following elements should be considered in the review for both criteria:

1. What is the potential for the proposed activity to
    a. Advance knowledge and understanding within its own field or across different fields (Intellectual Merit); and
    b. Benefit society or advance desired societal outcomes (Broader Impacts)?
2. To what extent do the proposed activities suggest and explore creative, original, or potentially transformative concepts?
3. Is the plan for carrying out the proposed activities well-reasoned, well-organized, and based on a sound rationale? Does the plan incorporate a mechanism to assess success?
4. How well qualified is the individual, team, or organization to conduct the proposed activities?
5. Are there adequate resources available to the PI (either at the home organization or through collaborations) to carry out the proposed activities?

Broader impacts may be accomplished through the research itself, through the activities that are directly related to specific research projects, or through activities that are supported by, but are complementary to, the project. NSF values the advancement of scientific knowledge and activities that contribute to achievement of societally relevant outcomes. Such outcomes include, but are not limited to: full participation of women, persons with disabilities, and underrepresented minorities in science, technology, engineering, and mathematics (STEM); improved STEM education and educator development at any level; increased public scientific literacy and public engagement with science and technology; improved well-being of individuals in society; development of a diverse, globally competitive STEM workforce; increased partnerships between academia, industry, and others; improved national security; increased economic competitiveness of the United States; and enhanced infrastructure for research and education.

Proposers are reminded that reviewers will also be asked to review the Data Management Plan and the Postdoctoral Researcher Mentoring Plan, as appropriate.

Additional Solicitation Specific Review Criteria

Reviewers may be requested to provide numeric NIH overall impact scores from 1 (highest) to 9 (lowest) based upon their evaluations of the intellectual merits and broader impacts of the applications.

Overall Impact is the likelihood for the project to exert a sustained, powerful influence on the research field(s) involved and is based on the following five core review criteria and relevant additional review criteria. An application does not need to be strong in all categories to be judged likely to have major scientific impact.

The five core review criteria for NIH are:

- **Significance.** Does the applicant discuss the strengths and weaknesses of the rigor of the prior research used to support the proposed project?(Rigor of the prior research, which includes preliminary and published results, concerns the quality and strength of the research being cited by the applicant as crucial to support the application; this is distinct from the hypothesis or justification.) How will the proposed research address weaknesses, gaps, important problems, or critical barriers to progress in the field? If the project aims are achieved, how will scientific knowledge, technical capability, and/or clinical practice be improved? Will successful completion of the aims change the concepts, methods, treatments, technologies, services, or preventative interventions that drive this field?
- **Investigator(s)**. Are the principal investigator (PI), project director (PD), collaborators, and other researchers well suited to the project? For those in the early stages of independent careers, do they have appropriate experience and training? For more established investigators, have they demonstrated an ongoing record of accomplishments that have advanced their field(s)? If the project is collaborative or multi-PD/PI, do the investigators have complementary and integrated expertise; are their leadership approach, governance, and organizational structure appropriate for the project?
- **Innovation**. Does the application challenge and seek to shift current research or clinical practice paradigms by utilizing novel theoretical concepts, approaches or methodologies, instrumentation, or interventions? Are the concepts, approaches or methodologies, instrumentation, or interventions novel to one field of research or novel in a broad sense? Is a refinement, improvement, or new application of theoretical concepts, approaches or methodologies, instrumentation, or interventions proposed?
- **Approach**. Are the overall strategy, methodology, and analyses well-reasoned, appropriate, and supported by rigor in the prior research to accomplish the project's specific aims? Is there scientific rigor in the proposed study? (Scientific rigor is defined as the strict application of the scientific method to ensure robust and unbiased experimental design, methodology, analysis, interpretation, and reporting of results.) Are potential problems, alternative strategies, and benchmarks for success presented? If the project is in the early stages of development, will the strategy establish feasibility, and will particularly risky aspects be managed? Have the investigators presented adequate plans to address relevant biological variables (e.g. sex, age, weight, health condition, human ethnicity, animal species and strains, etc.) for studies in vertebrate animals or human subjects? If the project involves human subjects, are there plans for the protection of human subjects from research risks, and the inclusion (or exclusion) of individuals on the basis of sex/gender, race, and ethnicity, as well as the inclusion (or exclusion) of individuals of all ages (including children and older adults), justified in terms of the scientific goals and research strategy proposed?
- **Environment**. Will the scientific environment in which the work will be done contribute to the probability of success? Are the institutional support, equipment, and other physical resources available to the investigators adequate for the project proposed? Will the project benefit from unique features of the scientific environment, subject populations, or collaborative arrangements?

As relevant to the proposed project, the following additional review criteria will be addressed and considered in the determination of scientific merit and rating as part of the Overall Impact score.

- **Protections for Human Subjects.** To be considered human subjects research, the participating individuals must be living and identifiable, and the data and/or specimens are specifically obtained for the proposed research. For research that involves human subjects but does not involve one of the categories of research that are exempt under 45 CFR Part 46.104, the committee will evaluate the justification for involvement of human subjects and the proposed protections from research risk relating to their participation according to the following review criteria: 1) risk to subjects, 2) adequacy of protection against risks, 3) potential benefits to the subjects and others, and 4) importance of the knowledge to be gained. For research that involves human subjects and meets the criteria for one or more of the eight categories of research that are exempt under 45 CFR Part 46.104, the committee will evaluate: 1) the justification for the exemption, 2) human subjects involvement and characteristics, and 3) sources of materials.
- **Inclusion of Women, Minorities, and Individuals Across the Lifespan**. When the proposed project involves human subjects and/or NIH-defined clinical research, the committee will evaluate the proposed plans for the inclusion (or exclusion) of individuals on the basis of sex/gender, race/ethnicity or if non-US residents, as well as the inclusion (or exclusion) of individuals of all ages including children (under 18 years old), adults (18 to 64 years old) and older adults (over 64 years old) to determine if it is justified in terms of the scientific goals and research strategy proposed.
- **Vertebrate Animals**. The committee will evaluate the involvement of live vertebrate animals as part of the scientific assessment according to the following criteria: (1) a concise description of proposed procedures involving animals, including identifying the species, strains, ages, sex, and total number to be used and if involved, the sources of dogs or cats; (2) the justifications that the species are appropriate for the proposed research and explaining why the research goals cannot be accomplished using an alternative model (e.g., computational, human, invertebrate, in vitro); (3) the interventions to minimize discomfort, distress, pain and injury; and (4) the justification for euthanasia method if NOT consistent with the American Veterinary Medical Association Guidelines for the Euthanasia of Animals. Reviewers will assess the use of chimpanzees as they would any other application proposing the use of vertebrate animals.
- **Biohazards**. Reviewers will identify potential biohazards (biological organisms or their products, such as toxins, that pose a threat to human health) and other hazards (such as radioactivity, dangerous chemicals, or recombinant DNA) that are known in their professional community to pose a particularly significant risk to research personnel and/or the environment. Reviewers will assess whether materials or procedures proposed are potentially hazardous to research personnel and/or the environment, and if needed, determine whether adequate protection is proposed.

As applicable for the proposed project, reviewers will address each of the following review considerations, but will not consider them in providing an NIH Overall Impact score.

- **Applications from Foreign Organizations.** If the organization of the contact principal investigator/project director is not US-based, reviewers will assess whether the project presents special opportunities for furthering research programs through the use of unusual talent, resources, populations, or environmental conditions that exist in other countries and either are not readily available in the United States or augment existing U.S. resources.
- **Select Agent Research.** If the study involves a Select Agent (refer to Ecology and Evolution of Infectious Diseases (EEID) (http://www.selectagents.gov/SelectAgentsandToxinsList.html), reviewers will assess the information provided in this section of the application, including 1) the identification of the Select Agent(s) to be used in the proposed research, 2) the registration status of all entities where the Select Agent(s) will be used, 3) the procedures that will be used to monitor possession use and transfer of Select Agent(s), and 4) plans for appropriate biosafety, biocontainment, and security of the Select Agent(s).
- **Budget and Period of Support**. Reviewers will consider whether the budget and the requested period of support are fully justified and reasonable in relation to the proposed research.

International Collaborations and Expenditures

For all proposals involving international collaborations, reviewers will consider: mutual benefits, true intellectual collaboration with the foreign partner(s), benefits

to be realized from the expertise and specialized skills, facilities, sites and/or resources of the international counterpart, and active research engagement of U.S. students and early-career researchers, where such individuals are engaged in the research. Furthermore, the justification for funding for an international branch campus of a US IHE, or involvement of a foreign organization (e.g., through use of subawards or consultant arrangements), as described in PAPPG Chapter I.E, will be specifically reviewed to assure that conditions for the justification of such expenditures have been met, as detailed inPAPPG Chapter I.E.6.

US-UK, US-Israel and US-China Collaborative Projects will also be reviewed with respect to the extent which they demonstrate a substantial collaboration between the US and foreign partners and enhance research on infectious disease transmission.

B. Review and Selection Process

NSF will manage the review of proposals in consultation with NIH and USDA, and in the case of US-UK, US-Israel or US-China Collaborative Projects, the UKRI, BSF or NSFC, respectively. Copies of proposals and unattributed reviews will be shared with the partner funding organizations, as appropriate. Upon conclusion of the review process, meritorious projects may be recommended for funding by any of the partner funding organizations at the option of the agencies, not the proposing organizations.

Proposals submitted in response to this program solicitation will be reviewed by Ad hoc Review and/or Panel Review.

Reviewers will be asked to evaluate proposals using two National Science Board approved merit review criteria and, if applicable, additional program specific criteria. A summary rating and accompanying narrative will generally be completed and submitted by each reviewer and/or panel. The Program Officer assigned to manage the proposal's review will consider the advice of reviewers and will formulate a recommendation.

NSF Process: Those proposals selected for funding by NSF will be handled in accordance with standard NSF procedures. After scientific, technical and programmatic review and consideration of appropriate factors, the NSF Program Officer recommends to the cognizant Division Director whether the proposal should be declined or recommended for award. NSF is striving to be able to tell applicants whether their proposals have been declined or recommended for funding within six months. The time interval begins on the deadline or target date, or receipt date, whichever is later. The interval ends when the Division Director accepts the Program Officer's recommendation.

A summary rating and accompanying narrative will be completed and submitted by each reviewer. In all cases, reviews are treated as confidential documents. Verbatim copies of reviews, excluding the names of the reviewers, are sent to the Principal Investigator/Project Director by the Program OfficerIn addition, the proposer will receive an explanation of the decision to award or decline funding.

In all cases, after programmatic approval has been obtained, the proposals recommended for funding will be forwarded to the Division of Grants and Agreements for review of business, financial, and policy implications and the processing and issuance of a grant or other agreement. Proposers are cautioned that only a Grants and Agreements Officer may make commitments, obligations or awards on behalf of NSF or authorize the expenditure of funds. No commitment on the part of NSF should be inferred from technical or budgetary discussions with a NSF Program Officer. A Principal Investigator or organization that makes financial or personnel commitments in the absence of a grant or cooperative agreement signed by the NSF Grants and Agreements Officer does so at their own risk.

NIH Process: Proposals selected for funding consideration by NIH will be invited to submit reformatted applications to the Division of Receipt and Referral (DRR) in NIH's Center for Scientific Review (CSR). A receipt date of approximately March 15 annually is in effect for the NIH formatted applications.Following the initial peer review, recommended applications that have been resubmitted to the NIH are required to go to second level review by the Advisory Council or Advisory Board of the awarding Institute or Center. The following will be considered in making funding decisions:

- Scientific and technical merit of the proposed project as determined by scientific peer review.
- Availability of funds.
- Relevance of the proposed project to program priorities.

Subsequent award processing and grant administration procedures will be in accordance with NIH policies and procedures.

USDA/NIFA Process: Applicants submitting proposals selected for funding by USDA/NIFA will receive specific instructions outlining what additional information is needed in accordance with the policies of the agency. USDA/NIFA will make final funding decisions based on the results of the peer review process. Applications selected for funding by NIFA will be forwarded to the USDA/NIFA Awards Management Division for award processing in accordance with the USDA/NIFA procedures. All proposals selected for funding by USDA/NIFA, in FY 2020 will be limited to 30 percent indirect cost rate. Therefore, the recovery of indirect costs on awards made by NIFA under this program area may not exceed the lesser of the institution's official negotiated indirect cost rate or the equivalent of 30 percent of total Federal funds awarded. If the limitation of indirect costs changes, the applicant will be notified.

US-UK Collaborative Projects: The UK component of the collaboration will be awarded through the UKRI in accordance with the policies of that agency. If the UKRI selects an application for funding, the costs for the UK element of the proposal must be submitted via the UKRI's Je-S application submission system before final sign-off. UK collaborators should therefore ensure they are registered Je-S users before the proposal is submitted.

US-Israel Collaborative Projects: The Israeli component of the collaboration will be awarded through the BSF in accordance with its policies and regulations. The collaborative proposal must also be submitted to the BSF by the Israeli scientists and include the US scientists' information, after being submitted to the NSF.

US-China Collaborative Projects: The Chinese component of the collaboration will be awarded through the NSFC in accordance with its policies and regulations. The collaborative proposal must be submitted by the Chinese scientists to the NSFC as a supplementary document to their online applications by the NSFC-established deadline.

VII. AWARD ADMINISTRATION INFORMATION

A. Notification of the Award

NSF Process: Notification of the award is made to *the submitting organization* by a Grants Officer in the Division of Grants and Agreements. Organizations whose proposals are declined will be advised as promptly as possible by the cognizant NSF Program administering the program. Verbatim copies of reviews, not including the identity of the reviewer, will be provided automatically to the Principal Investigator. (See Section VI.B. for additional information on the review process.)

NIH Process: If the application is under consideration for NIH funding, NIH will request "just-in-time" information from the applicant as described in the NIH Grants Policy Statement.

A formal notification in the form of a Notice of Award (NoA) will be provided to the applicant organization for successful applications. The NoA signed by the grants management officer is the authorizing document and will be sent via email to the grantee's business official.

NIFA Process: Notification of a recommended award is made to the submitting PI by a National Program Leader at NIFA. Verbatim copies of reviews, not including the identity of the reviewers, will be provided to the Principal Investigator at the time of the award recommendation notification.

B. Award Conditions

An NSF award consists of: (1) the award notice, which includes any special provisions applicable to the award and any numbered amendments thereto; (2) the budget, which indicates the amounts, by categories of expense, on which NSF has based its support (or otherwise communicates any specific approvals or disapprovals of proposed expenditures); (3) the proposal referenced in the award notice; (4) the applicable award conditions, such as Grant General Conditions (GC-1)*; or Research Terms and Conditions* and (5) any announcement or other NSF issuance that may be incorporated by reference in the award notice. Cooperative agreements also are administered in accordance with NSF Cooperative Agreement Financial and Administrative Terms and Conditions (CA-FATC) and the applicable Programmatic Terms and Conditions. NSF awards are electronically signed by an NSF Grants and Agreements Officer and transmitted electronically to the organization via e-mail.

*These documents may be accessed electronically on NSF's Website at https://www.nsf.gov/awards/managing/award_conditions.jsp?org=NSF. Paper copies may be obtained from the NSF Publications Clearinghouse, telephone (703) 292-8134 or by e-mail from nsfpubs@nsf.gov.

More comprehensive information on NSF Award Conditions and other important information on the administration of NSF awards is contained in the NSF *Proposal & Award Policies & Procedures Guide* (PAPPG) Chapter VII, available electronically on the NSF Website at https://www.nsf.gov/publications/pub_summ.jsp?ods_key=pappg.

Special Award Conditions:

Proposals funded by NIH:

Selection of an application for award is not an authorization to begin performance. Any costs incurred before receipt of the Notice of Award are at the recipient's risk. These costs may be reimbursed only to the extent considered allowable pre-award costs.

Any application awarded by NIH in response to this solicitation will be subject to the DUNS, CCR Registration, and Transparency Act requirements as noted on the Award Conditions and Information for NIH Grants website.

All NIH grant and cooperative agreement awards include the *NIH Grants Policy Statement* as part of the NoA. For these terms of award, see the NIH Grants Policy Statement Part II: Terms and Conditions of NIH Grant Awards, Subpart A: General and Part II: Terms and Conditions of NIH Grant Awards, Subpart B: Terms and Conditions for Specific Types of Grants, Grantees, and Activities. More information is provided at Award Conditions and Information for NIH Grants.

Proposals funded by USDA/NIFA:

Awards issued as a result of this RFA will have designated the Automated Standard Applications for Payment System (ASAP), operated by the Department of Treasury's Bureau of the Fiscal Service, as the payment system for funds. For more information see https://www.fiscal.treasury.gov/.

Several federal statutes and regulations apply to grant applications considered for review and to project grants awarded under this program. These may include, but are not limited to, the ones listed on the NIFA web page - http://nifa.usda.gov/federal-regulations.

NIFA Federal Assistance Policy Guide—a compendium of basic NIFA policies and procedures that apply to all NIFA awards, unless there are statutory, regulatory, or award-specific requirements to the contrary is available at http://nifa.usda.gov/policy-guide.

Other Requirements

USDA/NIFA:

1. Delegation of Fiscal Responsibility

Unless the terms and conditions of the grant state otherwise, the grantee may not, in whole or in part, delegate or transfer to another person, institution, or organization the responsibility for use or expenditure of grant funds.

2. Changes in Project Plans

The permissible changes by the grantee, PD(s), or other key project personnel in the approved project grant shall be limited to changes in methodology, techniques, or other similar aspects of the project to expedite achievement of the project's approved goals. If the grantee or the PD(s) is uncertain as to whether a change complies with this provision, the question must be referred to the Authorized Departmental Officer (ADO) for a final determination. The ADO is the signatory of the award document, not the program contact.

- Changes in approved goals or objectives shall be requested by the grantee and approved in writing by the ADO prior to effecting such changes. In no event shall requests for such changes be approved which are outside the scope of the original approved project.
- Changes in approved project leadership or the replacement or reassignment of other key project personnel shall be requested by the grantee and approved in writing by the ADO prior to effecting such changes.
- Transfers of actual performance of the substantive programmatic work in whole or in part and provisions for payment of funds, whether or not Federal funds are involved, shall be requested by the grantee and approved in writing by the ADO prior to effecting such transfers, unless prescribed otherwise

in the terms and conditions of the grant.
- Changes in Project Period: The project period may be extended by USDA/NIFA without additional financial support, for such additional period(s) as the ADO determines may be necessary to complete or fulfill the purposes of an approved project, but in no case shall the total project period exceed ten years. Any extension of time shall be conditioned upon prior request by the grantee and approval in writing by the ADO, unless prescribed otherwise in the terms and conditions of a grant.
- Changes in Approved Budget: Changes in an approved budget must be requested by the grantee and approved in writing by the ADO prior to instituting such changes if the revision will involve transfers or expenditures of amounts requiring prior approval as set forth in the applicable Federal cost principles, Departmental regulations, or grant award.

US-UK Collaborative projects:

UKRI Awardees are subject to UKRI reporting and administration requirements as appropriate and outlined in the Research Funding Guide at http://www.bbsrc.ac.uk/funding/apply/grants-guide.aspx. US-UK Collaborative Projects should report on activities of the entire collaborative effort and submit that information to both NSF and UKRI as part of the annual and final reports.

US-Israel Collaborative projects:

BSF Awardees are subject to BSF reporting and administration requirements as appropriate and outlined in the BSF website: http://www.bsf.org.il/BSFPublic/DefaultPage1.aspx?PageId=41&innerTextID=41. US-Israel Collaborative Projects should report on activities of the entire collaborative effort and submit that information to both NSF and BSF as part of the annual and final reports.

US-China Collaborative projects:

NSFC Awardees are subject to NSFC reporting and administration requirements as appropriate and outlined in the NSFC website: http://www.nsfc.gov.cn/publish/portal2/tab193/info24527.htm. US-China Collaborative Projects should report on activities of the entire collaborative effort and submit that information to both NSF and NSFC as part of the annual and final reports.

C. Reporting Requirements

For all multi-year grants (including both standard and continuing grants), the Principal Investigator must submit an annual project report to the cognizant Program Officer no later than 90 days prior to the end of the current budget period. (Some programs or awards require submission of more frequent project reports). No later than 120 days following expiration of a grant, the PI also is required to submit a final project report, and a project outcomes report for the general public.

Failure to provide the required annual or final project reports, or the project outcomes report, will delay NSF review and processing of any future funding increments as well as any pending proposals for all identified PIs and co-PIs on a given award. PIs should examine the formats of the required reports in advance to assure availability of required data.

PIs are required to use NSF's electronic project-reporting system, available through Research.gov, for preparation and submission of annual and final project reports. Such reports provide information on accomplishments, project participants (individual and organizational), publications, and other specific products and impacts of the project. Submission of the report via Research.gov constitutes certification by the PI that the contents of the report are accurate and complete. The project outcomes report also must be prepared and submitted using Research.gov. This report serves as a brief summary, prepared specifically for the public, of the nature and outcomes of the project. This report will be posted on the NSF website exactly as it is submitted by the PI.

More comprehensive information on NSF Reporting Requirements and other important information on the administration of NSF awards is contained in the *NSF Proposal & Award Policies & Procedures Guide* (PAPPG) Chapter VII, available electronically on the NSF Website at https://www.nsf.gov/publications/pub_summ.jsp?ods_key=pappg.

Reporting on NIH Awards:

Awardees will be required to submit the Research Performance Progress Report (RPPR) annually and financial statements as required in the NIH Grants Policy Statement.

A final progress report, invention statement, and the expenditure data portion of the Federal Financial Report are required for closeout of an award, as described in the *NIH Grants Policy Statement*.

The Federal Funding Accountability and Transparency Act of 2006 (Transparency Act), includes a requirement for awardees of Federal grants to report information about first-tier subawards and executive compensation under Federal assistance awards issued in FY2011 or later. All awardees of applicable NIH grants and cooperative agreements are required to report to the Federal Subaward Reporting System (FSRS) available at www.fsrs.gov on all subawards over $25,000. See the NIH Grants Policy Statement for additional information on this reporting requirement.

Reporting on USDA Awards:
Grantees are to submit initial project information and annual summary reports to NIFA's electronic, Web-based inventory system that facilitates both grantee submissions of project outcomes and public access to information on Federally-funded projects. The details of these reporting requirements are included in the award terms and conditions.

Any additional reporting requirements will be identified in the terms and conditions of the award (see Part VII, B. above for a link to view the NIFA award terms and conditions).

For informational purposes, the "Federal Financial Report," Form SF-425, consolidates into a single report the former Financial Status Report (SF-269 and SF-269A) and the Federal Cash Transactions Report (SF-272 and SF-272A). The NIFA Agency-specific Terms and Conditions include the requirement that Form SF-425 is due on a **annual basis no later than 90 days following the award's anniversary date *(i.e.*, one year following the month and day of which the project period begins and each year thereafter up until a final report is required). A final "Federal Financial Report," Form SF-425, is due 90 days after the expiration date of this award.**

US-UK Collaborative projects:

UKRI Awardees are subject to UKRI reporting requirements as outlined in the Research Funding Guide at http://www.bbsrc.ac.uk/funding/apply/grants-

guide.aspx. US-UK Collaborative Projects should report on activities of the entire collaborative effort and submit that information to both NSF and UKRI as part of the annual and final reports.

US-Israel Collaborative projects:

BSF Awardees are subject to BSF reporting and administration requirements as appropriate and outlined in the BSF website: http://www.bsf.org.il/BSFPublic/DefaultPage1.aspx?PageId=41&innerTextID=41 US-Israel Collaborative Projects should report on activities of the entire collaborative effort and submit that information to both NSF and BSF as part of the annual and final reports.

US-China Collaborative projects:

NSFC Awardees are subject to NSFC reporting and administration requirements as appropriate and outlined in the NSFC website: http://www.nsfc.gov.cn/publish/portal2/tab193/info24527.htm US-China Collaborative Projects should report on activities of the entire collaborative effort and submit that information to both NSF and NSFC as part of the annual and final reports.

VIII. AGENCY CONTACTS

Please note that the program contact information is current at the time of publishing. See program website for any updates to the points of contact.

General inquiries regarding this program should be made to:

- Katharina Dittmar, Program Director, NSF/BIO, telephone: (703) 292-7799, email: kdittmar@nsf.gov
- Christine Jessup, Program Director, NIH/FIC, telephone: (301) 496-1653, fax: (301) 402-0779, email: christine.jessup@nih.gov
- Timothy Sullivan, National Program Leader, USDA/NIFA, telephone: (816) 527-5434, email: timothy.sullivan@usda.gov
- Iain Templeman, Portfolio Manager, UKRI/BBSRC, telephone: 44(0)1793-413368, email: iain.templeman@bbsrc.ukri.org
- Rachel (Heni) Haring, Deputy Executive Director, BSF, telephone: 972 2 5828239, email: heni@bsf.org.il
- Xiuping Liu, Division Director, NSFC, telephone: 86 10-62325377, email: liuxp@nsfc.gov.cn
- Daniel Janes, Program Director, NIH/NIGMS, telephone: (301) 594-0943, email: daniel.janes@nih.gov
- Stephanie Coomes, Health Scientist Administrator, NIH/NIAID, telephone: (301) 761-6855, email: stephanie.coomes@nih.gov
- Jing Chen, Program Manager, NSFC, telephone: 86 10-62326877, email: chenjing@nsfc.gov.cn

- Daniel J. Thornhill, Program Director, NSF/GEO, telephone: (703) 292-8143, email: dthornhi@nsf.gov
- Joaquin Martinez Martinez, NSF/GEO, telephone: (703) 292-8580, email: jmartine@nsf.gov
- Samuel M. Scheiner, Program Director, NSF/BIO, telephone: (703) 292-7175, email: sscheine@nsf.gov

For questions related to the use of FastLane or Research.gov, contact:

- FastLane and Research.gov Help Desk: 1-800-673-6188

  FastLane Help Desk e-mail: fastlane@nsf.gov.

  Research.gov Help Desk e-mail: rgov@nsf.gov

For questions relating to Grants.gov contact:

- Grants.gov Contact Center: If the Authorized Organizational Representatives (AOR) has not received a confirmation message from Grants.gov within 48 hours of submission of application, please contact via telephone: 1-800-518-4726; e-mail:support@grants.gov.

IX. OTHER INFORMATION

The NSF website provides the most comprehensive source of information on NSF Directorates (including contact information), programs and funding opportunities. Use of this website by potential proposers is strongly encouraged. In addition, "NSF Update" is an information-delivery system designed to keep potential proposers and other interested parties apprised of new NSF funding opportunities and publications, important changes in proposal and award policies and procedures, and upcoming NSF Grants Conferences. Subscribers are informed through e-mail or the user's Web browser each time new publications are issued that match their identified interests. "NSF Update" also is available onNSF's website.

Grants.gov provides an additional electronic capability to search for Federal government-wide grant opportunities. NSF funding opportunities may be accessed via this mechanism. Further information on Grants.gov may be obtained athttps://www.grants.gov.

A notice on the Ecology and Evolution of Infectious Disease research initiative and this announcement is also posted in the NIH Guide to Grants and Contracts https://grants.nih.gov/grants/guide/index.html along with all NIH opportunities.

ABOUT THE NATIONAL SCIENCE FOUNDATION

The National Science Foundation (NSF) is an independent Federal agency created by the National Science Foundation Act of 1950, as amended (42 USC 1861-75). The Act states the purpose of the NSF is "to promote the progress of science; [and] to advance the national health, prosperity, and welfare by supporting research and education in all fields of science and engineering."

NSF funds research and education in most fields of science and engineering. It does this through grants and cooperative agreements to more than 2,000 colleges, universities, K-12 school systems, businesses, informal science organizations and other research organizations throughout the US. The Foundation accounts for about one-fourth of Federal support to academic institutions for basic research.

NSF receives approximately 55,000 proposals each year for research, education and training projects, of which approximately 11,000 are funded. In addition, the Foundation receives several thousand applications for graduate and postdoctoral fellowships. The agency operates no laboratories itself but does support National Research Centers, user facilities, certain oceanographic vessels and Arctic and Antarctic research stations. The Foundation also supports cooperative research between universities and industry, US participation in international scientific and engineering efforts, and educational activities at every academic level.

Facilitation Awards for Scientists and Engineers with Disabilities(FASED) provide funding for special assistance or equipment to enable persons with disabilities to work on NSF-supported projects. See the *NSF Proposal & Award Policies & Procedures Guide* Chapter II.E.6 for instructions regarding preparation of these types of proposals.

The National Science Foundation has Telephonic Device for the Deaf (TDD) and Federal Information Relay Service (FIRS) capabilities that enable individuals with hearing impairments to communicate with the Foundation about NSF programs, employment or general information. TDD may be accessed at (703) 292-5090 and (800) 281-8749, FIRS at (800) 877-8339.

The National Science Foundation Information Center may be reached at (703) 292-5111.

The National Science Foundation promotes and advances scientific progress in the United States by competitively awarding grants and cooperative agreements for research and education in the sciences, mathematics, and engineering.

To get the latest information about program deadlines, to download copies of NSF publications, and to access abstracts of awards, visit the NSF Website at https://www.nsf.gov

- **Location:** 2415 Eisenhower Avenue, Alexandria, VA 22314
- **For General Information** (NSF Information Center)**:** (703) 292-5111

- **To Locate NSF Employees:** (703) 292-5111

PRIVACY ACT AND PUBLIC BURDEN STATEMENTS

The information requested on proposal forms and project reports is solicited under the authority of the National Science Foundation Act of 1950, as amended. The information on proposal forms will be used in connection with the selection of qualified proposals; and project reports submitted by awardees will be used for program evaluation and reporting within the Executive Branch and to Congress. The information requested may be disclosed to qualified reviewers and staff assistants as part of the proposal review process; to proposer institutions/grantees to provide or obtain data regarding the proposal review process, award decisions, or the administration of awards; to government contractors, experts, volunteers and researchers and educators as necessary to complete assigned work; to other government agencies or other entities needing information regarding applicants or nominees as part of a joint application review process, or in order to coordinate programs or policy; and to another Federal agency, court, or party in a court or Federal administrative proceeding if the government is a party. Information about Principal Investigators may be added to the Reviewer file and used to select potential candidates to serve as peer reviewers or advisory committee members. See System of Record Notices, NSF-50, "Principal Investigator/Proposal File and Associated Records," and NSF-51, "Reviewer/Proposal File and Associated Records." Submission of the information is voluntary. Failure to provide full and complete information, however, may reduce the possibility of receiving an award.

An agency may not conduct or sponsor, and a person is not required to respond to, an information collection unless it displays a valid Office of Management and Budget (OMB) control number. The OMB control number for this collection is 3145-0058. Public reporting burden for this collection of information is estimated to average 120 hours per response, including the time for reviewing instructions. Send comments regarding the burden estimate and any other aspect of this collection of information, including suggestions for reducing this burden, to:

GACETILLA

Convalescent plasma with high antibody titers applied in the first days of disease turns COVID-19 into a bad cold in older people.

A randomized, double-blind, placebo-controlled study conducted by the INFANT Foundation evaluated the efficacy of early administration of convalescent plasma with high titers of antibodies in older adults and observed that its application **decreases the possibility that these patients** require oxygen during illness.

The study, conducted by a team of scientists led by Dr. Fernando Polack (Director of the INFANT Foundation), demonstrated that convalescent plasma administered to people infected patients over 65 years of age with comorbidities and in all those over 75 years of age it is effective to prevent COVID-19 from becoming a serious respiratory illness, provided you **give it to you within 72 hours of symptom onset.**

In this way, and in line with the use of plasma derivatives - such as gamma globulin hyperimmune- and antiviral drugs in other diseases-, antibody-rich plasma acts at the beginning of the disease preventing it from progressing, unlike trials performed in critically ill patients where stopping the progression of COVID-19 becomes more difficult and

no conclusive benefits have been found in its use.

"Plasma is just a vehicle that carries antibodies. E **l 28% of people have, as our study, the amount of antibodies needed to donate plasma for this treatment.** By restricting donors to those with higher antibody concentrations, it is possible to improve plasma performance even further. Although this leaves out the donation to a group of convalescent, between 4 and 8 recovered patients have the antibodies needed to be a donor. Patients who had pneumonia or needed hospitalization they are the ones who usually produce the most antibodies, "Polack explained.

The researchers identified the desirable amounts of protective antibodies in the plasma bags using the COVIDAR antibody test developed by the Institute Leloir in Buenos Aires. This information is an extremely important tool for the design of public policies, since it will allow the design of donation campaigns that aim directly to identify the correct donors, optimizing time, effort and resources.

Page 2

"This study describes the first strategy in the world to stop the progression of SARS-COV2 with an economic intervention, universal, not subject to patents, proven safe and that it can be administered on an outpatient basis in care units without the need for hospitalization, "Polack said.

The trial, which was carried out between the months of June and last October, involved 160 adults older than 65 years with at least one comorbidity (hypertension, diabetes, obesity, kidney failure and / or chronic obstructive pulmonary disease), and to all those over 75 years. The program coordinated efforts from the public and private sectors, bringing together hospitals from the Province of Buenos Aires and sanatoriums of the Federal Capital and had the support of the Ministry and the respective Ministry of Health, PAMI, the Military Hospital, various actors from the health and hundreds of volunteers.

An independent Data and Safety Monitoring Committee (DSMB) supervised the study. monitoring its quality and the well-being of patients. The study was funded by a grant from the Bill & Melinda Gates Foundation and the INFANT Foundation Pandemic Fund that brings together numerous national companies and private contributors.

The research was carried out with the collaboration of the Institute of Clinical Effectiveness and Sanitaria (IECS) and the Sarmiento Hematology Foundation at the Dr. Carlos Bocalandro Hospital, the

Hospital San Juan de Dios, Hospital Simply Evita, Hospital Central de San Isidro Dr. Melchor Ángel Posse, the Olivos Clinic and a network of geriatric care units linked to the PAMI in the Province of Buenos Aires, and in the Central Military Hospital, the Galician Center, the Sanatorio de los Arcos, CEMIC University Hospital, Sanatorio Sagrado Corazón, Sanatorio Anchorena and Sanatorio Finochietto in the Autonomous City of Buenos Aires.

About the study

The design of this study was randomized, double-blind, and placebo-controlled. This means that half of the patients randomly received high antibody titer plasma and half remaining placebo (physiological solution), without doctors or participants knowing which substance was administered to each individual. This method is used to ensure fairness in the evaluation of the results.

Once all recruited patients received plasma or placebo, the evolution of the disease in both groups. **Of the patients actually treated with plasma only 9 required oxygen versus 23 who received placebo treatment.** I know estimates that one in 6 people treated with plasma who would have had disease severe if he had not received it, he did not develop it.

"This is the only study in the world against SARS-COV2 that was done with this methodology rigorous early comparison of one group against another and thus provides evidence that the disease did not progress due to the administration of plasma and not other reasons ", explained Dr. Romina Libster, one of the main authors of the work, medical pediatrician specialized in vaccines and researcher at the INFANT Foundation.

For this study to be possible, the work required the detection of donors of plasma, the identification of patients in the nursing homes of the Province and Capital of the elderly with early mild symptoms, his rapid home swab test for SARS CoV2 in the laboratory of the Central Military Hospital, and the transfer of those infected who wish participate in the study institutions in charge of a mobile group provided free of charge by Swiss Medical who toured the region for months.

There, a team from the Sarmiento Hematology Foundation coordinated the administration of plasma

or placebo taking care that nobody knew who received each product. This continued with a daily monitoring of participants for up to 25 days duration and analysis of the entire information by a group of experts in research and statistics from INFANT and the IECS.

In the first weeks of May, against the clock and in the midst of a pandemic with enormous uncertainty, the **INFANT** team of researchers **trained more than 200 physicians** from participating health centers. The goal was to reduce the chances of error in all procedures.

At the same time, a large group of volunteers were actively working in search of donors. Every day they called a hundred people recovered from COVID-19 to invite them to participate in the program and make them aware of the importance that this contribution could have for new patients.

More than 100 volunteers were trained who helped us day and night in identifying possible patients to enroll in the study, coming from their homes and nursing homes from the Buenos Aires suburbs, referred through the collaboration of PAMI, or arrived at consultations in the clinics of Capital Federal.

"During all stages, the project, which involved around 400 people, required meticulousness to assemble the different links and cover both scientific needs as logistics ", said Gonzalo Pérez Marc, pediatrician, deputy director of the Department Maternal and Child of the Central Military Hospital and also one of the main authors of the job.

This study, carried out with Argentine scientists, **is the first evidence in the world of a universal, accessible and safe treatment** that can save lives until vaccines are available available.

About Fundación INFANT

INFANT is a non-profit organization, whose mission is to investigate the causes of respiratory diseases that affect the population such as bronchiolitis, asthma, pneumonia and the flu. In its 17 years of existence, the institution carried out important scientific discoveries of great health impact.

Faced with the arrival of SARS CoV2 in Argentina, the INFANT Foundation catalyzed a project collaborative with public and private sector actors, supported by experts in respiratory diseases and clinical research, epidemiologists, physicians, biologists and more than 400 volunteers to devise and explore a possible solution against COVID-19 with the support generous of international and national entities and private contributors.

FUNDACIÓN INFANT
TRADUCIENDO CIENCIA EN SALUD INFANTIL

GACETILLA

El plasma de convaleciente con altos títulos de anticuerpos aplicado en los primeros días de enfermedad transforma el COVID-19 en un mal catarro en personas mayores.

Un estudio randomizado, doble-ciego y contra placebo realizado por la Fundación INFANT evaluó la eficacia de la administración temprana de plasma de convaleciente con altos títulos de anticuerpos en adultos mayores y observó que su aplicación **disminuye un 61 % la posibilidad de que estos pacientes** necesiten oxígeno durante la enfermedad.

El estudio, a cargo de un equipo de científicos liderados por el Dr. Fernando Polack (Director de la Fundación INFANT), demostró que el plasma de convalescientes administrado en personas infectadas mayores de 65 años con comorbilidades y en todos los mayores de 75 años es eficaz para evitar que el COVID-19 se transforme en una enfermedad respiratoria grave, siempre que **se lo administre dentro de las primeras 72 horas de la aparición de síntomas.**

De esta manera, y en línea con el uso de derivados del plasma -como la gammaglobulina hiperinmune- y las drogas antivirales en otras enfermedades-, el plasma rico en anticuerpos actúa al comienzo de la enfermedad evitando que avance, a diferencia de los ensayos realizados en pacientes graves donde detener la progresión del COVID-19 se hace más difícil y no se han encontrado beneficios concluyentes en su utilización.

“El plasma es sólo un vehículo que lleva anticuerpos. E**l 28% de las personas tiene, según nuestro estudio, la cantidad de anticuerpos necesarios para donar plasma para este tratamiento.** Restringiendo los donantes a los de mayores concentraciones de anticuerpos, es posible mejorar el rendimiento del plasma aún más. Si bien esto deja afuera de la donación a un grupo de convalecientes, enrtre 4 y 8 enfermos recuperados tiene los anticuerpos necesarios para ser donante. Los pacientes que tuvieron neumonía o necesitaron internarse son quienes más anticuerpos suelen producir”, explicó Polack.

Los investigadores identificaron las cantidades deseables de anticuerpos protectores en las bolsas de plasma utilizando el ensayo de anticuerpos COVIDAR desarrollado por el Instituto Leloir en Buenos Aires. Esta información es una herramienta de suma importancia para el diseño de políticas públicas, ya que permitirá diseñar campañas de donación que apunten directamente a identificar a los donantes correctos, optimizando tiempo, esfuerzo y recursos.

“Este estudio describe la primera estrategia en el mundo para detener la progresión del SARS-COV2 con una intervencion económica, universal, no sujeta a patentes, probadamente segura y que puede admnistrarse en forma ambulatoria en unidades de atención sin necesidad de hospitalizacion”, dijo Polack.

El ensayo, que se realizó entre los meses de junio y octubre últimos, involucró a 160 adultos mayores de 65 años con al menos una comorbilidad (hipertensión, diabetes, obesidad, insuficiencia renal y/o enfermedad pulmonar obstructiva crónica), y a todos los mayores de 75 años. El programa articuló esfuerzos del sector público y privado, congregando hospitales de la Provincia de Buenos Aires y sanatorios de la Capital Federal y contó con el apoyo del Ministerio y Secretaría de Salud respectivos, el PAMI, el Hospital Militar, diversos actores del área de salud y centenares de voluntarios.

Un Comité de Monitoreo de Seguridad y Datos (DSMB) independiente supervisó el estudio monitoreando su calidad y el bienestar de los pacientes. El estudio se financió mediante un subsidio de la Fundación Bill & Melinda Gates y el Fondo de Pandemia de la Fundación INFANT que congrega a numerosas empresas nacionales y aportantes privados.

La investigación se llevó a cabo con la colaboración del Instituto de Efectividad Clínica y Sanitaria (IECS) y la Fundación Hematológica Sarmiento en el Hospital Dr. Carlos Bocalandro, el Hospital San Juan de Dios, el Hospital Simplemente Evita, el Hospital Central de San Isidro Dr. Melchor Ángel Posse, la Clínica Olivos y una red de unidades geriátricas de atención ligadas al PAMI en la Provincia de Buenos Aires, y en el Hospital Militar Central, el Centro Gallego, el Sanatorio de los Arcos, el Hospital Universitario CEMIC, el Sanatorio Sagrado Corazón, el Sanatorio Anchorena y el Sanatorio Finochietto en la Ciudad Autónoma de Buenos Aires.

Acerca del estudio

El diseño de este estudio fue aleatorio, doble ciego y controlado con placebo. Esto significa que la mitad de los pacientes recibió al azar plasma de alto título de anticuerpos y la mitad restante placebo (solución fisiológica), sin que médicos ni participantes supieran qué sustancia se administró a cada individuo. Este método se usa para garantizar la imparcialidad en la evaluación de los resultados.

Una vez que todos los pacientes reclutados recibieron plasma o placebo se comparó la evolución de la enfermedad en ambos grupos. **De los pacientes efectivamente tratados con plasma sólo 9 necesitaron oxígeno contra 23 que recibieron tratamiento con placebo.** Se estima que una de cada 6 personas tratadas con plasma que hubiera tenido enfermedad severa de no haberlo recibido, no llegó a desarrollarla.

“Este es el único estudio en el mundo contra el SARS-COV2 que se hizo con esta metodología rigurosa de comparación temprana de un grupo contra otro y, por lo tanto, otorga evidencia de que la enfermedad no avanzó debido a la administración del plasma y no por otras razones”, explicó la Dra. Romina Libster, una de las autoras principales del trabajo, médica pediatra especialista en vacunas e investigadora de la Fundación INFANT.

Para que este estudio fuera posible, el trabajo requiriró de la detección de donantes de plasma, la identificacionpacientes en los geriátricos de Provincia y Capital de personas mayores con síntomas leves tempranos, su testeo rápido en domicilio por hisopado para SARS CoV2 en el laboratorio del Hospital Militar Central, y el traslado de los infectados que deseasen participar a las instituciones del estudio a cargo de un grupo móvil provisto en forma gratuita por Swiss Medical que recorrió durante meses la región.

Allí, un equipo de la Fundación Hematológica Sarmiento coordinó la administración de plasma o placebo cuidando que nadie supiese quién recibió cada producto. Esto continuó con un monitoreo diario de los participantes de hasta 25 días de duración y el análisis de toda la información por un grupo de expertos en investigación y estadistíca de INFANT y el IECS.

En las primeras semanas de mayo, contrarreloj y en plena pandemia con enorme incertidumbre, el equipo de investigadores de **INFANT entrenó en el protocolo a más de 200 médicos** de los centros de salud participantes. El objetivo fue reducir las posibilidades de error en todos los procedimientos.

Al mismo tiempo, un nutrido grupo de voluntarios trabajaba activamente en busca de donantes. Todos los días llamaban a un centenar de personas recuperadas de COVID-19 para invitarlas a participar del programa y concientizarlas sobre la importancia que este aporte podía tener para nuevos enfermos.

Se capacitaron **a más de 100 voluntarios** que nos ayudaron día y noche en la identificación de posibles pacientes para enrolar en el estudio, provenientes de sus hogares y geriátricos del conurbano bonaerense, referidos a través de la colaboración del PAMI, o llegados a consultas en las clínicas de Capital Federal.

“Durante todas las etapas, el proyecto, que involucró a alrededor de 400 personas, requirió de minuciosidad para ensamblar los distintos eslabones y cubrir tanto las necesidades científicas como logísticas”, contó Gonzalo Pérez Marc, médico pediatra subdirector del Departamento Materno Infantil del Hospital Militar Central y también uno de los principales autores del trabajo.

Este estudio, realizado con científicos argentinos, **es la primera evidencia en el mundo de un tratamiento universal, accesible y seguro** que puede salvar vidas hasta que haya vacunas disponibles.

Acerca de Fundación INFANT

INFANT es una organización sin fines de lucro, cuya misión es investigar las causas de enfermedades respiratorias que afectan a la población como la bronquiolitis, el asma, la neumonía y la gripe. En sus 17 años de existencia, la institución realizó importantes descubrimientos científicos de gran impacto sanitario.

Frente a la llegada del SARS CoV2 a la Argentina, la Fundación INFANT catalizó un proyecto colaborativo con actores del sector público y el sector privado, sostenido por expertos en enfermedades respiratorias e investigación clínica, epidemiólogos, médicos, biólogos y más de 400 voluntarios para idear y explorar una posible solución contra el COVID-19 con el apoyo generoso de entidades internacionales, nacionales y aportantes particulares .

0 | Abstract

In the absence of effective countermeasures, human convalescent plasma has been widely used to treat severe acute respiratory syndrome coronavirus 2 including among patients with innate or acquired immunodeficiency. However, the association between COVID-19-associated mortality in patients with immunodeficiency and therapeutic use of convalescent plasma is unknown. We review clinical features and treatment protocols of COVID-19 patients with immunodeficiency after treatment with human convalescent plasma. We also discuss the time course and clinical features of recovery. These insights provide evidence for the need to develop a clear treatment protocol for COVID-19 patients with immunodeficiency and support the efficacy of convalescent plasma in patients with primary or secondary immunodeficiency.

1 | Introduction

Convalescent plasma represents a passive antibody therapy that has been used to prevent or treat infectious diseases for more than a century.[1,2] In the context of the novel coronavirus disease 2019 (COVID-19) pandemic, convalescent plasma has received full or conditional regulatory authorization in the United States for therapeutic use in adults and children hospitalized with suspected or laboratory confirmed SARS-CoV-2 positive COVID-19.[3–5] Although early signals for efficacy and optimal use of convalescent plasma have emerged,[6–10] additional large randomized controlled trials are needed to garner clinical consensus regarding the therapeutic effectiveness of convalescent plasma.

Inasmuch as convalescent plasma confers antiviral properties for the recipient, evidence of therapeutic effectiveness may be confounded by endogenous anti-SARS-CoV-2 antibody responses, particularly when convalescent plasma transfusion occurs late in the disease course.[11] Hence, evaluation of the clinical responses to convalescent plasma transfusion in immunosuppressed patients who cannot generate innate immune responses may provide an optimal opportunity to assess the effect of convalescent plasma *per se.*[12] Thus, herein we summarize the literature detailing the clinical experiences of patients with primary and secondary immunosuppression who were transfused with COVID-19 convalescent plasma. We hypothesize that patients with immunodeficiency syndromes, or patients with diseases associated with blunted endogenous antibody responses to COVID-19, may provide evidence of improved clinical status when given plasma containing anti-SARS-CoV-2 antibodies, with improvements over and above expectation in light of their underlying clinical conditions and the severity of COVID-19.

This review highlights 40 reports including 104 COVID-19 patients with primary immunosuppression due to Agammaglobulinemia (X-linked or autosomal) or Common Variable Immunodeficiency, and secondary immunodeficiencies related to hematological malignancies and solid organ transplants who were transfused with convalescent plasma. We also highlight additional cases of patients with COVID-19, including but not limited to patients with other forms of immunosuppression, transfused with convalescent plasma. We provide a summary overview of patient characteristics, COVID-19 therapies used, including convalescent plasma, and clinical symptomology (**table**).

Search strategy and selection criteria

References for this Review were identified through searches of PubMed for articles published from Jan 1, 2020 to Nov 1, 2020, using the Medical Subject Headings terms "COVID-19", "convalescent plasma", "convalescent serum", "immunosuppression", "cancer", "transplant", "agammaglobulinemia", "malignancy", and any relevant entry terms and supplementary concepts (**figure**). Relevant articles and data were also identified through searches in Google Scholar, medRxiv, and other websites. Articles resulting from these searches and relevant references cited in those articles were reviewed. Articles published in English were identified and included. All procedures accessed public information and did not require ethical review as determined by the Mayo Clinic Institutional Review Board in accordance with the Code of Federal Regulations, 45 CFR 46.102, and the Declaration of Helsinki.

2 | Primary Immunodeficiency

2.1 | Patients with Agammaglobulinemia

This narrative includes one patient with Autosomal Agammaglobulinemia and six patients with X-linked Agammaglobulinemia (XLA), six of whom were reported in peer-reviewed articles and one patient who was identified in a media report.[13–16] Patients with Agammaglobulinemia do not produce endogenous antibodies and require regular intravenous infusions (monthly) or subcutaneous injections (bi-weekly) of immunoglobulins to avoid serial infections from various common pathogens.[17] However, immunoglobulin replacement therapy cannot protect patients against pathogens for which antibodies are uncommon or absent in the immunoglobulin donor pool, such as the SARS-CoV-2 virus.[17] The clinical narratives describing patients with Agammaglobulinemias all demonstrate a prolonged course of disease and absent antibody response to COVID-19. However, all patients with Agammaglobulinemia demonstrated clinical improvement and symptom resolution following convalescent plasma transfusion, with three patients improving rapidly and demonstrating SARS-CoV-2 serum antibodies after transfusion. In addition to immunoglobulin therapy, some patients also received the experimental COVID-19 therapies remdesivir and hydroxychloroquine.

2.2 | Patients with Common Variable Immunodeficiency

We identified four patients with Common Variable Immunodeficiency transfused with convalescent plasma for COVID-19 therapy.[16] Common Variable Immunodeficiency represents a heterogeneous collection of immunodeficiencies commonly characterized by intrinsic B-cell defects and suppressed antibody production.[18] Patients with Common Variable Immunodeficiency often present with inflammatory and autoimmune disorders, which are suspected to elevate these patients risk for progression to severe COVID-19.[16,18] The four patients described here were all antibody deficient and diagnosed with severe or life-threatening COVID-19. Notably, three of these patients survived following convalescent plasma transfusion, including two patients whose clinical symptomatology required mechanical ventilation or extracorporeal membrane oxygenation.

3 | Secondary Immunodeficiency

3.1 | Patients with Hematological Malignancies

We identified 54 patients with hematological malignancies transfused with convalescent plasma in 18 peer-reviewed reports.[19,20,28,29,29–36,21–24,24–27] The largest cohort of patients with hematological malignancies was a group of 17 patients with B-cell depletion whose immunodeficiency was secondary to therapies for various types of lymphoma or leukemia.[19] These patients experienced protracted severe COVID-19 symptoms and absent endogenous SARS-CoV-2 antibody responses due to cancer-directed therapies that suppress B-cell proliferation, such as rituximab. Within 48 hours of convalescent plasma transfusion the majority of patients demonstrated improved clinical status and viral clearance. Similarly, in a separate cohort of 14 patients with hematological malignancies, most patients exhibited improvements in clinical symptomatology, including reduced oxygen requirements,[20] after treatment with convalescent plasma. Other case-reports are of lymphoma (n = 11), leukemia (n = 5), multiple myeloma (n = 3), and myelodysplastic syndrome (n = 1) and include one four year old pediatric patient with leukemia who received two convalescent plasma doses over two days.[28] A majority of patients with hematological malignancies recovered following convalescent plasma transfusion, with many demonstrating rapid clinical improvements shortly after transfusion. Notably, a patient with protracted COVID-19, evidenced by three separate COVID-19-related hospitalisations over a 100+ day period, and with lymphoma-associated B-cell immunodeficiency demonstrated rapid reductions in fever, oxygen requirements, and lung infiltrates (via chest computed tomography) forthwith after two separate convalescent plasma transfusions separated by ~90 days.[22]

3.2 | Solid Organ Transplant Patients

Among nine peer-reviewed articles and two media reports we identified a total of 29 COVID-19 patients transfused with convalescent plasma whom were receiving immunosuppressive therapies for previous solid organ transplants.[37–47] In a cohort of 13 transplant recipients transfused with convalescent plasma concomitant to hydroxychloroquine, steroids and anticoagulants therapies for COVID-19, eight patients demonstrated improved oxygen requirements and were promptly discharged [37]. In the other nine reports, a majority of the 17 patients with COVID-19 demonstrated improved clinical symptomatology following convalescent plasma transfusion. Improvement was even seen in a liver transplant patient discharged home after a convalescent plasma transfusion that occurred during a seventeen day medically-induced coma due to COVID-19 complications.[44]

4 | Conclusion

These data provide evidence and encouraging anecdotal statements (**panel**) supporting the efficacy of convalescent plasma in patients with primary or secondary immunodeficiency, and are consistent with the historical evidence demonstrating that passive antibody therapies for infectious diseases are especially effective when given early in the course of disease prior to an endogenous antibody response.[2,48,49] In contrast to ongoing studies of convalescent plasma efficacy in clinical trials where the majority of patients are not immunosuppressed and thus mount their own protective antibody responses,[6,11,50] convalescent plasma use in these immunosuppressed patients represents a situation where exogenous antibody is provided in the setting of an immune deficit.[17] This is particularly true in the case for patients with Agammaglobulinemia, who represent in effect a natural 'immunological knockout' providing the opportunity to evaluate the value of adding specific antibody to a host unable to make antibody to SARS-CoV-2.

The results for patients with Agammaglobulinemia are striking for the beneficial effects of convalescent plasma, and even though the reports lack a control group, the rapid time course of clinical improvement following administration of specific antibody in a situation where no endogenous antibody was present is impressive. Convalescent plasma was also found to be safe and efficacious in COVID-19 patients with common variable immunodeficiency, myasthenia gravis, and Sjögren's syndrome, in addition to COVID-19 patients with heart rhythm abnormalities and gravida.[51–57] Hence, from the viewpoint of establishing the efficacy of convalescent plasma administration in COVID-19 therapy, the experience with this patient set provides the important criterion that addition of specific antibody to a host with no antibodies resulted in a favorable therapeutic effect.

Panel: Anecdotal statements supporting the efficacy of convalescent plasma

- ∀ In the present case, the rapid clinical improvement followed by viral clearance after administration of hyperimmune plasma argue that passively transferred antibodies played a key role in COVID-19 recovery.[23]
- ∀ One day later [after convalescent plasma transfusion], the patient was afebrile for the first time in 3 weeks and had improved energy.[13]
- ∀ On day 122 (of illness), due to worsening symptoms, the patient was given convalescent plasma. He defervesced within 24 hours and was discharged nine days later.[31]
- ∀ …she was transferred to the intensive care unit for intubation. In the meantime…the patient received convalescent therapy instead and did not undergo intubation following the immediate improvement after plasma therapy infusion.[52]
- ∀ Based on the lack of clinical improvement…we transfused 1 unit of convalescent plasma…Importantly, the patient did not receive any other treatment potentially having an effect on the course of COVID-19…After transfusion of the convalescent plasma, the patient showed a dramatic clinical improvement, became asymptomatic, and was discharged home only 2 days later.[36]
- ∀ The patient was discharged after 2 weeks [convalescent plasma transfusion] with a dramatic response to therapy. Both newborns had no COVID-19 symptoms and negative PCR results.[54]
- ∀ 36 hours after [convalescent plasma] transfusion, the patient was discharged from the hospital reporting that he felt improved.[53]
- ∀ COVID-19 antibody testing showed complete lack of COVID-19 antibodies…She received 2 units of convalescent plasma…with rapid improvement in oxygen requirements. She was weaned off high-flow nasal cannula within 48 h and within a few days was discharged home in stable condition.[32]
- ∀ Intravenous convalescent plasma…was administered…Her health condition quickly improved, allowing [withdrawal of oxygen supplementation]…[23]
- ∀ Within a day of receiving her first transfusion of convalescent plasma, she reported improvement in shortness of breath and cough, had fever resolution, and decreasing oxygen requirements.[24]
- ∀ She received COVID convalescent plasma…She showed remarkable improvement [the next day]…with reduction of respiratory rate…and oxygen requirements.[21]
- ∀ …the patient received a transfusion of convalescent plasma…one day later her [arterial oxygen saturation] increased to 98%...clinical symptoms and pathological criteria improved rapidly within 3 days.[29]
- ∀ Within hours after receiving the convalescent plasma… [The patient's] fever started going down. Days later, his breathing and kidney function improved.[45]
- ∀ [The patient]…received a transfusion of convalescent plasma…He is recovering at home after spending two and a half weeks in a coma fighting for his life...[44]
- ∀ …received 217 mL of convalescent plasma…24 hours later, his heart rate had improved to 60-70 bpm with less frequent premature atrial contractions and premature ventricular contractions and he was breathing comfortably on room air…36 hours after transfusion the patient was discharged from the hospital…[53]
- ∀ Stagnancy in the patient's evolution, as represented by the lack of response to any of the treatments dispensed....we administered on day 23 COVID-19 convalescent plasma...after 24 hours of infusion, fever ceased without subsequent reappearance and with progressive improvement of asthenia.[14]

Introduction

Coronavirus disease (COVID-19) pandemic has started to affect Saudi Arabia in the beginning of March 2020 and is expected to cause significant morbidity to many patients, especially to elderly, who might require intensive care unit (ICU) support to survive as its lethality increases with the increasing age. Recent publications suggested the benefit of utilizing convalescent plasma from recovered donors as a therapeutic approach in treating COVID-19 patients. Convalescent plasma could provide our first-line defense for people with COVID-19, especially those who are older and at a much higher risk for complications.. therefore, we developed a national protocol to investigate the safety, benefit and applicability at larger scale and at different health care

complications; therefore, we developed a national protocol to investigate the safety, benefit and applicability at larger scale and at different health care facilities in Saudi Arabia (KSA).

Objectives

Primary endpoints are:

1. ICU (or designated area for critical patients) length of stay
2. Safety of convalescent plasma

Secondary endpoints included:

1. 30 days mortality
2. Number of days on mechanical ventilation
3. Days to clinical recovery

Method

Eligible convalescent plasma donors will be invited to participate in trial. The arrangement for plasmapheresis will start after obtaining donor informed consent. The collected plasma will be treated with pathogen reduction system. The convalescent plasma units will be labelled, stored and shipped as per the standard transfusion medicine protocols. It will be used only for eligible patients' "recipients" as per the following eligibility criteria:

1- Inclusion criteria:

- Confirmed case of SARS-CoV-2 infection with POSITIVE rRT PCR test
- 18 or older
- Must have been requiring ICU care or severe or immediately life-threatening care (any one of the following):
    1. Patient requiring ICU care/admission.
    2. Severe disease is defined as:
        a. Dyspnea
        b. Respiratory frequency ≥ 30/min
        c. Blood oxygen saturation ≤ 93%
        d. Partial pressure of arterial oxygen to fraction of inspired oxygen ratio < 300, and/or Lung infiltrates > 50% within 24 to 48 hours
    3. Life-threatening disease is defined as:
        a. Respiratory failure
        b. Septic shock, and/or
        c. Multiple organ dysfunction or failure

2- Exclusion criteria:

- Negative or non-conclusive test COVID-19 rRT PCR test
- Mild symptoms
- Hospitalization not requiring ICU care/admission

Eligible Patients will be infused with the convalescent plasma (200-400 ml / treatment dose) at least once & if possible, daily, for up to 5 sessions. Other supportive and therapeutic measures should continue according to the locally approved protocols with due diligence.

Sample size was calculated with 80% power and 5% level of significance based on the recently published data to detect statistical difference in the study outcome. Therefore, we plan to recruit total of 575 patients.

- Convalescent plasma Recipient Group:
    - 115 patients (recipients) who have COVID 19 as per the inclusion criteria.
- Comparative control Group:
    - 460 Patients who are eitherCOVID 19 historical control or only consent for sharing their clinical and laboratory data

Matching for age, gender, Hypertension, Diabetes and intubation status were done based on the propensity score. Continuous variables will be presented as the median and interquartile range (IQR). Statistical software SPSS 24.0 will be used. Demographic, Clinical, imaging and laboratory information of all enrolled patients will be retrieved from the hospital electronic/paper records system to be used for the outcomes analysis.

Results

22 sites across KSA that participated in the study. Tertiary, secondary, academic and non-academic centers participated (real world data). There were no unusual safety issues related to convalescent plasma infusion since all mortalities in the plasma group were not related to plasma infusion which represent similar finding from other the published international reports. Keeping in-mind that our data is still maturing, 30 survival probability in the plasma group was 69% compared to 56% in the comparative group (p value = 0.066) (figure-1). This benefit to seem to be more noticeable in the COVID-19 cases who did not meet the criteria for life-threatening disease (figure-2).

Conclusion

Conclusion

Our study supports the safety of convalescent plasma in treating COVID-19 patients. Patients who are in the category of life-threating/end organs failure do not seem to benefit. There might be a benefit in the other subgroups.

Figure-1: Survival Probability between Convalescent Plasma to Treat Severe COVID-19 and matched comparative patients

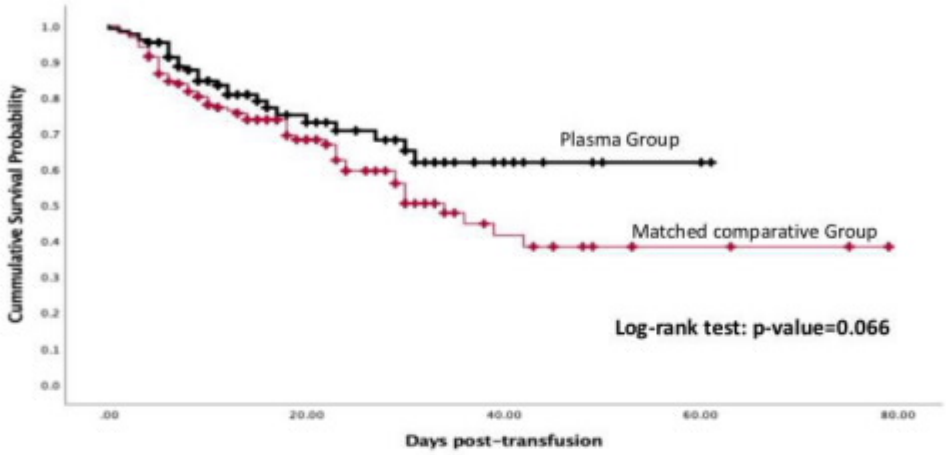

Figure-2: Survival Probability for Convalescent Plasma recipients patients among one of the three inclusion criteria (3 subgroups)

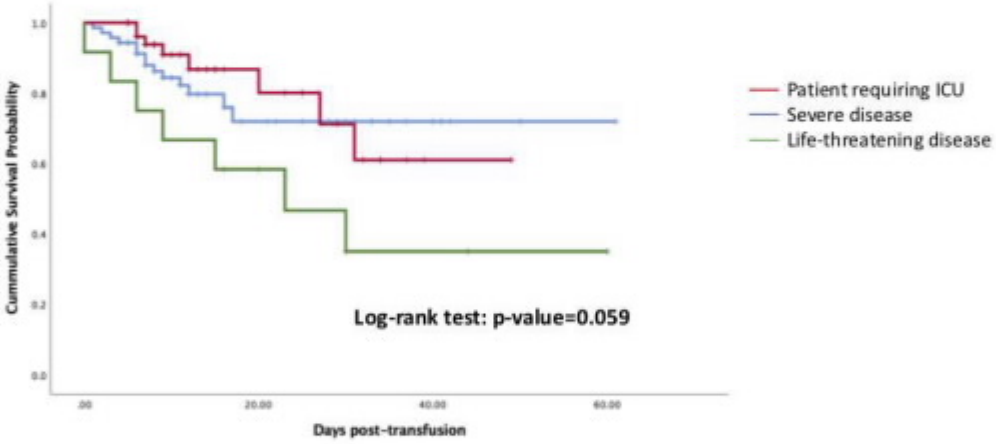

Disclosures: No relevant conflicts of interest to declare.

Highlights

- Convalescent plasma is adjunct treatment in COVID-19 moderate and severe disease.
- Clinical improvement is noticed in COVID-19 disease after convalescent plasma.
- Mortality is significantly reduced after COVID-19 convalescent plasma treatment.

Abstract

Objective: To study the effectiveness of CCP therapy for moderate and severe COVID-19 disease patients in Kuwait.

Methods: This non-randomized prospective cohort study was conducted from May 21, 2020, to June 30, 2020, at four major tertiary hospitals in Kuwait. CCP was administered to 135 patients. The control group comprised 233 patients who received standard treatment. All patients (N=368, median age 54 [range 15-82] years) had laboratory-confirmed SARS-CoV-2 infection and either moderate or severe COVID-19 disease.

Journal Pre-proof

Results: CCP treatment was significantly associated with a higher rate of clinical improvement in patients with moderate or severe disease. Among those with moderate COVID-19 disease, time to clinical improvement was 7 days in the CCP group versus 8 days in the control group (p=0·006). For severe COVID-19 disease, time to clinical improvement was 7 days in the CCP group versus 15.5 days in the control group (p=0·003). In the adjusted analysis, the CCP-treated patients with moderate disease had significantly lower 30-day mortality. Compared to the control group, oxygen saturation improved within 3 days of CCP transfusion, and lymphocyte counts improved from day 7 in patients with moderate disease and day 11 in patients with severe disease. Furthermore, C-reactive protein declined throughout the first 14 days after CCP transfusion. None of the CCP patients developed a serious transfusion reaction.

Conclusions: The data show that administration of CCP is a safe treatment option for patients with COVID-19 disease, with a favorable outcome in the rate and time to clinical improvement.

Keywords: convalescent plasma, COVID-19, SARS-CoV-2, pneumonia, clinical improvement, mortality.

Introduction

The novel coronavirus disease of 2019 (COVID-19) pandemic is considered one of the greatest global public health crises since the 1918 influenza pandemic.[1] COVID-19 is caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), a single-stranded RNA virus that belongs to *coronaviridae*.[2,3] The clinical spectrum of infection is broad, ranging from asymptomatic to severe pneumonia, multiorgan failure, and death. Due to the absence of established antiviral treatment for COVID-19, the historical choice of therapeutic convalescent plasma (CP) was globally appealing, especially with its prior success against RNA viruses.[1] CP has been proposed not only to neutralize the pathogen, but provide passive immunomodulatory properties that allow the recipient to control the

Journal Pre-proof

exaggerated inflammatory cascade.[4,5] However, the mechanism of action of therapeutic CP remains unclear. Reports from open label trials and case series suggest that plasma collected from convalescent COVID-19 patients is safe to administer and may be effective in treating patients with COVID-19.[6–8] Therefore, the World Health Organization (WHO) and United States Food and Drug Administration (FDA) have issued guidelines for the usage of COVID-19 convalescent plasma (CCP) and standardized donor selection, which was further supported by an Emergency Use Authorization (EUA) from the FDA.[9,10]

A number of reports have demonstrated promising results of CCP in severe and critically ill COVID-19 patients, albeit not consistently.[8,11-12] The effectiveness of CCP in less than severe cases remains unclear. The aim of the current study was to assess the effectiveness of CCP in both moderate and severe COVID-19 cases compared to the standard treatment alone. The CCP effectiveness was evaluated in terms of time to clinical improvement and hospital mortality, the changes in oxygen saturation and laboratory markers (lymphocytes, neutrophils counts, lactate dehydrogenase [LDH], and C-reactive protein [CRP]).

Patients and Methods

Study design

This prospective multicenter interventional study was conducted in four major tertiary hospitals in Kuwait (Al-Sabah, Farwaniya, Mubarak Al-Kabeer, and Jahra) from May 21 to June 30, 2020, with the last follow-up data collected July 12, 2020. All patients and CCP donors had confirmed SARS-CoV-2 infection by an EUA-approved real-time reverse transcriptase-polymerase chain reaction (RT-PCR) using nasopharyngeal swabs (Cobas 6800 Systems, Roche, Switzerland and Taq Path, Thermo-Fisher Scientific, USA). The CCP donors were tested for SARS-CoV-2 IgG using a CE-marked rapid test (BIOZEK COVID-19 IgG/IgM qualitative test: Inzek International Trading, Apeldoom, the Netherlands).

The study protocol was approved by the Ethics and Research Committee of Kuwait Ministry of Health (#2020/1417). Written informed consent was obtained from all patients or next of

Journal Pre-proof

kin. If the patient was unconscious and next of kin not available, the healthcare proxy provided written informed consent.

Inclusion criteria

We included patients aged ≥18 years with confirmed laboratory diagnosis of SARS-CoV-2 infection and admission diagnosis of COVID-19. Patients <18 years old were enrolled after thorough evaluation and discussion among an interdisciplinary team. Patients were eligible for CCP if they had moderate or severe COVID-19 as determined according to the WHO classification at admission by the treating physician.[9] Patients with moderate disease exhibited clinical signs of pneumonia (fever, cough, dyspnea, fast breathing) and had SpO2 >90% in room air. Patients with severe disease exhibited clinical signs of pneumonia and at least one of the following: respiratory rate >30 breaths/minutes, SpO2<90% in room air, or admission to intensive care unit (ICU) for respiratory support (i.e., non-invasive mechanical ventilation and intubation).

Exclusion criteria

Patients were excluded if they had a contraindication to transfusion (volume overload, history of anaphylaxis to blood products), acute severe multiorgan failure, hemodynamic instability, severe disseminated intravascular coagulopathy (DIC), septic shock, or expected survival of less than 48 hours.

Control sampling procedure

After screening for the inclusion and exclusion criteria, we applied a systematic stratified sampling technique to identify control patients from the COVID-19 national registry. For

Journal Pre-proof

each patient who received CCP, we selected the first two patients with the same disease severity strata admitted on that calendar date from the same participating center.

Standard treatment

Standard treatment was based on our institutional protocol and international guidelines.[13] The majority of patients received antibiotics and low molecular weight heparin. None of our patients received antiviral therapy or hydroxychloroquine. Special therapy (i.e., steroids and/or tocilizumab) was prescribed at the discretion of treating physicians.

Data collection

Clinical and laboratory data were extracted from patient medical records using a standardized data collection sheet. We captured pre-existing medical conditions, including diabetes mellitus, hypertension, and obesity. Specific therapies, such as anticoagulants, antibiotics, steroids, and tocilizumab, was also collected. Complete blood counts (CBCs), CRP, D-dimer, and LDH were also collected on days 1, 3, 7, 11, and 14 of hospitalization. We followed the patients' progress daily from day 1 through day 30 or until discharge, whichever came first. Clinical improvement was defined as a two-grade decrease from hospitalization by assessing the clinical status based on the WHO ordinal scale.[9]

Selection of CCP donors

The CP was collected from individuals who had recovered from RT-PCR-confirmed COVID-19 disease and tested positive for IgG antibodies against SARS-CoV-2. All donors tested positive for SARS-CoV-2 by an EUA-approved RT-PCR test on a specimen collected by nasopharyngeal swab at the time of illness and a positive EUA-approved qualitative serological test for SARS-CoV-2 IgG antibodies after recovery. Donors who tested negative or were positive only for SARS-CoV-2 IgM were excluded. All donors were negative for HLA antibodies. Additional donor eligibility criteria and qualification were based on the American Association of Blood Banks (AABB) standards and the FDA guidance on CCP

Journal Pre-proof

administration, including questionnaires and testing for relevant transfusion-transmitted infections.[10,14] CCP was only collected from individuals who met all donor eligibility requirements according to the United States Code of Federal Regulations (21 CFR 630.10 and 21 CFR 630.15). Pathogen inactivation was also performed for each unit.

CCP administration

A total of 135 patients with moderate to severe COVID-19 were enrolled in this cohort (89 patients with moderate disease and 46 patients with severe disease). All patients were pre-medicated (paracetamol, antihistamine, steroids) according to an institutional protocol. Overall, 107 (79·3%) patients received 2 units of ABO-compatible CCP (each unit containing 200 ml of CCP) 12 hours apart and 28 (20·7%) received 1 unit of CCP according to the treating physician and protocol dosage range (200-400 mL). All patients received CCP within 24 hours of admission. Three patients (2%) had allergic skin reactions that were completely resolved after transfusion.

Statistical analysis

Categorical variables are presented as number and percentage (%). Continuous variables are presented as median and interquartile range (IQR). Pairwise comparisons were performed using Pearson's chi-squared test for categorical variables and Kruskal-Wallis test or Mann-Whitney U test for continuous variables. For the primary end point, time to clinical improvement between the groups before 30 days was right censored at day 30. We used the Kaplan Meier analysis to assess the time to clinical improvement and the log rank test to compare the endpoint among groups. Mixed ordinal logistic regression modeling was used to measure the effect size (odds ratio [OR] and 95% confidence interval [CI]) of CCP on the WHO ordinal scale, stratified by disease severity.

A Cox proportional hazards model was used to assess the overall 30-day clinical improvement. Hazard ratios (HRs) with 95% CIs were reported in the Cox model. For the

Journal Pre-proof

secondary endpoint, we calculated the OR and 95% CI using logistic regression analysis. Variables included in the multivariate Cox proportional hazard and logistic regression models were age, baseline SpO2 < 88%, lymphocyte count <1 x10^9, and CRP.

We also examined whether an interaction occurred between CCP and adjunct therapy (i.e., steroids and/or tocilizumab) that affected the outcomes. We tracked laboratory results, including lymphocyte and neutrophil counts, CRP, D-dimer, and LDH, in addition to oxygen saturation over time. For the analysis of repeated measures, we used a linear fixed model (regression coefficient β with 95% CI) to analyze the effect of CCP on laboratory markers and oxygen saturation at baseline and during the first 14 days of hospitalization.

Missing data were not handled in a specific manner. Statistical analyses were carried out using Stata 14 software (StataCorp, College Station, Texas). Two-sided p-values <0·05 were considered significant.

Results

A total of 368 patients were included in the cohort; 135 received CCP and 233 were in the control group (Figure 1). Demographic and baseline characteristics are shown in Table 1. The median age was 54 (range 15-82) years, and the majority of patients were male (n=304, 82·6%). We found no differences among groups in the baseline characteristics or admission laboratory values, with the exception of baseline CRP, which was significantly higher in the CCP-treated patients with severe disease than other groups.

Primary outcomes

Overall 30-day clinical improvement was observed in 77 (86·5%) of the CCP-treated patients with moderate disease and 106 (68·4%) of corresponding controls (p=0·001). Among those with severe disease, clinical improvement was observed in 28 (60·8%) of the CCP-treated patients and 27 (34·6%) of their control counterparts (p=0·001). The median time to clinical improvement among those with moderate disease was 7 (IQR 4-9) days with CCP treatment and 8 (IQR 6-12) days in the control group (p=0·006), and among those with severe disease

Journal Pre-proof

was 7 (IQR 5-12) days with CCP treatment and 15.5 (IQR 10-20) days in the control group (p=0·003, Figure 2). The distribution of patients in the WHO ordinal scale categories over the 30 days of hospitalization are shown in eFigure1 and eFigure 2 in Supplement 2. For both moderate and severe disease, CCP treatment was associated with a significantly lower score on the WHO ordinal scale compared to the control group on days 7, 14, and 30. On day 7, the score reduction was significant in both the moderate (OR, 0·25 [95% CI 0·13-0·47]) and severe disease groups (OR, 0·33 [95% CI 0·14-0·82]). We also noted a score reduction in both moderate and severe disease on day 14 (OR, 0·17 [95% CI 0·08-0·34] and OR, 0·28 [95% CI 0·11-0·73], respectively) and day 30 (OR, 0·17 [95% CI 0·07-0·36] and OR, 0·11 [95% CI 0·04-0·31], respectively).

In the adjusted Cox model, the overall CCP group had a significantly higher rate of clinical improvement than the control group (HR, 1·9 [95% CI 1·4-2·7]). The effect was seen among both the moderate (HR, 1·9 [95% CI 1·3-2·8]) and severe disease (HR, 2·5 [95% CI 1·2-5·2]) groups (Table 2). There was no significant interaction effects between CCP and steroids (p=0·40), tocilizumab (p=0·12), or steroids plus tocilizumab (p=0·44) on the clinical improvement.

Secondary outcome

Effect of CCP on Mortality

In univariate analysis, the CCP-treated patients in both severity groups had lower mortality rates than the control groups (n=10, 11·4% and n=14, 30·4% versus n=46, 29·7% and n=44, 57·1%; p=0·001 and p=0·006, respectively). In the adjusted model, the risk of mortality was significantly lower in the CCP-treated patients with moderate disease (adjusted OR, 0·27 [95% CI 0·12–0·62]) compared to the control group, but not significantly different in the CCP-treated patients with severe disease (adjusted OR, 0·38 [95% CI 0·14–1·02]) compared to the control group. no significant interaction effects between CCP and steroids (p=0·36 for interaction), CCP and tocilizumab (p=0·56 for interaction), or CCP and steroids plus tocilizumab (p=0·75 for interaction) on mortality.

Journal Pre-proof

Effect of CCP on oxygen saturation and laboratory value kinetics

The effects of CCP on patients' oxygen saturation and laboratory markers over the first 14 days of the hospital stay are shown in Table 3. Relative to baseline, CCP treatment improved oxygen saturation by 5·4% [95% CI 3·3–7·4] on day 1 and 4·1% [95% CI 2·3-5·9] on day 3 in patients with moderate disease, but not among those with severe disease (eFigure 3 in Supplement). Lymphocyte counts increased significantly on days 7 (β=0·46 [95% CI 0·15-0·78]) and 14 (β=0·59 [95% CI 0·11-1·1]) post-hospital admission in the moderate CCP group. Similarly, lymphocyte counts increased on days 11 (β=0·76 [95% CI 0·03–1·5]) and 14 (β=0·98 [95% CI 0·04–1·9]) in the severe disease CCP group (eFigure 4 in Supplement). Total neutrophil counts were not significantly different among the groups at baseline or any other time point (eFigure 5 in Supplement). Relative to baseline, CRP significantly decreased in both the moderate and severe groups at every time point after CCP treatment (p=0·001; eFigure 6 in Supplement). D-dimer was not significantly different between the groups at baseline or in the first 11 days, but the levels were lower 14 days post-admission after CCP in the moderate disease group (eFigure 7 in Supplement). Furthermore, LDH was not significantly different among moderate and severe disease groups at baseline or in the first 14 days, but was lower at day 14 in the overall CCP group (eFigure 8 in Supplement).

Discussion

Currently, no vaccine or specific antiviral treatments are approved for COVID-19 patients. CP is a widely available non-pharmaceutical treatment that has been used with varying degrees of success in prior pandemics, including SARS, MERS, and Ebola.[15–18] In our study, we investigated the effect of CCP on time to clinical improvement, 30-day mortality, changes in oxygen saturation and laboratory values within 14 days of hospital admission in both moderate and severe COVID-19 patients. Many prior studies focused on severe and critically ill patients whereas we included severe cases as well as moderate cases where the risk benefit balance is more delicate. Improved clinical symptoms and mortality among

Journal Pre-proof

patients with severe and critical COVID-19 after CCP transfusion has been previously reported.[8,11] In a randomized clinical trial of CCP in severe and life-threatening COVID-19, Li et al. could not detect a significant reduction in time to clinical improvement within 28 days after CCP treatment.[7] However, the study was terminated early after enrollment of 52 patients who received CCP and 51 in the control group and may have been underpowered to detect significant differences. In contrast, our study included 135 patients in the CCP arm and 233 controls. Another report, concluded that CCP treatment did not reduce mortality and suggested that earlier adminstration of CCP might be beneficial.[12] The fact that patients in our study received CCP within 24 hours of hospital admission may have contributed to improving outcomes. In our study, CCP administration was associated with both a higher rate of and faster time to clinical improvement among patients with moderate and severe disease. The clinical improvement was observed in 80·6% of the CCP group compared to 58·6% of the control group. In addition, median time to clinical improvement in the CCP group was 7 days compared to 10 days in the control group. This is consistent with a prior case series of 10 patients, in which symptoms resolved within the first 72 hours with complete improvement on radiological examination within 7 days post-CCP administration.[19] In the H1N1 pandemic, CP was associated with a significant reduction in mortality, especially if administered early.[20] An exploratory post hoc meta-analysis revealed a significant reduction in the pooled odds of mortality following CP treatment of SARS coronavirus infection and severe influenza compared to placebo or no therapy.[21] Li et al. did not detect a significant reduction in 28-day mortality among CCP-treated patients. [7] In our study, 30-day mortality was significantly reduced in moderate, but not severe, COVID-19 cases. This may imply that CCP is more effective in reducing 30-day mortality in moderate disease, or may be attributed to inclusion of a relatively small number of severe cases. Our results are also consistent with those of a single arm study of 46 patients with moderate to severe disease where 7-day mortality was 6.5% in patients who received CCP compared to the 15% average national statistics and 30% in a concurrent cohort of 23 patients.[22]

Journal Pre-proof

CCP in our study was also associated with significantly improved oxygen saturation and recovery in lymphocyte counts and CRP within 14 days post-CCP treatment. These findings are consistent with recent reports of the effect of CCP.[8,11,23]

Prior studies have associated lower lymphocyte counts and high CRP levels with adverse outcomes in COVID-19 patients.[1,19] In our study, lymphocyte counts started to increase 1 day after CCP transfusion, with a significant increase 7 days post-admission in the CCP group compared to the control group. Furthermore, CRP was remarkably decreased starting day 1 in the CCP group. The improvement of both lymphocyte counts and CRP in our study may be attributed in part to a previously postulated immunomodulatory effect of CCP such as providing passive immunity by blocking inflammatory cytokines, autoantibodies, and complement pathways.[24] CCP may also inhibit inflammatory cascades and immune cell infiltration within the lungs.[25] These effects can clinically be seen as improvement in oxygen saturation and pulmonary radiological lesions.[19]

In our study, oxygen saturation significantly increased in CCP-treated patients during the first 72 hours. This finding is consistent with earlier studies reporting associations between CCP and improved oxygen saturation.[8,23]

All CCP recipients tolerated the transfusion except for 3 (2%) who had minor allergic skin reactions, which resolved completely without preventing administration of the full CCP dose. A recent study of early safety indicators for CCP reported 36 cases (0·72%) with serious adverse effects (SAEs).[26] The incidence of severe allergic reaction in that study was 0·06%, and the incidence of less than severe allergic reactions was not reported.

Our study has a number of limitations, including a lack of randomization. However, randomization was not feasible during the pandemic in our region. The administration of CCP within 24 hours of hospital admission was intended to limit selection bias. Another limitation is that at the time of analysis some patients were still hospitalized which may have biased the results. The clinical management of a potentially life-threatening illness with an unpredictable clinical course was the main contributor to this limitation. In addition, there was not an approved standard protocol for the treatment during our study, especially regarding

Journal Pre-proof

steroid and tocilizumab use. However, this stems from the lack of universally established treatments for COVID-19. We did not observe an interaction between the administration of either/both of the drugs and the observed effect of CCP in our patients. Finally, we were not able to determine the titer of SARS-CoV-2 IgG antibodies in CCP donors or whether the detected antibodies were neutralizing antibodies due to a lack of these tests in Kuwait at the time of the study. We did exclude any donors who were negative for IgG antibodies. Not performing additional antibody characterizing tests could only lead to underestimation of the benefit of this therapeutic modality due to potential inclusion of CCP units with low IgG levels or antibodies of limited neutralizing capacity. In addition, in many parts of the world, including some developed countries, there is a striking shortage of testing for COVID-19 in general, and particularly for more specialized tests, such as neutralizing antibodies.

To the best of our knowledge, this study is the first to investigate the effectiveness and feasibility of CCP in COVID-19 patients in the Middle East. Although we did not perform an a priori sample size calculation, 135 patients in the CCP group demonstrated significant differences. The involvement of multiple centers supports the generalizability of the results. Throughout the worldwide lockdown, the supply of CCP was consistently available in Kuwait, which offers free access to this therapeutic intervention. This contrasts pharmaceuticals subject to supply chain limitations. Availability is crucial in the Middle East, which relies on pharmaceutical manufacturing that is currently concentrated in Western countries.

Conclusion

In our prospective interventional study including patients with moderate and severe COVID-19, CCP administration was significantly associated with improved clinical outcomes. Thirty-day survival was significantly improved in the moderate group. In addition, administration of CCP in both moderate and severe cases was also associated with improved oxygen saturation and recovery of lymphocytes and CRP. Larger multicenter controlled randomized trials to further evaluate the effectiveness of CCP in COVID-19 patients with particular emphasis on CCP donor qualification based on neutralizing antibody levels are warranted.

Abstract

Background: Convalescent plasma (CP) is being used as a treatment option in hospitalized patients with COVID-19. Till date, there is conflicting evidence on efficacy of CP in reducing COVID-19 related mortality.

Objective: to evaluate the effect of CP on 28-day mortality reduction in patients with COVID-19.

Methods: We did a multi-center, retrospective case control observational study from 1st May 2020 to 31st August 2020. A total of 1079 adult patients with moderate and severe COVID-19 requiring oxygen, were reviewed. Of these, 694 patients were admitted to ICU. Out of these, 333 were given CP along with best supportive care and remaining 361 received best supportive care only.

Results: In the overall group of 1079 patients, mortality in plasma vs no plasma group was statistically not significant (22.4% vs 18.5%; p = 0.125). However, in patients with COVID-19 admitted to ICU, mortality was significantly lower in plasma group (25.5% vs 33.2%; p = 0.026). This benefit of reduced mortality was most seen in age group 60 to 74 years (26.7% vs 43.0%; p = 0.004), driven mostly by females of this age group (23.1% vs 53.5%; p = 0.013). Significant difference in mortality was observed in patients with one comorbidity (22.3% vs 36.5%; p = 0.004). Moreover, patients on ventilator had significantly lower mortality in the plasma arm (37.2% vs 49.3%; p = 0.009); particularly so for patients on invasive mechanical ventilation (63.9% vs 82.9%; p = 0.014).

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

Conclusion: The use of CP reduced mortality in COVID-19 elderly patients admitted in ICU, above 60 years of age, particularly females, those with comorbidities and especially those who required some form of ventilation.

Key words: Convalescent plasma therapy, COVID-19, ICU cases, Mortality, Subgroup analysis

Introduction

Severe acute respiratory syndrome coronavirus 2 (SARS-COV-2), the novel coronavirus causing COVID-19, originated from Wuhan, China and has spread rapidly across the globe[1]. As no definitive treatment options are currently available for COVID-19, researchers the world over have been investigating a variety of drugs like azithromycin, hydroxychloroquine, remdesivir, Tociluzimab and dexamethasone[2-6]. Some of these are repurposed drugs and have been approved by regulators of various countries to be used as "Emergency Use Approval" (EUA) or "off label" medication[7].

Convalescent plasma (CP) has been used as a passive source of antibodies against various bacterial (tetanus and diphtheria) and viral diseases (poliomyelitis, measles, mumps)[8] and influenza A H1N1[9]. CP was also considered in earlier pandemics of Spanish flu, West Nile Virus, Middle East Respiratory Syndrome (MERS), Severe Acute Respiratory Syndrome (SARS), and more recently Ebola virus[10,11,12]. The convalescent plasma therapy (CPT) for COVID-19 has also been recently approved by US FDA and Indian Central Drugs Standard Control Organization[13]. It has been approved by the Ministry of Health and Family Welfare (MoHFW), Govt. of India, as "off label" use in patients with moderate and severe COVID-19 who are not improving and have increasing oxygen requirement despite use of steroids[7].

Evidence suggests that CP contains receptor binding domain specific antibodies which have potent antiviral activity[14-15]. Use of convalescent plasma, is known to be a well-tolerated with only a few easily managed adverse effects[16].

There have been, till date, few larger randomized controlled trials (RCT)[17,18], some retrospective observational studies[16,19,20] and many small case reports[21,22,23] on the benefits of CPT in COVID-19 patients with conflicting results. There is still no clarity whether CPT offers mortality benefit and, if yes, in which category of COVID-19 patients. The present study was designed to answer some of these questions.

Patients and Methods

Study Design

This is a multicentre, retrospective, observational case control study. COVID-19 patients admitted at various tertiary care teaching hospitals in Delhi of the same network, with electronic heath records (EHR), were included. Clinical and laboratory data were retrieved from EHR. Patients admitted from 01 May 2020 to 31 Aug 2020, with moderate and severe and / or

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

life threatening COVID-19, who needed oxygen therapy, were included. Of a total of 1249 such patients admitted during this period, 170 patients were excluded due to unavailability of sufficient clinical data. Remaining 1079 patients were included in the final analysis. All patients in either arm received various treatments as per physician discretion, institutional protocol or national guidelines for the management of COVID-19,issued by the government from time to time. A variety of medicines were used in these patients and included hydroxychloroquine (HCQ), azithromycin, doxycycline, ivermectin, remdesivir, other broad spectrum antibiotics, steroids (methylprednisolone or dexamethasone), tocilizumab and oxygen support/ventilation as required. Figure 1 shows the CONSORT diagram. All were followed for 28 days after discharge by tele-calling. The detailed analysis was performed on 694 patients admitted to ICU – 333 of these received plasma in addition to best supportive care and the other 361 were on best supportive care only.

Majority of COVID-19 patients who were given CP came from one major hospital complex, which contributed to 239 out of 333 (71.8%) patients. The physicians in this hospital had started using CP from very early days of COVID-19 outbreak in India and, because of this, significant use was observed in this hospital complex. Other hospitals, where either the usage of CP or availability of CP, was low, contributed 28.2% of plasma cases and a greater number of no plasma cases. Otherwise, the standard of care in all hospitals, across the network remained uniform.

Inclusion Criteria

Eligible patients included adults (> 18 years) with evidence of SARS-COV-2 infection by RT-PCR test of nasopharyngeal or oropharyngeal swab. Criteria for classifying patients into moderate and severe category were as per the clinical management protocols of MoHFW[7].

Moderate disease: pneumonia with no signs of severe disease, and having one or more:

- Dyspnoea, fever and cough
- SPO2 < 94% on room air
- Respiratory rate > 24 / minute

Severe disease: patient having one or more of the following conditions:

- Clinical signs of pneumonia plus one of the following: respiratory rate > 30/min or severe respiratory distress requiring ventilation or SPO2 < 90% on room air.
- ARDS (new onset bilateral opacities & SpO2 / FiO2 ≤ 315)
- Sepsis
- Septic shock

Based on these criteria, we selected only patients who needed oxygen therapy.

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

Donor Selection Criteria[24]

Donors had to meet the following criteria: 1) prior diagnosis of COVID-19 documented by a laboratory test, 2.a) complete resolution of symptoms at least 28 days prior to donation or 2.b) complete resolution of symptoms at least 14 days prior to donation. In such cases, if the patient has been discharged without negative RT-PCR for COVID-19, 2 samples of naso- and oropharyngeal swab have to be sent for RT-PCR for COVID-19, collected 24 hours apart and negative result ascertained before considering the recovered patients as a potential donor. 3) only males and nulliparous female donors of weight > 55 kg, 4) Donor with Hb>12.5g/dL and platelet count > 150 000 per microliter of blood and TLC within normal limits, 5) HIV, HBV and HCV by serology and NAT negative patients, 6) syphilis and malaria negative donors and 7) total serum protein > 6 g/dL all donor selection criteria for blood donation were followed as per Drugs and Cosmetics (second Amendment) Rules, 2020[25] .

In the absence of a standard viral neutralization test, and limited possibility of assessment of neutralizing antibody titres of > 1:640, we adopted a policy of the use of an assay to assess quantitative antibodies of anti-SARS COV2 antibodies prior to harvest of CP from the eligible donors. Antibody testing was done prospectively in donors from mid June onwards, prior to which donor samples were stored at -80° C and were retrospectively tested. For the 36 donors who's assays were done retrospectively, 12% were found have inadequate antibodies. In our larger centre, the available platform which we used was an FDA approved (Diaosorin), Quantitative IgG antibody assay against the S1&S2 protein of SARS COVID-2 virus. The cut-off of 15 AU/ml was taken for a positive result which is equivalent to 1:40 Plaque Neutralization antibody & 80 AU/ml is equivalent to 1:160 plaque neutralizing antibody assay. In the other two smaller centres, Ortho Clinical Diagnostic Vitros Anti SARS-COV-2 IgG Chemiluminescent Immuno Assay was used. The Ortho Clinical IgG is a qualitative assay. Result of this assay are based on the sample signal-to-cut-off (S/CO) ratio, with values <1.0 and ≥ 1.0 corresponding the Negative and Positive results.

Volume of donated plasmas was 400 ml. The first 200 ml (one unit) plasma was infused over one to one and half hours and if the patient did not show any improvement after 24 h, based on the decision of responsible physician, another unit of plasma was administered.

Exclusion Criteria

Patients not requiring oxygen therapy were excluded. Pregnant and lactating mothers were also excluded.

Objectives

Primary objective of the study was to study 28-day mortality in patients who received convalescent plasma therapy versus those who did not.

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

Secondary objectives were to assess if CP reduced the chances of patients going on to invasive ventilation and whether it offered any mortality benefits in critically ill patients on ventilator and vasopressors.

Statistical Analysis

Baseline characteristics such as age, gender, and comorbidities in the plasma and no plasma group were compared by chi-square test. The number of patients on invasive and non-invasive ventilators and mortality in plasma and no plasma group in various subgroup of patients were also compared with chi-square test. P-value < 0.05 was considered statistically significant. SPSS21 was used for statistical calculations. The sample size in the two groups was adequate to detect a difference of at least 10% in overall mortality between plasma and no plasma group with power of 80% when the mortality in ICU cases in the standard care group is 25%.

Results

The mean (SD) age of patients was 60.1 $\pm$ 12.1 years vs 58.9 $\pm$ 13.8 years in plasma vs no plasma group (p = 0.231). However, the age-gender distribution and the comorbidity-gender distribution was different for the following subgroups (Table I).

Males were significantly higher in the plasma group (80.2% vs 72.3%) (p = 0.015) and less of younger age (12.3% vs 19.2%) (p = 0.023). There were more females in the plasma group with multiple comorbidities, than in the no plasma group. Specific comorbidities examined were hypertension (HTN), diabetes mellitus (DM), coronary artery disease (CAD) and hypothyroidism. These were the most commonly occurring comorbidities in these cases. All other comorbidities (CKD, cancer, stroke, etc.) were reported in less than 10% cases. Hypertension was more common in plasma group (54.7% vs 43.5%, p = 0.003) and CAD less common (7.5% vs 14.1%, p = 0.005). However, the difference in mortality in these subgroups was not statistically significant.

The percentage of patients on ventilator, invasive and non-invasive, and on vasopressor were not significantly different (minimum p = 0.166) between the two groups (Table 2).

For the total of 1079 patients on oxygen, overall mortality in patients was 22.4% in the plasma group and 18.5% in the no plasma group (p = 0.125). Total 694 (64.3%) patients required transfer to intensive care unit (ICU). Three hundred thirty-three (48.0%) patients received convalescent plasma in addition to the best supportive care and the remaining 361 (52.0%) were on best supportive care only. In the ICU patients, mortality was 25.5% vs 33.2% in plasma vs no plasma group (p = 0.026). Reduced mortality in plasma group was particularly seen in patients of age 60–74 years (26.7% vs 43.0%, p = 0.004), driven mostly by females of this age group (23.1% vs 53.5%, p = 0.013).

In one of the main hospitals, where the experience with the use of CP was maximum, out of a total of 342 patients in ICU, 239 (69.8%) received plasma while 103 (30.1%) did not. Overall

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

mortality in the plasma group was 49/239 (20.5%) as compared to 36/103 (36.9%) in the no plasma group (p = 0.0014).

Significant difference in mortality was observed in patients with one comorbidity (22.3% vs 36.5%, p = 0.004). This also was primarily due to females in this subgroup (mortality 6.7% vs 49.1%, p < 0.001) in the plasma vs no plasma group (Table 3). We observed a similar reduction in mortality in patients with 2 comorbidities (35.1% vs 49.2%) but this did not reach statistical significance (p=0.099). The mortality in patients with specific comorbidity such as hypertension, diabetes and coronary artery disease were not different (least p = 0.099) but was significantly different in patients with hypothyroidism (19.0% vs 42.4%, p = 0.027). Of 38 women of age 60–74 years with one comorbidity, 12 were in plasma group and 26 in the no plasma group. Only one of these (8.3%) died in the plasma group and 13 (50.0%) in the no plasma group (p = 0.013).

Out of a total of 694 patients with severe COVID-19 in ICU, 101 (14.6%) patients worsened on non-invasive ventilation (NIV) and needed to be shifted to invasive ventilator. Fifty-four (53.46%) of these patients were given CP. There were 316 (45.5%) patients, who remained on NIV only and out of these 157 (49.6%) received CP. Overall, CP did not reduce the chances of being put on invasive ventilator from NIV (p = 0.508).

Patients on ventilator had significantly lower mortality in plasma arm (37.2% vs 49.3%, p=0.009) (Table 4). This was particularly so for patients on invasive ventilator (IV) with mortality 63.9% vs 82.9% (p = 0.014), respectively in plasma vs no plasma group. Patients on an invasive ventilator and on vasopressor had high (almost 90%) mortality in both the groups (Table 4).

Twenty-six out of 333 (7.8%) received second unit of CP, as per the physician's decision. Ten of these patients (38%) died.

Safety of CPT

Convalescent plasma infusion was largely safe and no major adverse effects were observed in any of our patients. Two patients with minor allergic reactions (rashes) were reported to the Blood Bank Officer.

Discussion

The current study was undertaken to evaluate the effectiveness of CP in patients with moderate and severe COVID-19 disease. To date, this is the largest retrospective case control study from India, presently reporting world's second largest number of COVID-19 cases.

There are a number of reports comprising small number of patients treated with CP[21,22,23] from different countries across the world. Duan et al. were first to report benefit of CP in a small cohort of 10 patients with improvement in all 10 patients and undetectable viral load in 7/10 patients[21]. In contrast, Zeng et al. reported mortality in 5/6 patients who received CP[26]. Table 5

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

summarizes the literature review of relevant studies on CP, with more than 100 patients and / or RCTs.

The results of our study are quite different from that of the only other large-scale study from India - a multicentre prospective RCT PLACID trial, which included 464 patients of moderate severity COVID-19, from 39 different hospitals across India[17]. This study did not find any difference in mortality between plasma vs no plasma group (15% vs 14%), respectively. However, this study did not include very severe or life threatening COVID-19 patients. Even in our study, if we see the overall cohort of 1079 patients (moderate and severe), CP did not have any mortality benefit (22.4% vs 18.5%; p = 0.125). The benefit emerged only in more critically ill patients of COVID-19 who were in ICU (25.5% vs 33.2%; p = 0.026). This happened despite plasma group had more elderly males, where anyway the mortality is expected to be higher[27]. Also, the main hospital, which had maximum experience with the use of CP, showed a highly significant mortality benefit in severe COVID-19 (20.5% vs 36.9%; p = 0.0014).

A similar study involving moderately ill COVID-19 patients by Abolghasemi et. al, showed that significantly higher number of patients who received CP were discharged from the hospital versus control (98.2% vs 78.7%)[28]. They reported that CP significantly reduced need for mechanical ventilation in treatment versus control group (7% vs 20.3%). All-cause mortality in CP group was 14.8% versus 24.3% in control arm in the study but this was not statistically significant (p = 0.09). RCT by Ling Li et al. also showed no significant difference in time to clinical improvement or in 28-day mortality between patients who received CP vs control[18].

Study by Xia et al. also showed that there was less likelihood of patient who received CP to be transferred to ICU as compared to those who did not receive CP (2.4% vs 5.1%)[20]. Our study did not show any benefit with CP, in terms of reducing the chances of patients going onto invasive ventilation from NIV. The Indian PLACID trial also showed no benefit of CP in terms of total and post enrolment duration of respiratory support, and proportion of patients who had to be put on invasive ventilation and those needing vasopressor support[17]. In the study by Altuntas et al., the duration of stay in ICU, rate of mechanical ventilation and vasopressor requirement were lower in the CP group versus control (p = 0.001, p = 0.02, p = 0.001 respectively)[29]. They however, found no statistically significant difference in the fatality rate between the CP and control groups (24.7% vs 27.7%, p = 0.150). In our study, however patients on ventilator had significantly lower mortality in plasma arm as compared to no plasma arm (37.2% vs 49.3%, p = 0.009). This was particularly so for patients on invasive ventilator with mortality 63.9% and 82.9% (p = 0.014) in plasma and no plasma arm, respectively.

The patient outcome in the current study was quite similar to the study by Salazar et al. where they found significant mortality reduction in severe and life threatening COVID-19 patients (p = 0.047) especially when CP was given within 72 hours of admission[30].

In our study, we found maximum benefit of CP in ICU patients, in the age group 60-74 years, where the mortality in the plasma group was 26.7% versus 43% in the no plasma group (p=

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

0.004). Similar findings were reported by Rogers et al. wherein a subgroup analysis of patients above 65-years-old or greater who received CP demonstrated a significantly increased hospital discharge rate among these patients (RR 1.86, 95% CI 1.03-3.36)[31].

Significant difference in mortality between plasma and no plasma group was also observed in patients in our study with one comorbidity largely driven by females. This finding has not been reported in literature so far. The mortality in patients with specific comorbidity such as HTN, DM and CAD was not different (minimum p = 0.099) but was significantly different in patients with hypothyroidism (19% vs 42.4%, p = 0.027). This needs further investigation.

Klassen et al. aggregated patient outcome data from various RCTs, matched-control, case series and case report studies and found that CP exhibited a 51% reduction in mortality rate compared to patients receiving standard treatments (19% vs. 29% mortality; OR:0.49, 95% CI: 0.37, 0.64, p< 0.001)[32].

Our study showed mortality benefit of CP in severely ill COVID-19 patients requiring some form of ventilation and in the age group >60 years, especially women with 1-2 medical comorbidities. We do not know the exact mechanism of action of CP in COVID-19 but it seems that plasma therapy played a significant role in reduction of mortality in the highly vulnerable patient population of elderly and on ventilator. Perhaps a little push by convalescent plasma in this segment of patients was able to tilt the balance towards recovery.

Limitations of the study

It is a retrospective study. During the study duration, patients received several treatments such as HCQs, remdesevir, ivermectin, azithromycin, steroids (dexamethasone or methylprednisolone), tociluzimab depending on prevailing guidelines at those time points and at treating physician's discretion. Majority of patients in plasma arm were recruited at one centre while no plasma arm patients were at other hubs. We also do not have information if some of the patients had already developed adequate antibodies when CP was performed. These limitations notwithstanding, we are able to identify a subset of patients with COVID-19 who are likely to benefit from CP.

Conclusions

The use of convalescent plasma reduced mortality in severe COVID-19 elderly patients, above 60 years of age, particularly females, those with comorbidities and especially those who require some form of ventilation. This beneficial effect was lost when the entire cohort of patients across varying severity of illness was compared. Plasma did not seem to offer any mortality benefit in patients of moderate severity or those who were terminally ill. Further research into the mechanism of actions of CP in COVID-19 may help predict the good responders.

Table 5. Review of various studies (larger RCTs and/or > 100 matched cases) on effectiveness of Convalescent Plasma in COVID-19

Ref	Number of patients	Study	Patient population	Antibody titre used	Results	Adverse Effects	Author Conclusions	Our comments
Ling Li et al.[18]	103	Open label RCT, multicentre	23 vs 22 Severe 29 vs 29 Life-threatening COVID-19	1:640	No significant difference in time to clinical improvement or in 28 days mortality between patients who received CP versus control	Chills and rashes -1 shortness of breath, cyanosis, and severe dyspnea -1	CP not effective	Not powered to predict the difference
Abolghasemi H et al.[28]	189 115 in plasma group and 74 in control group	Multicentre nonrandomized clinical study	Moderate severity	Antibody titer cut off > 1.1 using semi quantitative ELISA and Rapid strip test	CP reduced all cause mortality in treatment group compared with control group (14.8% vs 24.3%); however this was not statistically significant (p=0.09). it had a significant impact of length of stay (p=0.002) and need for intubation (p=0.006)		CP effective	Control group was much smaller and had milder cases
Salazar E et al.[30]	136 cases and 251 controls	Prospective propensity matched study	Severe and/or life threatening COVID-19	Anti-RBD IgG titre of 1:1350	Significant reduction (p= 0.047) in mortality within 28 days, specifically in patients transfused within 72 hours of admission with CP with anti-RBD IgG titre of > 1:1350		Transfusion of high anti-RBD IgG titre CP early in hospitalisation reduces mortality	
Xia X et al.[20]	138 cases and 1568 controls	Retrospective observational study	Severe or critical COVID-19		Mortality in CP group was 2.2% as compared to 4.1% in non CP group also from CP group, only 2.4% got shifted to ICU whereas in non CP group, 5.1% patients got ICU transfer	3 patients had minor allergic reactions (pruritus or erythema) during transfusion	Patients with SCSS > 5 before therapy showed no improvement after CP.	Authors classified patients who were given CP into responders, partial responders and nonresponders.
Altuntas F et al.[29]	Cases 888 Control 888	Retrospective case control study	Severe and critically ill COVID-19	IgG antibody not routinely done	Duration in ICU, rate of mechanical ventilation support and vasopressor support were lower in CP group (p = 0.001, p = 0.02, p = 0.001, respectively).	Not available		Antibody titres of plasma donors were not available

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

					CFR was 24.7 in CP group and 27.7 in control group (p = 0.15)			
Agarwal A et al & PLACID trial collaborators[17]	Cases: 235 Controls: 229	Open label parallel are phase II Multicentre randomized controlled trial	Moderately ill COVID- 19 patients	Nearly 2 / 3rd of donor had NAb titre > 1:20 with a median titre of 1:40	Mortality in intervention arm was 14.5% vs 13.5% in control arm (odd ratios was 1.06). There was no difference in the 2 arms with respect to duration of respiratory support, proportion of patient requiring invasive ventilation and vasopressor support	Minor adverse event of pain, chills, nausea in one patient; fever and tachycardia in 3 patients; dyspnoea and IV catheter blockage in 2 patients each. Mortality was assessed as possibly related to CP in 3 patients (1.3%).	CP not effective	Three reported cases of mortality related to CP raised a significant concern regarding safety profile of CP.
OUR STUDY	1079 (total cases in ward and ICU) In ICU : 694 Plasma group in ICU :333 No plasma group in ICU : 361	Retrospective case control observational study	Moderate and Severe COVID-19	Quantitative IgG antibody assay with cut off 15 AU/ml equivalent to 1:40 plaque neutralization antibody	Overall no statistically significant difference in mortality between CP and non CP group (22.4% vs 18.5%; p=0.125. However, significantly reduced mortality in COVID-19 patients admitted in ICU (25.5% vs 33.2%; p=0.026)especially in age group 60-74 (26.7% vs 43%; p=0.004), females (23.1% vs 53.5%; p=0.013), those with one comorbid medical condition(22.3% vs 36.5%; p=0.004) and on invasive mechanical ventilation (63.9%vs 82.9%; p =0.014)	2 patients had mild allergic reaction (rashes) during plasma transfusion	Highest mortality benefit with CP seen in COVID-19 patients above 60 years of age, admitted in ICU, especially females and those on ventilator and having medical comorbid conditions.

Introduction

Coronavirus disease (COVID-19) pandemic has started to affect Saudi Arabia in the beginning of March 2020 and is expected to cause significant morbidity to many patients, especially to elderly, who might require intensive care unit (ICU) support to survive as its lethality increases with the increasing age. Recent publications suggested the benefit of utilizing convalescent plasma from recovered donors as a therapeutic approach in treating COVID-19 patients. Convalescent plasma could provide our first-line defense for people with COVID-19, especially those who are older and at a much higher risk for complications.. therefore, we developed a national protocol to investigate the safety, benefit and applicability at larger scale and at different health care

complications; therefore, we developed a national protocol to investigate the safety, benefit and applicability at larger scale and at different health care facilities in Saudi Arabia (KSA).

Objectives

Primary endpoints are:

1. ICU (or designated area for critical patients) length of stay
2. Safety of convalescent plasma

Secondary endpoints included:

1. 30 days mortality
2. Number of days on mechanical ventilation
3. Days to clinical recovery

Method

Eligible convalescent plasma donors will be invited to participate in trial. The arrangement for plasmapheresis will start after obtaining donor informed consent. The collected plasma will be treated with pathogen reduction system. The convalescent plasma units will be labelled, stored and shipped as per the standard transfusion medicine protocols. It will be used only for eligible patients' "recipients" as per the following eligibility criteria:

1- Inclusion criteria:

- Confirmed case of SARS-CoV-2 infection with POSITIVE rRT PCR test
- 18 or older
- Must have been requiring ICU care or severe or immediately life-threatening care (any one of the following):
    1. Patient requiring ICU care/admission.
    2. Severe disease is defined as:
        a. Dyspnea
        b. Respiratory frequency ≥ 30/min
        c. Blood oxygen saturation ≤ 93%
        d. Partial pressure of arterial oxygen to fraction of inspired oxygen ratio < 300, and/or Lung infiltrates > 50% within 24 to 48 hours
    3. Life-threatening disease is defined as:
        a. Respiratory failure
        b. Septic shock, and/or
        c. Multiple organ dysfunction or failure

2- Exclusion criteria:

- Negative or non-conclusive test COVID-19 rRT PCR test
- Mild symptoms
- Hospitalization not requiring ICU care/admission

Eligible Patients will be infused with the convalescent plasma (200-400 ml / treatment dose) at least once & if possible, daily, for up to 5 sessions. Other supportive and therapeutic measures should continue according to the locally approved protocols with due diligence.

Sample size was calculated with 80% power and 5% level of significance based on the recently published data to detect statistical difference in the study outcome. Therefore, we plan to recruit total of 575 patients.

- Convalescent plasma Recipient Group:
    - 115 patients (recipients) who have COVID 19 as per the inclusion criteria.
- Comparative control Group:
    - 460 Patients who are eitherCOVID 19 historical control or only consent for sharing their clinical and laboratory data

Matching for age, gender, Hypertension, Diabetes and intubation status were done based on the propensity score. Continuous variables will be presented as the median and interquartile range (IQR). Statistical software SPSS 24.0 will be used. Demographic, Clinical, imaging and laboratory information of all enrolled patients will be retrieved from the hospital electronic/paper records system to be used for the outcomes analysis.

Results

22 sites across KSA that participated in the study. Tertiary, secondary, academic and non-academic centers participated (real world data). There were no unusual safety issues related to convalescent plasma infusion since all mortalities in the plasma group were not related to plasma infusion which represent similar finding from other the published international reports. Keeping in-mind that our data is still maturing, 30 survival probability in the plasma group was 69% compared to 56% in the comparative group (p value = 0.066) (figure-1). This benefit to seem to be more noticeable in the COVID-19 cases who did not meet the criteria for life-threatening disease (figure-2).

Conclusion

Conclusion

Our study supports the safety of convalescent plasma in treating COVID-19 patients. Patients who are in the category of life-threating/end organs failure do not seem to benefit. There might be a benefit in the other subgroups.

Figure-1: Survival Probability between Convalescent Plasma to Treat Severe COVID-19 and matched comparative patients

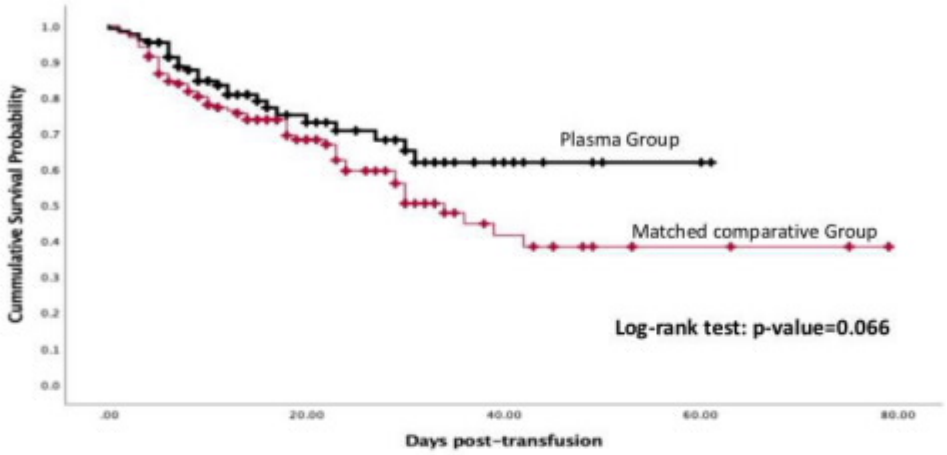

Figure-2: Survival Probability for Convalescent Plasma recipients patients among one of the three inclusion criteria (3 subgroups)

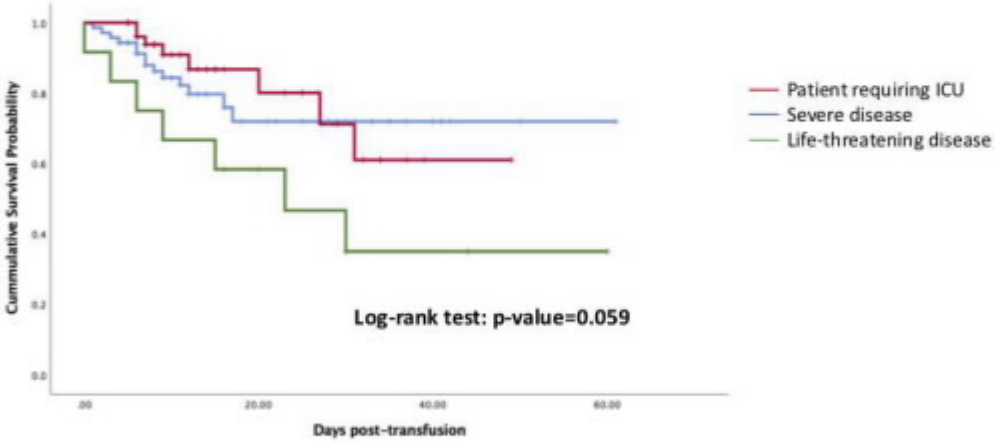

Disclosures: No relevant conflicts of interest to declare.

Highlights

- Convalescent plasma is adjunct treatment in COVID-19 moderate and severe disease.
- Clinical improvement is noticed in COVID-19 disease after convalescent plasma.
- Mortality is significantly reduced after COVID-19 convalescent plasma treatment.

Abstract

Objective: To study the effectiveness of CCP therapy for moderate and severe COVID-19 disease patients in Kuwait.

Methods: This non-randomized prospective cohort study was conducted from May 21, 2020, to June 30, 2020, at four major tertiary hospitals in Kuwait. CCP was administered to 135 patients. The control group comprised 233 patients who received standard treatment. All patients (N=368, median age 54 [range 15-82] years) had laboratory-confirmed SARS-CoV-2 infection and either moderate or severe COVID-19 disease.

Journal Pre-proof

Results: CCP treatment was significantly associated with a higher rate of clinical improvement in patients with moderate or severe disease. Among those with moderate COVID-19 disease, time to clinical improvement was 7 days in the CCP group versus 8 days in the control group (p=0·006). For severe COVID-19 disease, time to clinical improvement was 7 days in the CCP group versus 15.5 days in the control group (p=0·003). In the adjusted analysis, the CCP-treated patients with moderate disease had significantly lower 30-day mortality. Compared to the control group, oxygen saturation improved within 3 days of CCP transfusion, and lymphocyte counts improved from day 7 in patients with moderate disease and day 11 in patients with severe disease. Furthermore, C-reactive protein declined throughout the first 14 days after CCP transfusion. None of the CCP patients developed a serious transfusion reaction.

Conclusions: The data show that administration of CCP is a safe treatment option for patients with COVID-19 disease, with a favorable outcome in the rate and time to clinical improvement.

Keywords: convalescent plasma, COVID-19, SARS-CoV-2, pneumonia, clinical improvement, mortality.

Introduction

The novel coronavirus disease of 2019 (COVID-19) pandemic is considered one of the greatest global public health crises since the 1918 influenza pandemic.[1] COVID-19 is caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), a single-stranded RNA virus that belongs to *coronaviridae*.[2,3] The clinical spectrum of infection is broad, ranging from asymptomatic to severe pneumonia, multiorgan failure, and death. Due to the absence of established antiviral treatment for COVID-19, the historical choice of therapeutic convalescent plasma (CP) was globally appealing, especially with its prior success against RNA viruses.[1] CP has been proposed not only to neutralize the pathogen, but provide passive immunomodulatory properties that allow the recipient to control the

Journal Pre-proof

exaggerated inflammatory cascade.[4,5] However, the mechanism of action of therapeutic CP remains unclear. Reports from open label trials and case series suggest that plasma collected from convalescent COVID-19 patients is safe to administer and may be effective in treating patients with COVID-19.[6–8] Therefore, the World Health Organization (WHO) and United States Food and Drug Administration (FDA) have issued guidelines for the usage of COVID-19 convalescent plasma (CCP) and standardized donor selection, which was further supported by an Emergency Use Authorization (EUA) from the FDA.[9,10]

A number of reports have demonstrated promising results of CCP in severe and critically ill COVID-19 patients, albeit not consistently.[8,11-12] The effectiveness of CCP in less than severe cases remains unclear. The aim of the current study was to assess the effectiveness of CCP in both moderate and severe COVID-19 cases compared to the standard treatment alone. The CCP effectiveness was evaluated in terms of time to clinical improvement and hospital mortality, the changes in oxygen saturation and laboratory markers (lymphocytes, neutrophils counts, lactate dehydrogenase [LDH], and C-reactive protein [CRP]).

Patients and Methods

Study design

This prospective multicenter interventional study was conducted in four major tertiary hospitals in Kuwait (Al-Sabah, Farwaniya, Mubarak Al-Kabeer, and Jahra) from May 21 to June 30, 2020, with the last follow-up data collected July 12, 2020. All patients and CCP donors had confirmed SARS-CoV-2 infection by an EUA-approved real-time reverse transcriptase-polymerase chain reaction (RT-PCR) using nasopharyngeal swabs (Cobas 6800 Systems, Roche, Switzerland and Taq Path, Thermo-Fisher Scientific, USA). The CCP donors were tested for SARS-CoV-2 IgG using a CE-marked rapid test (BIOZEK COVID-19 IgG/IgM qualitative test: Inzek International Trading, Apeldoom, the Netherlands).

The study protocol was approved by the Ethics and Research Committee of Kuwait Ministry of Health (#2020/1417). Written informed consent was obtained from all patients or next of

Journal Pre-proof

kin. If the patient was unconscious and next of kin not available, the healthcare proxy provided written informed consent.

Inclusion criteria

We included patients aged ≥18 years with confirmed laboratory diagnosis of SARS-CoV-2 infection and admission diagnosis of COVID-19. Patients <18 years old were enrolled after thorough evaluation and discussion among an interdisciplinary team. Patients were eligible for CCP if they had moderate or severe COVID-19 as determined according to the WHO classification at admission by the treating physician.[9] Patients with moderate disease exhibited clinical signs of pneumonia (fever, cough, dyspnea, fast breathing) and had SpO2 >90% in room air. Patients with severe disease exhibited clinical signs of pneumonia and at least one of the following: respiratory rate >30 breaths/minutes, SpO2<90% in room air, or admission to intensive care unit (ICU) for respiratory support (i.e., non-invasive mechanical ventilation and intubation).

Exclusion criteria

Patients were excluded if they had a contraindication to transfusion (volume overload, history of anaphylaxis to blood products), acute severe multiorgan failure, hemodynamic instability, severe disseminated intravascular coagulopathy (DIC), septic shock, or expected survival of less than 48 hours.

Control sampling procedure

After screening for the inclusion and exclusion criteria, we applied a systematic stratified sampling technique to identify control patients from the COVID-19 national registry. For

Journal Pre-proof

each patient who received CCP, we selected the first two patients with the same disease severity strata admitted on that calendar date from the same participating center.

Standard treatment

Standard treatment was based on our institutional protocol and international guidelines.[13] The majority of patients received antibiotics and low molecular weight heparin. None of our patients received antiviral therapy or hydroxychloroquine. Special therapy (i.e., steroids and/or tocilizumab) was prescribed at the discretion of treating physicians.

Data collection

Clinical and laboratory data were extracted from patient medical records using a standardized data collection sheet. We captured pre-existing medical conditions, including diabetes mellitus, hypertension, and obesity. Specific therapies, such as anticoagulants, antibiotics, steroids, and tocilizumab, was also collected. Complete blood counts (CBCs), CRP, D-dimer, and LDH were also collected on days 1, 3, 7, 11, and 14 of hospitalization. We followed the patients' progress daily from day 1 through day 30 or until discharge, whichever came first. Clinical improvement was defined as a two-grade decrease from hospitalization by assessing the clinical status based on the WHO ordinal scale.[9]

Selection of CCP donors

The CP was collected from individuals who had recovered from RT-PCR-confirmed COVID-19 disease and tested positive for IgG antibodies against SARS-CoV-2. All donors tested positive for SARS-CoV-2 by an EUA-approved RT-PCR test on a specimen collected by nasopharyngeal swab at the time of illness and a positive EUA-approved qualitative serological test for SARS-CoV-2 IgG antibodies after recovery. Donors who tested negative or were positive only for SARS-CoV-2 IgM were excluded. All donors were negative for HLA antibodies. Additional donor eligibility criteria and qualification were based on the American Association of Blood Banks (AABB) standards and the FDA guidance on CCP

Journal Pre-proof

administration, including questionnaires and testing for relevant transfusion-transmitted infections.[10,14] CCP was only collected from individuals who met all donor eligibility requirements according to the United States Code of Federal Regulations (21 CFR 630.10 and 21 CFR 630.15). Pathogen inactivation was also performed for each unit.

CCP administration

A total of 135 patients with moderate to severe COVID-19 were enrolled in this cohort (89 patients with moderate disease and 46 patients with severe disease). All patients were pre-medicated (paracetamol, antihistamine, steroids) according to an institutional protocol. Overall, 107 (79·3%) patients received 2 units of ABO-compatible CCP (each unit containing 200 ml of CCP) 12 hours apart and 28 (20·7%) received 1 unit of CCP according to the treating physician and protocol dosage range (200-400 mL). All patients received CCP within 24 hours of admission. Three patients (2%) had allergic skin reactions that were completely resolved after transfusion.

Statistical analysis

Categorical variables are presented as number and percentage (%). Continuous variables are presented as median and interquartile range (IQR). Pairwise comparisons were performed using Pearson's chi-squared test for categorical variables and Kruskal-Wallis test or Mann-Whitney U test for continuous variables. For the primary end point, time to clinical improvement between the groups before 30 days was right censored at day 30. We used the Kaplan Meier analysis to assess the time to clinical improvement and the log rank test to compare the endpoint among groups. Mixed ordinal logistic regression modeling was used to measure the effect size (odds ratio [OR] and 95% confidence interval [CI]) of CCP on the WHO ordinal scale, stratified by disease severity.

A Cox proportional hazards model was used to assess the overall 30-day clinical improvement. Hazard ratios (HRs) with 95% CIs were reported in the Cox model. For the

Journal Pre-proof

secondary endpoint, we calculated the OR and 95% CI using logistic regression analysis. Variables included in the multivariate Cox proportional hazard and logistic regression models were age, baseline SpO2 < 88%, lymphocyte count <1 x10^9, and CRP.

We also examined whether an interaction occurred between CCP and adjunct therapy (i.e., steroids and/or tocilizumab) that affected the outcomes. We tracked laboratory results, including lymphocyte and neutrophil counts, CRP, D-dimer, and LDH, in addition to oxygen saturation over time. For the analysis of repeated measures, we used a linear fixed model (regression coefficient β with 95% CI) to analyze the effect of CCP on laboratory markers and oxygen saturation at baseline and during the first 14 days of hospitalization.

Missing data were not handled in a specific manner. Statistical analyses were carried out using Stata 14 software (StataCorp, College Station, Texas). Two-sided p-values <0·05 were considered significant.

Results

A total of 368 patients were included in the cohort; 135 received CCP and 233 were in the control group (Figure 1). Demographic and baseline characteristics are shown in Table 1. The median age was 54 (range 15-82) years, and the majority of patients were male (n=304, 82·6%). We found no differences among groups in the baseline characteristics or admission laboratory values, with the exception of baseline CRP, which was significantly higher in the CCP-treated patients with severe disease than other groups.

Primary outcomes

Overall 30-day clinical improvement was observed in 77 (86·5%) of the CCP-treated patients with moderate disease and 106 (68·4%) of corresponding controls (p=0·001). Among those with severe disease, clinical improvement was observed in 28 (60·8%) of the CCP-treated patients and 27 (34·6%) of their control counterparts (p=0·001). The median time to clinical improvement among those with moderate disease was 7 (IQR 4-9) days with CCP treatment and 8 (IQR 6-12) days in the control group (p=0·006), and among those with severe disease

Journal Pre-proof

was 7 (IQR 5-12) days with CCP treatment and 15.5 (IQR 10-20) days in the control group (p=0·003, Figure 2). The distribution of patients in the WHO ordinal scale categories over the 30 days of hospitalization are shown in eFigure1 and eFigure 2 in Supplement 2. For both moderate and severe disease, CCP treatment was associated with a significantly lower score on the WHO ordinal scale compared to the control group on days 7, 14, and 30. On day 7, the score reduction was significant in both the moderate (OR, 0·25 [95% CI 0·13-0·47]) and severe disease groups (OR, 0·33 [95% CI 0·14-0·82]). We also noted a score reduction in both moderate and severe disease on day 14 (OR, 0·17 [95% CI 0·08-0·34] and OR, 0·28 [95% CI 0·11-0·73], respectively) and day 30 (OR, 0·17 [95% CI 0·07-0·36] and OR, 0·11 [95% CI 0·04-0·31], respectively).

In the adjusted Cox model, the overall CCP group had a significantly higher rate of clinical improvement than the control group (HR, 1·9 [95% CI 1·4-2·7]). The effect was seen among both the moderate (HR, 1·9 [95% CI 1·3-2·8]) and severe disease (HR, 2·5 [95% CI 1·2-5·2]) groups (Table 2). There was no significant interaction effects between CCP and steroids (p=0·40), tocilizumab (p=0·12), or steroids plus tocilizumab (p=0·44) on the clinical improvement.

Secondary outcome

Effect of CCP on Mortality

In univariate analysis, the CCP-treated patients in both severity groups had lower mortality rates than the control groups (n=10, 11·4% and n=14, 30·4% versus n=46, 29·7% and n=44, 57·1%; p=0·001 and p=0·006, respectively). In the adjusted model, the risk of mortality was significantly lower in the CCP-treated patients with moderate disease (adjusted OR, 0·27 [95% CI 0·12–0·62]) compared to the control group, but not significantly different in the CCP-treated patients with severe disease (adjusted OR, 0·38 [95% CI 0·14–1·02]) compared to the control group. no significant interaction effects between CCP and steroids (p=0·36 for interaction), CCP and tocilizumab (p=0·56 for interaction), or CCP and steroids plus tocilizumab (p=0·75 for interaction) on mortality.

Journal Pre-proof

Effect of CCP on oxygen saturation and laboratory value kinetics

The effects of CCP on patients' oxygen saturation and laboratory markers over the first 14 days of the hospital stay are shown in Table 3. Relative to baseline, CCP treatment improved oxygen saturation by 5·4% [95% CI 3·3–7·4] on day 1 and 4·1% [95% CI 2·3-5·9] on day 3 in patients with moderate disease, but not among those with severe disease (eFigure 3 in Supplement). Lymphocyte counts increased significantly on days 7 (β=0·46 [95% CI 0·15-0·78]) and 14 (β=0·59 [95% CI 0·11-1·1]) post-hospital admission in the moderate CCP group. Similarly, lymphocyte counts increased on days 11 (β=0·76 [95% CI 0·03–1·5]) and 14 (β=0·98 [95% CI 0·04–1·9]) in the severe disease CCP group (eFigure 4 in Supplement). Total neutrophil counts were not significantly different among the groups at baseline or any other time point (eFigure 5 in Supplement). Relative to baseline, CRP significantly decreased in both the moderate and severe groups at every time point after CCP treatment (p=0·001; eFigure 6 in Supplement). D-dimer was not significantly different between the groups at baseline or in the first 11 days, but the levels were lower 14 days post-admission after CCP in the moderate disease group (eFigure 7 in Supplement). Furthermore, LDH was not significantly different among moderate and severe disease groups at baseline or in the first 14 days, but was lower at day 14 in the overall CCP group (eFigure 8 in Supplement).

Discussion

Currently, no vaccine or specific antiviral treatments are approved for COVID-19 patients. CP is a widely available non-pharmaceutical treatment that has been used with varying degrees of success in prior pandemics, including SARS, MERS, and Ebola.[15–18] In our study, we investigated the effect of CCP on time to clinical improvement, 30-day mortality, changes in oxygen saturation and laboratory values within 14 days of hospital admission in both moderate and severe COVID-19 patients. Many prior studies focused on severe and critically ill patients whereas we included severe cases as well as moderate cases where the risk benefit balance is more delicate. Improved clinical symptoms and mortality among

Journal Pre-proof

patients with severe and critical COVID-19 after CCP transfusion has been previously reported.[8,11] In a randomized clinical trial of CCP in severe and life-threatening COVID-19, Li et al. could not detect a significant reduction in time to clinical improvement within 28 days after CCP treatment.[7] However, the study was terminated early after enrollment of 52 patients who received CCP and 51 in the control group and may have been underpowered to detect significant differences. In contrast, our study included 135 patients in the CCP arm and 233 controls. Another report, concluded that CCP treatment did not reduce mortality and suggested that earlier adminstration of CCP might be beneficial.[12] The fact that patients in our study received CCP within 24 hours of hospital admission may have contributed to improving outcomes. In our study, CCP administration was associated with both a higher rate of and faster time to clinical improvement among patients with moderate and severe disease. The clinical improvement was observed in 80·6% of the CCP group compared to 58·6% of the control group. In addition, median time to clinical improvement in the CCP group was 7 days compared to 10 days in the control group. This is consistent with a prior case series of 10 patients, in which symptoms resolved within the first 72 hours with complete improvement on radiological examination within 7 days post-CCP administration.[19] In the H1N1 pandemic, CP was associated with a significant reduction in mortality, especially if administered early.[20] An exploratory post hoc meta-analysis revealed a significant reduction in the pooled odds of mortality following CP treatment of SARS coronavirus infection and severe influenza compared to placebo or no therapy.[21] Li et al. did not detect a significant reduction in 28-day mortality among CCP-treated patients. [7] In our study, 30-day mortality was significantly reduced in moderate, but not severe, COVID-19 cases. This may imply that CCP is more effective in reducing 30-day mortality in moderate disease, or may be attributed to inclusion of a relatively small number of severe cases. Our results are also consistent with those of a single arm study of 46 patients with moderate to severe disease where 7-day mortality was 6.5% in patients who received CCP compared to the 15% average national statistics and 30% in a concurrent cohort of 23 patients.[22]

Journal Pre-proof

CCP in our study was also associated with significantly improved oxygen saturation and recovery in lymphocyte counts and CRP within 14 days post-CCP treatment. These findings are consistent with recent reports of the effect of CCP.[8,11,23]

Prior studies have associated lower lymphocyte counts and high CRP levels with adverse outcomes in COVID-19 patients.[1,19] In our study, lymphocyte counts started to increase 1 day after CCP transfusion, with a significant increase 7 days post-admission in the CCP group compared to the control group. Furthermore, CRP was remarkably decreased starting day 1 in the CCP group. The improvement of both lymphocyte counts and CRP in our study may be attributed in part to a previously postulated immunomodulatory effect of CCP such as providing passive immunity by blocking inflammatory cytokines, autoantibodies, and complement pathways.[24] CCP may also inhibit inflammatory cascades and immune cell infiltration within the lungs.[25] These effects can clinically be seen as improvement in oxygen saturation and pulmonary radiological lesions.[19]

In our study, oxygen saturation significantly increased in CCP-treated patients during the first 72 hours. This finding is consistent with earlier studies reporting associations between CCP and improved oxygen saturation.[8,23]

All CCP recipients tolerated the transfusion except for 3 (2%) who had minor allergic skin reactions, which resolved completely without preventing administration of the full CCP dose. A recent study of early safety indicators for CCP reported 36 cases (0·72%) with serious adverse effects (SAEs).[26] The incidence of severe allergic reaction in that study was 0·06%, and the incidence of less than severe allergic reactions was not reported.

Our study has a number of limitations, including a lack of randomization. However, randomization was not feasible during the pandemic in our region. The administration of CCP within 24 hours of hospital admission was intended to limit selection bias. Another limitation is that at the time of analysis some patients were still hospitalized which may have biased the results. The clinical management of a potentially life-threatening illness with an unpredictable clinical course was the main contributor to this limitation. In addition, there was not an approved standard protocol for the treatment during our study, especially regarding

Journal Pre-proof

steroid and tocilizumab use. However, this stems from the lack of universally established treatments for COVID-19. We did not observe an interaction between the administration of either/both of the drugs and the observed effect of CCP in our patients. Finally, we were not able to determine the titer of SARS-CoV-2 IgG antibodies in CCP donors or whether the detected antibodies were neutralizing antibodies due to a lack of these tests in Kuwait at the time of the study. We did exclude any donors who were negative for IgG antibodies. Not performing additional antibody characterizing tests could only lead to underestimation of the benefit of this therapeutic modality due to potential inclusion of CCP units with low IgG levels or antibodies of limited neutralizing capacity. In addition, in many parts of the world, including some developed countries, there is a striking shortage of testing for COVID-19 in general, and particularly for more specialized tests, such as neutralizing antibodies.

To the best of our knowledge, this study is the first to investigate the effectiveness and feasibility of CCP in COVID-19 patients in the Middle East. Although we did not perform an a priori sample size calculation, 135 patients in the CCP group demonstrated significant differences. The involvement of multiple centers supports the generalizability of the results. Throughout the worldwide lockdown, the supply of CCP was consistently available in Kuwait, which offers free access to this therapeutic intervention. This contrasts pharmaceuticals subject to supply chain limitations. Availability is crucial in the Middle East, which relies on pharmaceutical manufacturing that is currently concentrated in Western countries.

Conclusion

In our prospective interventional study including patients with moderate and severe COVID-19, CCP administration was significantly associated with improved clinical outcomes. Thirty-day survival was significantly improved in the moderate group. In addition, administration of CCP in both moderate and severe cases was also associated with improved oxygen saturation and recovery of lymphocytes and CRP. Larger multicenter controlled randomized trials to further evaluate the effectiveness of CCP in COVID-19 patients with particular emphasis on CCP donor qualification based on neutralizing antibody levels are warranted.

Abstract

Convalescent plasma with severe acute respiratory disease coronavirus 2 (SARS-CoV-2) antibodies (CCP) may hold promise as treatment for Coronavirus Disease 2019 (COVID-19). We compared the mortality and clinical outcome of patients with COVID-19 who received 200mL of CCP with a Spike protein IgG titer ≥1:2,430 (median 1:47,385) within 72 hours of admission to propensity score-matched controls cared for at a medical center in the Bronx, between April 13 to May 4, 2020. Matching criteria for controls were age, sex, body mass index, race, ethnicity, comorbidities, week of admission, oxygen requirement, D-dimer, lymphocyte counts, corticosteroids, and anticoagulation use. There was no difference in mortality or oxygenation between CCP recipients and controls at day 28. When stratified by age, compared to matched controls, CCP recipients <65 years had 4-fold lower mortality and 4-fold lower deterioration in oxygenation or mortality at day 28. For CCP recipients, pre-transfusion Spike protein IgG, IgM and IgA titers were associated with mortality at day 28 in univariate analyses. No adverse effects of CCP were observed. Our results suggest CCP may be beneficial for hospitalized patients <65 years, but data from controlled trials is needed to validate this finding and establish the effect of ageing on CCP efficacy.

Introduction:

Severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) (1), a highly transmissible enveloped positive-strand RNA virus (2), is the causative agent of the Coronavirus disease 2019 (COVID-19) pandemic (3). The first case was reported in December 2019, and by November 2020 more than 61 million infections were reported worldwide, with one fifth of the cases and deaths occurring in the United States (U.S.) (4). In April 2020, New York City (NYC), especially the borough of the Bronx, was an early epicenter of the COVID-19 pandemic in the U.S. (5, 6). Since then, an antiviral that reduced duration of illness (7), Remdesivir, received FDA approval on October 22, 2020, and corticosteroids, which reduced mortality in severely ill patients in a large randomized clinical trial and prospective meta-analysis (8, 9), have become standard of care. As of November 2020, there is no approved therapy for COVID-19 that reduces mortality of hospitalized patients with respiratory manifestations of severe or life-threatening disease.

Convalescent plasma (CP) obtained from recovered persons was deployed for previous respiratory pandemics, including 1918 and 2009 influenza and Severe Acute Respiratory Syndrome (SARS) (10-13). Given the lack of established therapies for COVID-19, CP containing SARS-CoV-2 antibodies (CCP) was proposed as a therapeutic option early in the pandemic (14). As of November 2020, it has shown a possible benefit in multiple studies. In early case series, CCP-treated patients exhibited viral clearance and reductions in inflammatory markers (15-19). Observational studies comparing CCP-treated patients to retrospective controls showed a reduction in mortality in non-intubated patients and/or those transfused within 72 hours of hospitalization with high titer CCP (20-24). Analysis of a subset of more than 3,000 CCP recipients in an open label study found a dose-response whereby non-intubated patients who

medRxiv preprint doi: https://doi.org/10.1101/2020.12.02.20242909 ; this version posted December 4, 2020. The copyright holder for this preprint

received high titer CCP had lower mortality than those who received low titer CCP (22). Several randomized controlled trials (RCT) have not shown a benefit of CCP, but were limited by premature termination due to a lack of patients to recruit (25, 26). One trial found CCP had an antiviral effect, but there was no effect on mortality (27), another found a reduction in mortality, albeit with a very small sample size (28), and another was terminated due to the presence of neutralizing antibodies in CCP recipients at the time of transfusion, despite being on track to meet the primary endpoint (29). A recent double-blind, placebo controlled, multicenter RCT did not show an effect of CCP on mortality (30). Evidence of safety and possible benefit led the FDA to issue an emergency use authorization (EUA) for CCP use in hospitalized patients with COVID-19 on August 23, 2020.

We treated 103 patients at Montefiore Medical Center (MMC), a 1,491-bed tertiary medical center in the Bronx, New York with serious or life-threatening COVID-19 with CCP between April 13 and May 4, 2020 and conducted a propensity score matched study. Herein, we report mortality and clinical and laboratory findings of CCP recipients compared to matched controls.

Results

Baseline characteristics of CCP recipients and retrospective controls

One hundred and three (103) patients were enrolled in the Mayo Clinic expanded access protocol (EAP) (31) and treated with one 200 mL unit of CCP within 72 hours of hospital admission. Clinical status and mortality on day 28 post-transfusion was compared to retrospective propensity score matched controls identified by querying the electronic medical record (Figure 1). Analysis included 90 CCP recipients and 258 controls after exclusion of twelve patients who did not meet the eligibility criteria because of mechanical ventilation for > 24 hours or CCP transfusion > 72 hours after admission, and one patient with missing data (Figure 1). Compared to controls, CCP recipients were younger (median 66 vs 72 years, $P = 0.002$), had higher BMI (28 vs 27 kg/m^2, $P = 0.05$), and lower rates of congestive heart failure (18 vs 29%, $P = 0.03$), and chronic kidney disease (29 vs 41%, $P = 0.03$). At baseline, a lower proportion of CCP recipients were on low-flow oxygen support (68 vs 81%, $P < 0.0001$) and a higher proportion required mechanical ventilation (20 vs 6%, $P < 0.0001$), had lower baseline lymphocyte counts (0.8 vs 1.0 x 10^9/L, $P = 0.001$), and received systemic corticosteroids (93 vs 63%, $P < 0.0001$) (Supplemental Table 1). After propensity score matching, 73 CCP recipients and 73 control patients were well balanced for all matching variables except in a subgroup analysis stratified by age; CCP recipients ≥ 65 years had lower lymphocyte counts than controls (median, 0.8 vs 1.0 x10^9/L) (Table 1, Supplemental Figure 1).

Convalescent plasma SARS-CoV-2 spike protein and neutralizing antibody (NAb) titers

Of the 200 mL units of CCP administered in this study, 95 of 103 were obtained from 46 persons who donated CP at MMC in April 2020. SARS-CoV-2 spike protein IgG endpoint titers were

medRxiv preprint doi: https://doi.org/10.1101/2020.12.02.20242909 ; this version posted December 4, 2020. The copyright holder for this preprint

measured in CCP obtained from these donors using the MMC in-house research full-length spike protein ELISA (32). Median IgG, IgM and IgA titers were, respectively, 1:47,385 (interquartile range [IQR], 21,870 – 65,610; n = 46), 1:810 (IQR, 810 – 2,430; n = 43) and 1:90 (IQR, 90 – 270; n = 43). Median NAb titer by pseudovirus neutralization assay was 1:938 (IQR, 407 – 2,784; n = 42). There was a direct correlation between NAb titer and spike protein IgG (Spearman $r = 0.78$, $P < 0.0001$), IgM ($r = 0.58$, $P < 0.0001$) and weakly with IgA ($r = 0.29$, $P = 0.05$) titers (Supplemental Figure 2). For the eight patients who did not receive MMC donor CCP, 7 received units that tested as 'reactive' by the New York State Department of Health (NYSDOH) Wadsworth Center's SARS-CoV-2 Microsphere Immunoassay for anti-Nucleocapsid antibody detection (33), and one received CCP with a spike protein IgG titer of 1:320 measured by the in-house spike protein ELISA assay at Mount Sinai Hospital (34) .

Comparison of clinical outcomes of CCP recipients and controls

There was no difference in mortality between 73 CCP recipients and 73 propensity score matched controls by day 28 ($P = 0.47$, Kaplan-Meier log rank test) (Figure 2). To account for the potential interaction between age and CCP treatment ($P = 0.11$, interaction term), analysis was stratified by age. Compared to matched controls, CCP recipients < 65 years had lower mortality by day 28 ($P = 0.04$, Kaplan-Meier log rank test), whereas the mortality of CCP recipients and matched controls ≥ 65 years did not differ significantly ($P = 0.61$, Kaplan-Meier log rank test) (Figure 2). There was no difference in mortality between groups when CCP recipients and controls were stratified by baseline oxygen requirement (Supplemental Figure 3).

There was no significant difference between CCP recipients and matched controls in all-cause mortality at 28 days (31.5 vs 38.4%; odds ratio [OR], 0.74; 95% confidence interval [CI],

medRxiv preprint doi: https://doi.org/10.1101/2020.12.02.20242909 ; this version posted December 4, 2020. The copyright holder for this preprint

0.37 – 1.46; $P = 0.37$) (Figure 3). When stratified by age, CCP recipients < 65 years had a 4-fold decrease in mortality (8.8 vs 29.4%; OR, 0.23; 95% CI, 0.05 – 0.95; $P = 0.04$) and a 4-fold decrease in deterioration in oxygenation or mortality (11.8 vs 35.3%; OR, 0.24; 95% CI, 0.06 – 0.87; $P = 0.03$). There was no significant difference in mortality of CCP recipients ≥ 65 years (52.6 vs 45.9%; OR, 1.07; $P = 0.89$) (Figure 3, Table 1). Among the 103 CCP recipients, mortality at day 28 was associated with time from symptom onset to transfusion (OR, 1.12; 95% CI, 1.01 – 1.24; $P = 0.04$), earlier week of admission (OR, 2.22; 95% CI, 1.00 – 5.00; $P = 0.05$) and being Hispanic/LatinX in ethnicity compared to not being Hispanic/LatinX (OR, 8.33; 95% CI, 1.69 – 33.3; $P = 0.009$), adjusted for age, sex, BMI, race, ethnicity, comorbid conditions, week of admission, duration of symptoms, baseline oxygen requirement, corticosteroids, anticoagulation use, D-dimer and lymphocyte counts (Table 2). There was no significant association between CCP NAb or spike protein IgG titers and mortality or oxygenation status in CCP recipients.

Multivariable analysis of 90 CCP recipients and 258 controls adjusted for covariates age, sex, BMI, race, ethnicity, comorbid conditions, week of admission, baseline oxygen requirement, corticosteroids, anticoagulation use, D-dimer and lymphocyte counts did not show any difference in outcome between the two groups. When stratified by age, CCP recipients < 65 years had lower mortality or deterioration in oxygenation but this was not statistically significant (OR, 0.23; 95% CI, 0.04 – 1.19; $P = 0.08$) (Supplemental Figure 4). Additionally, multivariable analysis indicated that age, use of mechanical ventilation at baseline, use of systemic corticosteroids, not being on anticoagulation in patients ≥ 65 years and earlier week of admission were associated with mortality at day 28 adjusted for covariates (Supplemental Table 2). Corticosteroid use was

medRxiv preprint doi: https://doi.org/10.1101/2020.12.02.20242909 ; this version posted December 4, 2020. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

associated with mortality in patients receiving low-flow oxygen at baseline (adjusted OR, 2.68; 95% CI, 1.27 – 5.68; $P = 0.009$) when analysis was stratified by baseline oxygen requirement.

CCP safety and adverse events

There were no adverse reactions, including no instances of transfusion-related acute lung injury or transfusion-associated circulatory overload attributable to CCP administration.

CCP recipient SARS-CoV-2 spike protein antibody titers

We measured CCP recipient spike protein IgG, IgM, and IgA in remnant serum samples obtained before (D -1) and after transfusion (Figure 4). Baseline spike protein IgG, IgM and IgA were significantly higher in patients mechanically ventilated at enrollment ($P = 0.009$, $P = 0.01$, $P = 0.02$, respectively) and those who died by day 28 ($P = 0.02$, $P = 0.02$, $P = 0.002$, respectively) (Supplemental Table 3, Figure 4, Supplemental Figure 5). There was no association between baseline antibody titers and time from symptom onset to transfusion or time from hospital admission to transfusion. Plateau in median IgG after CCP administration was reached earlier in patients ≥ 65 than < 65 years, mechanically ventilated at baseline versus not, and those who died by versus those alive at day 28 (Figure 4). Baseline IgA was higher in patients ≥ 65 than those < 65 years ($P = 0.04$) (Supplemental Table 3).

There was a direct association between mortality at day 28 and baseline (D -1) IgG (OR, 1.4; 95% CI, 1.04 – 1.78; $P = 0.03$), IgM (OR, 1.39; 95% CI, 1.00 – 1.92; $P = 0.048$) and IgA (OR, 1.45; 95% CI, 1.11 – 1.91; $P = 0.007$) in the univariate analyses but not in the multivariable analysis adjusted for covariates (Table 2). Baseline spike protein IgG titer was significantly correlated with D-dimer ($r = 0.46$; $P = 0.0002$; n = 60) (Figure 4). In addition, there was a direct,

medRxiv preprint doi: https://doi.org/10.1101/2020.12.02.20242909 ; this version posted December 4, 2020. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

albeit weak correlation between baseline spike protein IgG titer and detected viral load measured by cycle threshold (Ct) value of nasopharyngeal SARS-CoV-2 reverse-transcriptase-polymerase-chain-reaction (RT-PCR) ($r = 0.39$; $P = 0.002$; n = 57) (Figure 4). There was no correlation between Ct value and age, duration of illness, or D-dimer.

CCP recipient inflammatory and hematology measures

There was no significant difference in change in lymphocyte counts, D-dimer, or CRP between day 0 and 28 in CCP recipients compared to controls (data not shown).

Discussion

CCP has been used as an investigational treatment for COVID-19 since the early days of the pandemic. Numerous observational studies report safety and signals of possible efficacy of CCP in hospitalized patients with COVID-19 (15, 20, 22-25, 35, 36). Here, we report the mortality and clinical outcomes of a cohort of 73 patients with severe to life-threatening COVID-19 who were transfused with one unit of CCP by 72 hours of hospitalization and 73 propensity score matched controls. There was no significant difference in mortality or improvement in oxygenation in CCP recipients compared to controls. Although treated within 72 hours of hospitalization, CCP treated patients had symptom duration of 5-9 days and multiple indicators of severe or life-threatening disease including lymphopenia, elevated D-dimer levels, and the need for supplemental oxygen. In this regard, our findings are similar to those of other studies in which there was no benefit of CCP in hospitalized patients with severe COVID-19 (25, 27, 30). Nonetheless in a subset of patients stratified by age, CCP recipients < 65 years had significantly lower mortality and deterioration in oxygenation by day 28 than controls. Age and duration of symptoms were independently associated with mortality at day 28 in CCP recipients. There were no adverse reactions directly attributable to CCP.

There was no evidence of benefit of CCP in patients ≥ 65 years. Age, a well-documented risk factor for COVID-19 severity and mortality (37, 38), was significantly associated with mortality in unadjusted and adjusted analyses. Patients ≥ 65 years had a higher frequency of co-morbid conditions, higher D-dimer, CRP and SARS-CoV-2 IgA values, and lower lymphocyte levels than those < 65 years, all of which are markers of severe disease (39-44). Notably in published case-control studies in which CCP was associated with reduced mortality, median ages of patients were < 60 years (21, 23, 45), and in the large open label Mayo Clinic study in which

medRxiv preprint doi: https://doi.org/10.1101/2020.12.02.20242909 ; this version posted December 4, 2020. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

there was a signal of reduced mortality in patients who received high titer CCP, 44% of the cohort was < 60, 70% was < 70 years, and CCP was less effective in those > 80 years (22). In addition, a small RCT comparing 80 patients randomized to CCP versus standard of care posted on the pre-print server on November 29th, 2020 found a benefit of CCP in patients < 67 years, but not in the entire cohort with a median age of 61 years (46). These data along with ours suggest that ageing may have a detrimental effect on CCP efficacy.

In a case-control study that also did not show a signal of CCP efficacy, Rogers et al. found a higher rate of hospital discharge in patients ≥ 65 years (47). In their study, 14% of CCP recipients were black/African American, 31% were Caucasian/white, 42% were Hispanic/LatinX, and 34% had hypertension, 25% had diabetes, and all received two units of CCP. Our cohort was older, more severely ill, and came from racial/ethnic populations at higher risk for severe COVID-19 and death (48): 26% of CCP recipients were black/African American, 9% were Caucasian/white, 51% were Hispanic/LatinX, which was associated with mortality in our multivariable analysis, and 82% had hypertension, 42% had diabetes, and all received one unit of CCP. This suggests social determinants of health may have adversely affected clinical outcomes of our cohort.

Reflecting practice at the peak of the pandemic at our center, the majority of patients in our cohort received corticosteroids and corticosteroid use was associated with mortality in those requiring low flow oxygen. In another propensity score matched study, corticosteroids use was also associated with higher mortality (49). Among CCP recipients ≥ 65 years in our study, 98% received corticosteroids concurrently with or before CCP. More CCP recipients than controls also received corticosteroids in the Rogers et al. study, which did not find evidence of CCP benefit (47). In addition, although not statistically significant, a higher proportion of CCP

medRxiv preprint doi: https://doi.org/10.1101/2020.12.02.20242909 ; this version posted December 4, 2020. The copyright holder for this preprint
(which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.
It is made available under a CC-BY-NC-ND 4.0 International license .

recipients than controls received corticosteroids in the Li et al. RCT, in which there was not a signal of CCP efficacy and the median age was 70 years (25). Corticosteroid use has been associated with lower mortality in patients with COVID-19 who require mechanical ventilation (8, 9), and not in the early course of the disease (9, 50). Viral clearance was slower in patients with SARS and MERS who received corticosteroids (51, 52) and corticosteroid use was associated with lower anti-spike protein receptor binding domain (RBD) IgG and neutralization titers in COVID-19 patients (53). Thus, we wonder if corticosteroid use further impaired the immune status of elderly patients in our cohort, who already had lower lymphocyte counts. Data from ongoing RCTs is needed to evaluate the effect of covariates, including corticosteroids on CCP efficacy.

The ability of CCP to affect the course of COVID-19 is most likely a function of viral neutralization early in disease (14, 54). The Mayo Clinic study analysis found that high titer CCP, as defined by signal to cut off ratio on the OrthoV platform, reduced COVID-19 mortality relative to low titer CCP (22). In a propensity score matched study, compared to controls, CCP with a RBD IgG titer ≥1:1,350 reduced mortality in non-intubated patients transfused within 72 hours of hospital admission (21). Although titers in our study cannot be directly compared with titers in other studies, CCP used in our study had high titer spike protein IgG and a median neutralizing titer of 1:938 based, respectively, on a highly specific full length spike protein ELISA (55-57) and a pseudovirus neutralization assay that correlates with live virus (plaque reduction) neutralization (42, 57, 58). Nonetheless, although there was a possible signal of efficacy in the sub-group < 65 years who received CCP within 72 hours of hospitalization, this was not the case in patients ≥ 65 years, who were more severely ill based on baseline data. It is possible elderly patients may require more than one dose of 200 mL of CCP, but two units did

not mediate an effect in the Rogers et al. cohort (47). While there are theoretical concerns of antibody-dependent enhancement (ADE) in the presence of sub-neutralizing concentrations of anti-viral antibodies (59, 60), ADE was not reported in other CCP treatment studies and the levels of spike protein antibody with neutralizing capability in CCP in this study make it very unlikely. Given the high mortality of COVID-19 in patients ≥ 65 years and lack of evidence of CCP efficacy in this group in our study and others (25, 61) there is a need for more data on the effect of aging on CCP efficacy in COVID-19 .

Consistent with other reports associating SARS-CoV-2 antibody titer with disease severity and/or mortality (53, 62-64), spike protein IgG at enrollment was directly associated with mortality among 60 CCP recipients who had remnant sera available. Although we observed post-transfusion increases in spike protein IgG in patients < 65 years or who were not intubated, this cannot be distinguished from endogenous antibody without comparison to untreated controls. While we did not measure post-transfusion viral loads, pre-transfusion antibody titers correlated with RT-PCR Ct values (inversely correlated with viral load). Thus, as in other studies (53, 65), endogenous antibody may have already contributed to viral control in CCP recipients. The Gharbharan et al. RCT was terminated early when it was discovered majority of the study patients had neutralizing titers at enrollment equivalent to donor CCP (29), although the study appeared on track to meet its expected endpoint. Patients in the PLACID RCT (27) who received CCP had earlier conversion to viral RNA negativity, despite having low levels of neutralizing antibodies at enrollment. In the ConPlas-19 RCT (26), in which 49% of the patients had positive SARS-CoV-2 IgG at enrollment, CCP did not confer benefit, but there was a trend towards reduced mortality. Nonetheless, in our study as in others (27, 66), antibody titers and symptom duration associated with disease severity and a lack of evidence of CCP efficacy. This

underscores the longstanding principle that convalescent antibody therapy is most likely to be effective early in the course of viral respiratory diseases (14) as shown for COVID-19 in propensity score matched studies (23, 49) and a recently published outpatient RCT (66).

A strength of our study is that it includes patients over the age of 65 years, who represent a population with disproportionately higher COVID-19 mortality. To date, studies of CCP and other potential therapies for COVID-19 in patients negatively affected by social determinants of health are lacking. The Bronx has a higher poverty rate than the other New York City (NYC) boroughs (5, 67) and our cohort was comprised predominantly of Hispanic or Latinx and black or African American populations who were severely affected by the surge conditions in NYC and experienced higher COVID-19 mortality (68-71). We attempted to control for hospital surge capacity and social determinants of health that can significantly contribute to COVID-19 outcome (72) by including week of admission, race, and ethnicity as propensity scores.

A major limitation of this study is its retrospective and non-randomized study design. The retrospectively identified controls differed in baseline characteristics from the cases, most notably in baseline oxygen requirement, proportion of corticosteroid use and baseline lymphocyte counts, suggesting a mismatch in severity of illness due to selection bias. While propensity score matching and multivariable analysis with adjustments were done to correct for confounding variables, there likely were additional latent and unmeasured variables that were not adjusted for. In addition, time-dependent variables such as hospital bed capacity during surge conditions and advances in clinical practice, such as use of proning techniques, lung protective ventilation strategies, improvement in sedation, may not have been accounted for in our analysis, despite matching and adjusting for baseline week. In addition, poor or absent documentation of oxygen requirement and inconsistencies in obtaining inflammatory markers during the height of

the pandemic resulted in missing data, precluding a more complete analysis. Finally, since we could not obtain antibody data for controls, we cannot assess CCP effects on antibody levels.

In summary, we report that CCP administration within 72 hours of hospitalization demonstrated a possible signal of reduced mortality in patients < 65 years. Similar to others, we found CCP was safe with no adverse events directly attributable to transfusion (21, 73, 74). Although our data suggest possible effects of age, disease severity, and corticosteroid use on CCP efficacy, prospective, randomized, controlled trials are needed to establish CCP efficacy and the effect of these and other covariates. Antibody-based therapies, including CCP have now shown promise in outpatients with mild to moderate COVID-19 (66, 75). However, nearly a year into the pandemic, effective therapies for hospitalized patients are still urgently needed, particularly for those who are elderly and at high risk for mortality. If effective in any group of hospitalized patients, CCP will have immense impact on healthcare resources and public health during this ongoing pandemic (76). CCP is rapidly available compared to other pharmaceuticals or vaccines and may be a more feasible option in surge conditions and/or resource limited settings (24).

Methods

Patient enrollment

One hundred and three (103) adult patients with laboratory (nasopharyngeal PCR)-confirmed COVID-19 were enrolled in the Mayo Clinic expanded access treatment protocol (31) to receive CCP between April 13 and May 4, 2020. Hospitalized patients were referred to the study team by hospitalists and/or infectious diseases consultants and were deemed eligible to receive CCP if they had been hospitalized for ≤ 3 days or were symptomatic for 3 to 7 days prior to transfusion and had severe and/or life-threatening COVID-19 disease. Patients who were on mechanical ventilation for more than 24 hours were excluded. Severe disease was defined as respiratory symptoms with hypoxemia requiring ≥ 5 liters of nasal cannula oxygen support. Life-threatening disease was defined as respiratory failure requiring mechanical ventilation, shock, and/or multiple organ dysfunction or failure. Ninety-one patients received CCP by day three of hospitalization. Patients or their legally authorized representatives provided informed consent prior to treatment.

Convalescent plasma procurement and transfusion

After obtaining informed consent, blood was collected between March and April 2020 from otherwise healthy adult volunteers residing in Westchester County, Rockland County and the Bronx, NY who had recovered from COVID-19. Potential donors had a documented positive nasopharyngeal swab by PCR for SARS-CoV-2 during illness and had been asymptomatic for ≥14 days prior to sample collection. Serum was obtained by venipuncture (BD Vacutainer, serum), aliquoted, heat-inactivated at 56°C for 30 minutes and stored at -4°C prior to antibody screening by enzyme-linked immunosorbent assay (ELISA). Donors with SARS-CoV-2 spike

medRxiv preprint doi: https://doi.org/10.1101/2020.12.02.20242909 ; this version posted December 4, 2020. It is made available under a CC-BY-NC-ND 4.0 International license .

protein titers >1:1,000 were referred for apheresis at the New York Blood Center (NYBC). CCP from 46 MMC donors and 8 donors from the general NYBC pool was administered to patients in the study.

Plasma recipients were transfused with 1 unit (~ 200 mL) of ABO-type matched CCP over 2-3 hours and monitored before, during and after infusion for signs of transfusion-related reactions per standard transfusion protocol.

Controls and data collection

We identified 1,347 non-CCP recipients with a positive SARS-CoV-2 PCR admitted to MMC between April 13 and May 4 by querying the electronic medical record (EMR). Since most CCP was administered by day 3 post-admission, baseline day was set at day +2 post-admission in non-CCP recipients. Of the 1,347 identified patients, the CCP recipients and 986 non-CCP recipients were excluded because they required < 5 L or no baseline oxygen support, or had a missing baseline oxygen value (n = 903), or were intubated for > 24 hours at baseline (n = 47), or had missing data (n = 36). This resulted in a retrospective control group of 258 non-CCP recipients (Figure 1). We collected age, sex, BMI, race, ethnicity, comorbidities, medications, laboratory findings, and day of death or discharge from CCP-treated and control patients. Additionally, we collected duration of symptoms and hospital day of transfusion from CCP-treated patients from the EMR. Specific laboratory values and clinical characteristics were obtained from EMR by using Structured Query Language.

For both control and CCP recipients, patient oxygen support was evaluated at day 0 and 28 post-CCP and the corresponding day post-admission for controls as follows: low-flow oxygen through nasal cannula or non-rebreather mask (5 - 15 liter), high-flow nasal cannula or non-

medRxiv preprint doi: https://doi.org/10.1101/2020.12.02.20242909 ; this version posted December 4, 2020. invasive ventilation, and invasive mechanical ventilation. If a patient's oxygen requirement increased or the patient died prior to the time-point of interest, patient's oxygenation status was considered to have worsened. Initial cycle threshold (Ct) value from the SARS-CoV-2 RT-PCR assay performed on a single platform was queried retrospectively for CCP recipients.

SARS-CoV-2 spike protein IgG, IgM and IgA titers before and after transfusion of CCP

SARS-CoV-2 spike protein-binding IgG, IgM and IgA titers were determined by ELISA using remnant sera obtained from baseline (Day -1 (D-1)) and 1, 3, 7 days after patients received CCP (D1, D3 and D7, respectively). Briefly, microtiter plates (Costar, Corning, NY) were coated with 25 µl of 2 µg/ml purified spike protein (55, 56, 77) in phosphate-buffered saline (PBS) overnight at 4°C, washed with 1X PBS/0.1% Tween (PBS-T), blocked with 3% (v/v) milk (Bio-Rad)/PBS-T for 1 hr at room temperature (RT), washed, and incubated with heat inactivated sera for 2 hrs at RT. Plates were then washed, incubated with isotype-specific horseradish phosphatase (HRP) labeled goat anti-human (GAH) IgG (Thermo Fisher), IgM, or IgA (Millipore Sigma) for 1 hr at RT. Following final washes, plates were incubated with ultra-TMB ELISA substrate (Thermo Scientific) and color development was stopped by addition of 0.5 M sulfuric acid (Sigma Aldrich). Well absorbances at 450 nm (A_{450}) were determined using a Cytation 5 (BioTek). The endpoint titer was determined as the highest dilution to give a signal three times the background A_{450} (wells with no sera).

rVSV-SARS-CoV-2 S Neutralization assay

The neutralization assay was done as previously described (57). Briefly, CCP samples were serially diluted and incubated with pre-titrated amounts of virus for 1 hr at RT, plasma-virus

medRxiv preprint doi: https://doi.org/10.1101/2020.12.02.20242909 ; this version posted December 4, 2020. The copyright holder for this preprint

mixtures were added to 96-well plates (Corning) containing monolayers of Vero cells, incubated for 7 hr at 37°C/5% CO2, fixed with 4% paraformaldehyde (Sigma) in PBS, washed with PBS, and stored in PBS containing Hoechst-33342 (1:2,000 dilution; Invitrogen). Viral infectivity was measured by automated enumeration of green fluorescent protein (GFP)-positive cells from captured images using a Cytation 5 automated fluorescence microscope (BioTek) and analyzed using the Gen 5 data analysis software (BioTek). The serum half-maximal inhibitory concentration (NC_{50}) was calculated using a nonlinear regression analysis with GraphPad Prism software.

Study outcomes

The primary outcome was all-cause mortality at day 28 post-CCP. The secondary outcomes were improvement in oxygenation status or mortality at day 28 post-CCP. Exploratory outcomes were associations between pre-CCP SARS-CoV-2 antibody titers and mortality at day 28.

Statistics

Patient characteristics and outcomes were reported as frequencies and proportions for categorical variables, and median and interquartile range (IQR) for continuous variables. Differences between groups (e.g., CCP versus non-CCP) were determined by student t-test or Mann Whitney U test for continuous variables, and Chi-square or Fischer's exact tests for categorical variables, as appropriate.

For the outcome analysis, we performed 1:1 propensity score matching using the nearest neighbor matching without replacement on 90 case and 258 control patients to optimize balance of baseline characteristics for assessing the independent effect of CCP on oxygenation and

medRxiv preprint doi: https://doi.org/10.1101/2020.12.02.20242909 ; this version posted December 4, 2020. The copyright holder for this preprint

survival. The distribution of O2 requirement prior to matching showed that the cases had higher oxygen requirement ($P < 0.001$). The primary matching criteria included age, sex, race, ethnicity, BMI, week of admission, D-dimer, lymphocyte count, corticosteroids use, anticoagulation use, hypertension, diabetes, chronic pulmonary disease, chronic kidney disease, coronary artery disease, hyperlipidemia with exact matching on baseline oxygen requirement and age group (categorical, < 65 vs ≥ 65 years). Propensity scores were calculated using a logistic regression model. After 1:1 propensity score matching, the analysis included 73 cases and 73 controls and the variables were not significantly different between CCP recipients and controls based on an omnibus test ($P = 0.80$) (78). The all-cause mortality at day 28 post-CCP was depicted by Kaplan-Meier curves. Differences between groups were compared using the log-rank test. Stratification analyses were done by age < 65 vs ≥ 65 years and by baseline oxygen requirement. Corticosteroids and anticoagulation use were not well balanced in the subgroups and were further adjusted for in age-stratified analysis.

As a sensitivity analysis, factors associated with oxygenation status at day 28 were evaluated by proportional odds model, and mortality at day 28 was evaluated using logistic regression model. Adjusted OR and corresponding 95% confidence intervals were calculated. To identify variables that predicted mortality in CCP group, we performed a stepwise model selection using the Akaike Information Criterion (AIC) in a logistic regression model with age, sex, BMI, race, ethnicity, comorbidities, week of admission, time from symptom onset to transfusion, baseline oxygen requirement, anticoagulation, corticosteroid use, D-dimer, and lymphocyte count. Log-transformed SARS-CoV-2 spike protein antibody titers were individually added to select models to evaluate their association with each outcome. A two-sided *P*-value of <

Author contributions

HY, LP, JD, KC designed the study. HY, LP wrote the manuscript with input from all authors. JD, IG, KC, TW contributed to critical revision of the manuscript. HY, RB, KF enrolled patients. MP, LS, JU provided CCP from the blood bank. HY, UNS, KC, SA, JA, AA, DB, AK, BL, AL, ML, AM, XY collected clinical data. IG, RR, RT, PS retrospectively identified control patients and collected clinical data. MRG, ASF provided clinical specimens and critical data interpretation. JR, AN, R Babb collected clinical specimens and performed ELISAs. RHBIII, ASW curated clinical specimens, performed ELISAs, and analyzed ELISA data. EL, CF, DH, MED, JMF assisted with clinical specimen processing and performed ELISAs. DH, MED, RKJ, RHBIII performed and analyzed viral neutralization assays. KT, MCM, OV performed ELISAs. GIG and RJM expressed and purified spike protein. JAQ assisted with management of clinical information. NGH, NCM and SJG expressed, purified and performed quality control on the spike protein. GJK and JMS assisted with specimen collection and transport. RS assisted with specimen collection. DYG provided data. TW, YL, HY performed statistical analysis. HY, LP, JD, KC, TW, IG, UNS, DYG, ASF assisted with data analysis and interpretation. JB acquired funding. All authors revised and approved the final version.

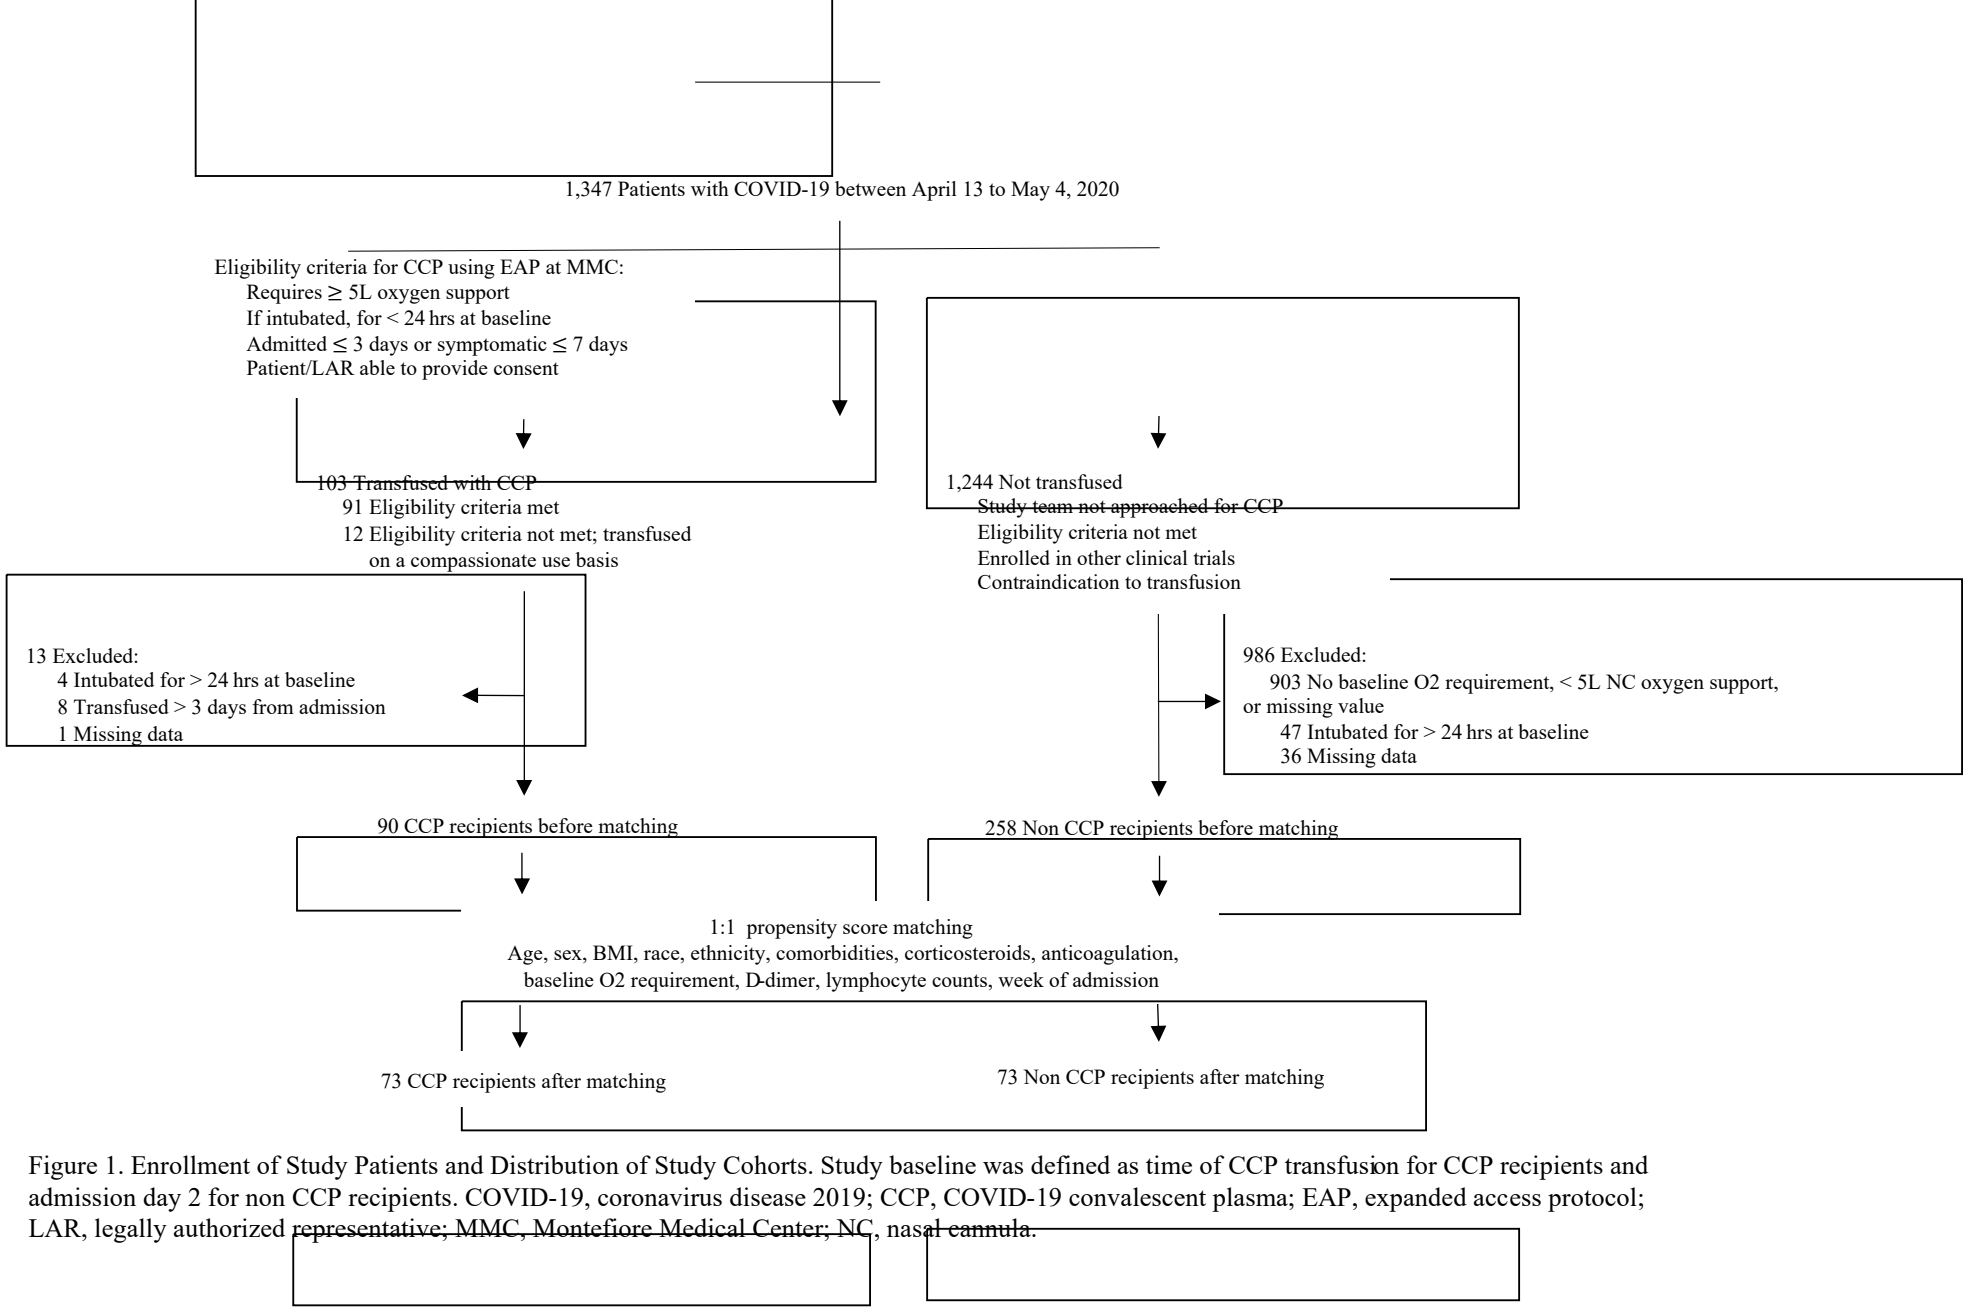

Figure 1. Enrollment of Study Patients and Distribution of Study Cohorts. Study baseline was defined as time of CCP transfusion for CCP recipients and admission day 2 for non CCP recipients. COVID-19, coronavirus disease 2019; CCP, COVID-19 convalescent plasma; EAP, expanded access protocol; LAR, legally authorized representative; MMC, Montefiore Medical Center; NC, nasal cannula.

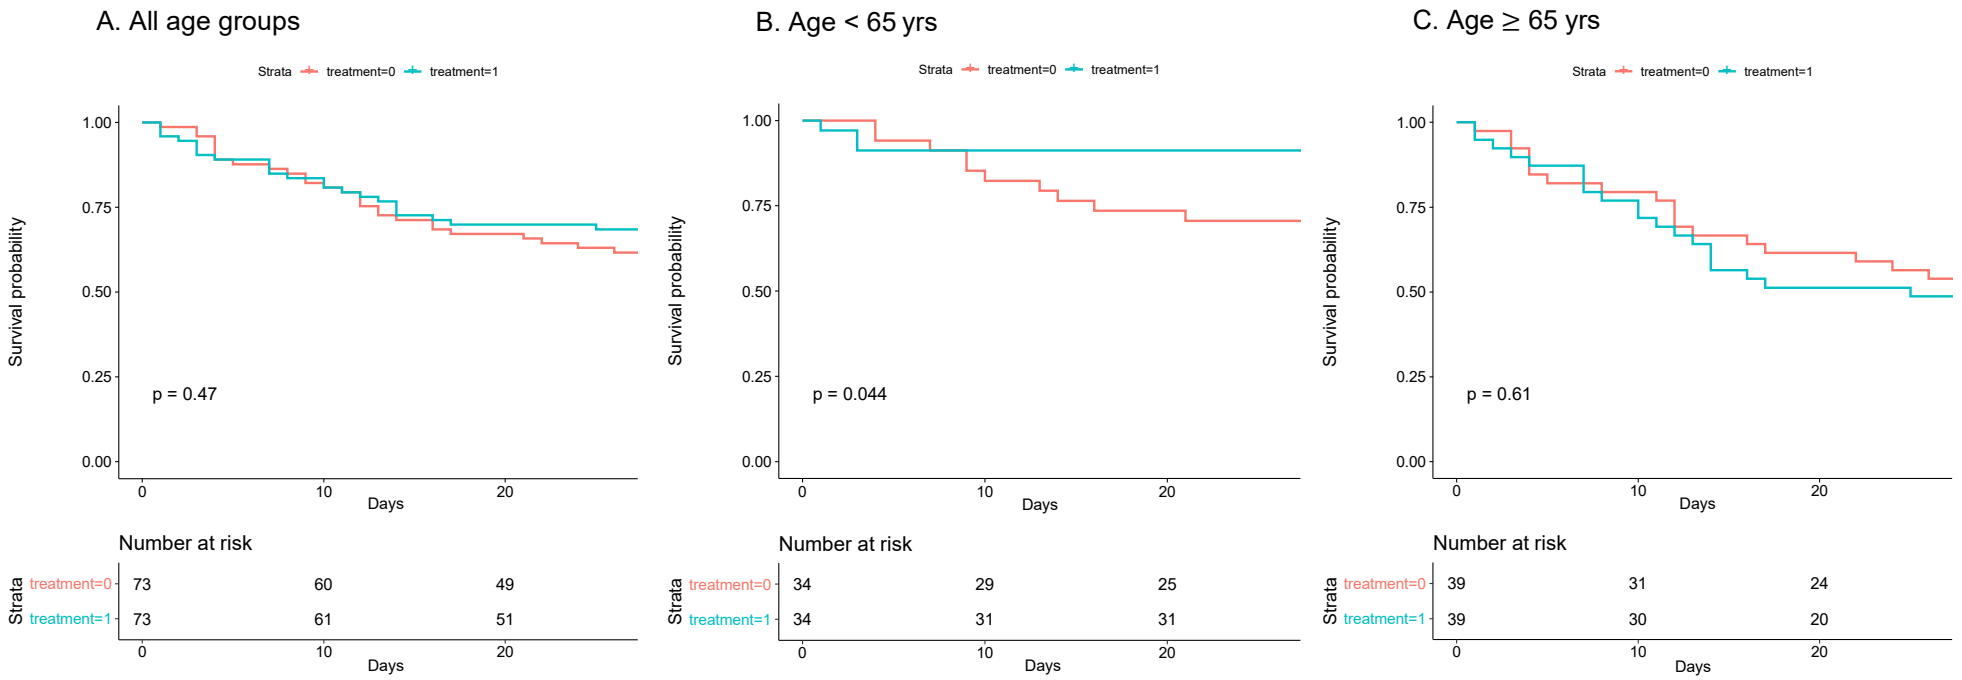

Figure 2. Kaplan–Meier Plot of the Probability of Survival from time of transfusion to day 28 in CCP recipients (n = 73) vs matched controls (n = 73). A. All age groups. B. Age < 65 years. C. Age ≥ 65 years.

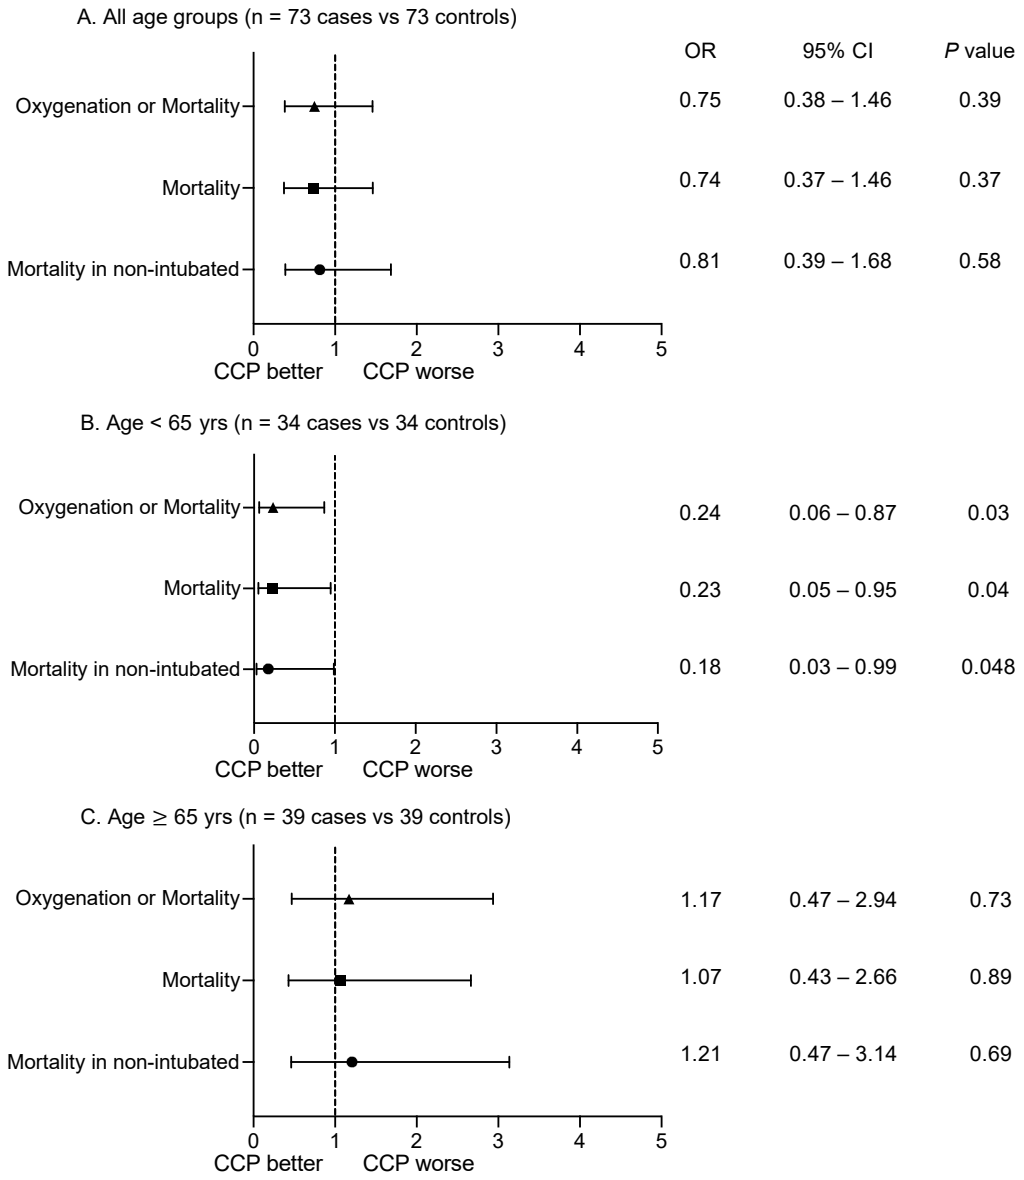

Figure 3. Day 28 outcomes for CCP recipients (n = 73) vs matched controls (n = 73) presented by odds ratio and 95% confidence intervals. A. All age groups (n = 73 cases vs 73 controls). B. Age < 65 years (n = 34 vs 34). C. Age ≥ 65 years (n = 39 vs 39). CCP, COVID-19 convalescent plasma; CI, confidence interval; OR, odds ratio.

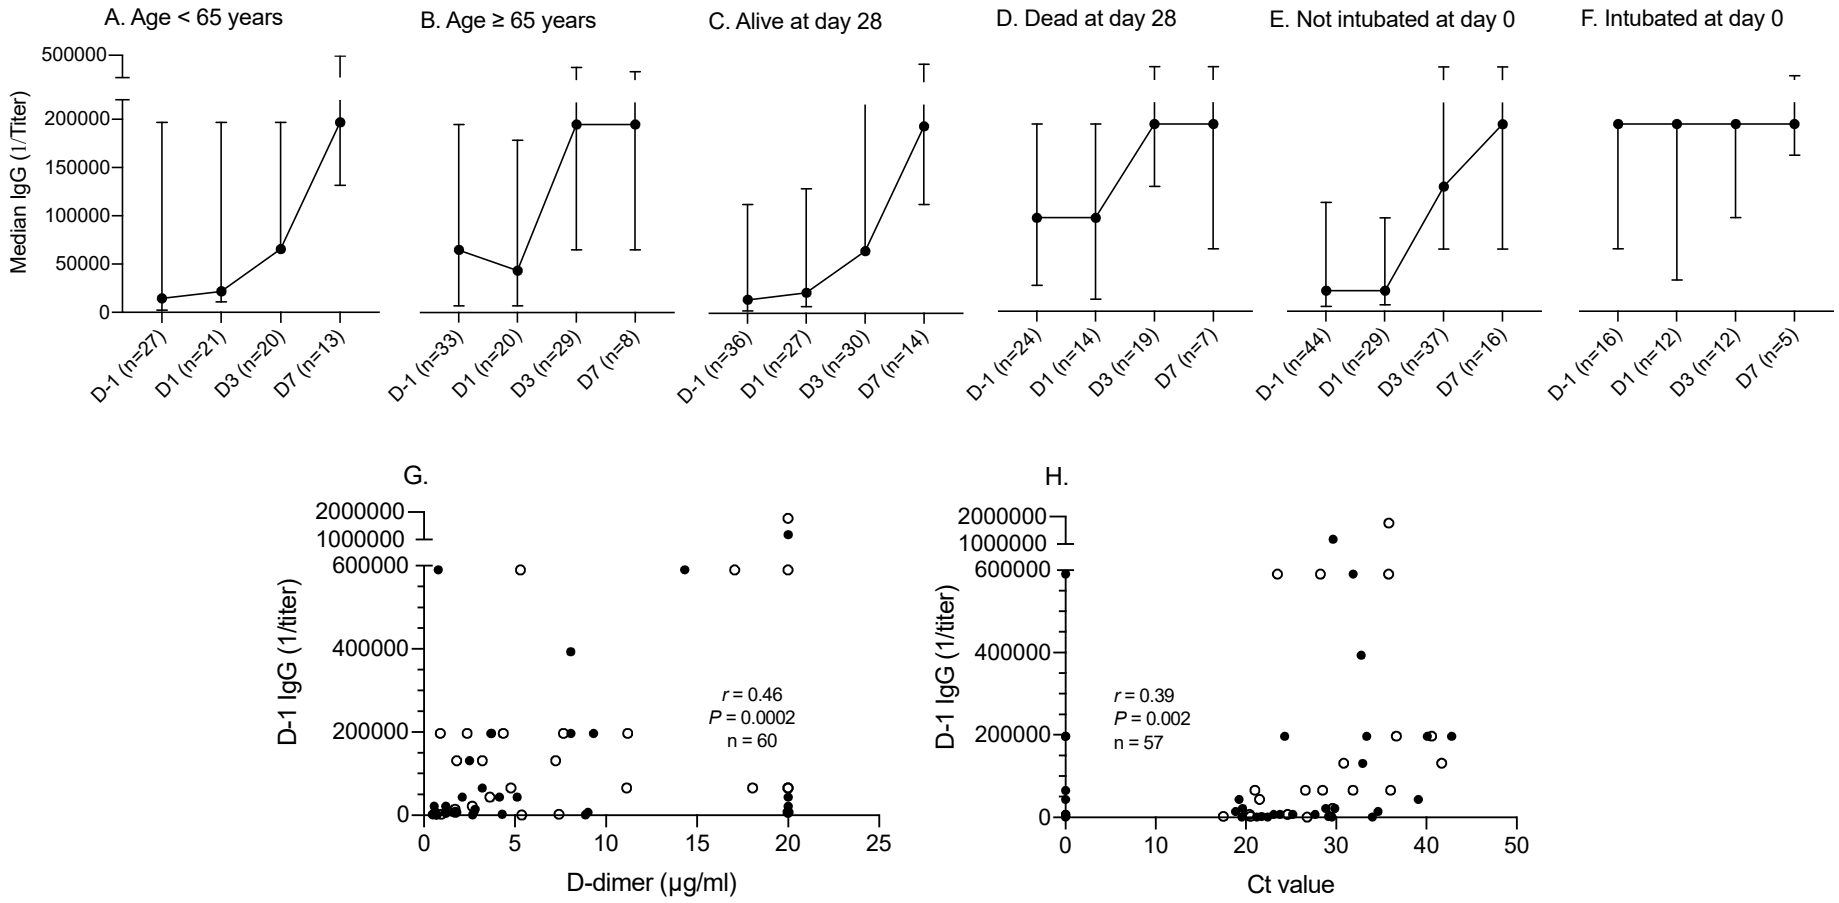

Figure 4. SARS-CoV-2 spike protein IgG titers determined by ELISA at baseline (Day-1 or D-1) and 1, 3 and 7 day after transfusion (D1, D3 and D7) in CCP recipients. (A) Age < 65 years. (B) Age ≥ 65 years. (C) Alive at day 28. (D) Died by day 28. (E) Not intubated on day of transfusion. (F) Intubated on day of transfusion. Correlation between baseline spike protein IgG titer and (G) D-dimer and (H) cycle threshold (Ct) value from initial nasopharyngeal SARS-CoV-2 RT-PCR in CCP recipients. The median titers and interquartile ranges are shown on the y-axis for each time point shown on the x-axis (A-F). X-axis shows days relative to convalescent plasma transfusion (A-F). Open circles show patients who died by day 28 (G, H). r: Spearman's correlation coefficient. Ct value, cycle threshold value.

Table 1. Baseline characteristics and outcomes in CCP recipients transfused by admission day 3 (n = 73) and propensity score matched controls (n = 73).

Abstract

Background: Convalescent plasma (CP) is being used as a treatment option in hospitalized patients with COVID-19. Till date, there is conflicting evidence on efficacy of CP in reducing COVID-19 related mortality.

Objective: to evaluate the effect of CP on 28-day mortality reduction in patients with COVID-19.

Methods: We did a multi-center, retrospective case control observational study from 1st May 2020 to 31st August 2020. A total of 1079 adult patients with moderate and severe COVID-19 requiring oxygen, were reviewed. Of these, 694 patients were admitted to ICU. Out of these, 333 were given CP along with best supportive care and remaining 361 received best supportive care only.

Results: In the overall group of 1079 patients, mortality in plasma vs no plasma group was statistically not significant (22.4% vs 18.5%; p = 0.125). However, in patients with COVID-19 admitted to ICU, mortality was significantly lower in plasma group (25.5% vs 33.2%; p = 0.026). This benefit of reduced mortality was most seen in age group 60 to 74 years (26.7% vs 43.0%; p = 0.004), driven mostly by females of this age group (23.1% vs 53.5%; p = 0.013). Significant difference in mortality was observed in patients with one comorbidity (22.3% vs 36.5%; p = 0.004). Moreover, patients on ventilator had significantly lower mortality in the plasma arm (37.2% vs 49.3%; p = 0.009); particularly so for patients on invasive mechanical ventilation (63.9% vs 82.9%; p = 0.014).

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

Conclusion: The use of CP reduced mortality in COVID-19 elderly patients admitted in ICU, above 60 years of age, particularly females, those with comorbidities and especially those who required some form of ventilation.

Key words: Convalescent plasma therapy, COVID-19, ICU cases, Mortality, Subgroup analysis

Introduction

Severe acute respiratory syndrome coronavirus 2 (SARS-COV-2), the novel coronavirus causing COVID-19, originated from Wuhan, China and has spread rapidly across the globe[1]. As no definitive treatment options are currently available for COVID-19, researchers the world over have been investigating a variety of drugs like azithromycin, hydroxychloroquine, remdesivir, Tociluzimab and dexamethasone[2-6]. Some of these are repurposed drugs and have been approved by regulators of various countries to be used as "Emergency Use Approval" (EUA) or "off label" medication[7].

Convalescent plasma (CP) has been used as a passive source of antibodies against various bacterial (tetanus and diphtheria) and viral diseases (poliomyelitis, measles, mumps)[8] and influenza A H1N1[9]. CP was also considered in earlier pandemics of Spanish flu, West Nile Virus, Middle East Respiratory Syndrome (MERS), Severe Acute Respiratory Syndrome (SARS), and more recently Ebola virus[10,11,12]. The convalescent plasma therapy (CPT) for COVID-19 has also been recently approved by US FDA and Indian Central Drugs Standard Control Organization[13]. It has been approved by the Ministry of Health and Family Welfare (MoHFW), Govt. of India, as "off label" use in patients with moderate and severe COVID-19 who are not improving and have increasing oxygen requirement despite use of steroids[7].

Evidence suggests that CP contains receptor binding domain specific antibodies which have potent antiviral activity[14-15]. Use of convalescent plasma, is known to be a well-tolerated with only a few easily managed adverse effects[16].

There have been, till date, few larger randomized controlled trials (RCT)[17,18], some retrospective observational studies[16,19,20] and many small case reports[21,22,23] on the benefits of CPT in COVID-19 patients with conflicting results. There is still no clarity whether CPT offers mortality benefit and, if yes, in which category of COVID-19 patients. The present study was designed to answer some of these questions.

Patients and Methods

Study Design

This is a multicentre, retrospective, observational case control study. COVID-19 patients admitted at various tertiary care teaching hospitals in Delhi of the same network, with electronic heath records (EHR), were included. Clinical and laboratory data were retrieved from EHR. Patients admitted from 01 May 2020 to 31 Aug 2020, with moderate and severe and / or

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

life threatening COVID-19, who needed oxygen therapy, were included. Of a total of 1249 such patients admitted during this period, 170 patients were excluded due to unavailability of sufficient clinical data. Remaining 1079 patients were included in the final analysis. All patients in either arm received various treatments as per physician discretion, institutional protocol or national guidelines for the management of COVID-19,issued by the government from time to time. A variety of medicines were used in these patients and included hydroxychloroquine (HCQ), azithromycin, doxycycline, ivermectin, remdesivir, other broad spectrum antibiotics, steroids (methylprednisolone or dexamethasone), tocilizumab and oxygen support/ventilation as required. Figure 1 shows the CONSORT diagram. All were followed for 28 days after discharge by tele-calling. The detailed analysis was performed on 694 patients admitted to ICU – 333 of these received plasma in addition to best supportive care and the other 361 were on best supportive care only.

Majority of COVID-19 patients who were given CP came from one major hospital complex, which contributed to 239 out of 333 (71.8%) patients. The physicians in this hospital had started using CP from very early days of COVID-19 outbreak in India and, because of this, significant use was observed in this hospital complex. Other hospitals, where either the usage of CP or availability of CP, was low, contributed 28.2% of plasma cases and a greater number of no plasma cases. Otherwise, the standard of care in all hospitals, across the network remained uniform.

Inclusion Criteria

Eligible patients included adults (> 18 years) with evidence of SARS-COV-2 infection by RT-PCR test of nasopharyngeal or oropharyngeal swab. Criteria for classifying patients into moderate and severe category were as per the clinical management protocols of MoHFW[7].

Moderate disease: pneumonia with no signs of severe disease, and having one or more:

- Dyspnoea, fever and cough
- SPO2 < 94% on room air
- Respiratory rate > 24 / minute

Severe disease: patient having one or more of the following conditions:

- Clinical signs of pneumonia plus one of the following: respiratory rate > 30/min or severe respiratory distress requiring ventilation or SPO2 < 90% on room air.
- ARDS (new onset bilateral opacities & SpO2 / FiO2 ≤ 315)
- Sepsis
- Septic shock

Based on these criteria, we selected only patients who needed oxygen therapy.

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

Donor Selection Criteria[24]

Donors had to meet the following criteria: 1) prior diagnosis of COVID-19 documented by a laboratory test, 2.a) complete resolution of symptoms at least 28 days prior to donation or 2.b) complete resolution of symptoms at least 14 days prior to donation. In such cases, if the patient has been discharged without negative RT-PCR for COVID-19, 2 samples of naso- and oropharyngeal swab have to be sent for RT-PCR for COVID-19, collected 24 hours apart and negative result ascertained before considering the recovered patients as a potential donor. 3) only males and nulliparous female donors of weight > 55 kg, 4) Donor with Hb>12.5g/dL and platelet count > 150 000 per microliter of blood and TLC within normal limits, 5) HIV, HBV and HCV by serology and NAT negative patients, 6) syphilis and malaria negative donors and 7) total serum protein > 6 g/dL all donor selection criteria for blood donation were followed as per Drugs and Cosmetics (second Amendment) Rules, 2020[25] .

In the absence of a standard viral neutralization test, and limited possibility of assessment of neutralizing antibody titres of > 1:640, we adopted a policy of the use of an assay to assess quantitative antibodies of anti-SARS COV2 antibodies prior to harvest of CP from the eligible donors. Antibody testing was done prospectively in donors from mid June onwards, prior to which donor samples were stored at -80° C and were retrospectively tested. For the 36 donors who's assays were done retrospectively, 12% were found have inadequate antibodies. In our larger centre, the available platform which we used was an FDA approved (Diaosorin), Quantitative IgG antibody assay against the S1&S2 protein of SARS COVID-2 virus. The cut-off of 15 AU/ml was taken for a positive result which is equivalent to 1:40 Plaque Neutralization antibody & 80 AU/ml is equivalent to 1:160 plaque neutralizing antibody assay. In the other two smaller centres, Ortho Clinical Diagnostic Vitros Anti SARS-COV-2 IgG Chemiluminescent Immuno Assay was used. The Ortho Clinical IgG is a qualitative assay. Result of this assay are based on the sample signal-to-cut-off (S/CO) ratio, with values <1.0 and ≥ 1.0 corresponding the Negative and Positive results.

Volume of donated plasmas was 400 ml. The first 200 ml (one unit) plasma was infused over one to one and half hours and if the patient did not show any improvement after 24 h, based on the decision of responsible physician, another unit of plasma was administered.

Exclusion Criteria

Patients not requiring oxygen therapy were excluded. Pregnant and lactating mothers were also excluded.

Objectives

Primary objective of the study was to study 28-day mortality in patients who received convalescent plasma therapy versus those who did not.

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

Secondary objectives were to assess if CP reduced the chances of patients going on to invasive ventilation and whether it offered any mortality benefits in critically ill patients on ventilator and vasopressors.

Statistical Analysis

Baseline characteristics such as age, gender, and comorbidities in the plasma and no plasma group were compared by chi-square test. The number of patients on invasive and non-invasive ventilators and mortality in plasma and no plasma group in various subgroup of patients were also compared with chi-square test. P-value < 0.05 was considered statistically significant. SPSS21 was used for statistical calculations. The sample size in the two groups was adequate to detect a difference of at least 10% in overall mortality between plasma and no plasma group with power of 80% when the mortality in ICU cases in the standard care group is 25%.

Results

The mean (SD) age of patients was 60.1 $\pm$ 12.1 years vs 58.9 $\pm$ 13.8 years in plasma vs no plasma group (p = 0.231). However, the age-gender distribution and the comorbidity-gender distribution was different for the following subgroups (Table I).

Males were significantly higher in the plasma group (80.2% vs 72.3%) (p = 0.015) and less of younger age (12.3% vs 19.2%) (p = 0.023). There were more females in the plasma group with multiple comorbidities, than in the no plasma group. Specific comorbidities examined were hypertension (HTN), diabetes mellitus (DM), coronary artery disease (CAD) and hypothyroidism. These were the most commonly occurring comorbidities in these cases. All other comorbidities (CKD, cancer, stroke, etc.) were reported in less than 10% cases. Hypertension was more common in plasma group (54.7% vs 43.5%, p = 0.003) and CAD less common (7.5% vs 14.1%, p = 0.005). However, the difference in mortality in these subgroups was not statistically significant.

The percentage of patients on ventilator, invasive and non-invasive, and on vasopressor were not significantly different (minimum p = 0.166) between the two groups (Table 2).

For the total of 1079 patients on oxygen, overall mortality in patients was 22.4% in the plasma group and 18.5% in the no plasma group (p = 0.125). Total 694 (64.3%) patients required transfer to intensive care unit (ICU). Three hundred thirty-three (48.0%) patients received convalescent plasma in addition to the best supportive care and the remaining 361 (52.0%) were on best supportive care only. In the ICU patients, mortality was 25.5% vs 33.2% in plasma vs no plasma group (p = 0.026). Reduced mortality in plasma group was particularly seen in patients of age 60–74 years (26.7% vs 43.0%, p = 0.004), driven mostly by females of this age group (23.1% vs 53.5%, p = 0.013).

In one of the main hospitals, where the experience with the use of CP was maximum, out of a total of 342 patients in ICU, 239 (69.8%) received plasma while 103 (30.1%) did not. Overall

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

mortality in the plasma group was 49/239 (20.5%) as compared to 36/103 (36.9%) in the no plasma group (p = 0.0014).

Significant difference in mortality was observed in patients with one comorbidity (22.3% vs 36.5%, p = 0.004). This also was primarily due to females in this subgroup (mortality 6.7% vs 49.1%, p < 0.001) in the plasma vs no plasma group (Table 3). We observed a similar reduction in mortality in patients with 2 comorbidities (35.1% vs 49.2%) but this did not reach statistical significance (p=0.099). The mortality in patients with specific comorbidity such as hypertension, diabetes and coronary artery disease were not different (least p = 0.099) but was significantly different in patients with hypothyroidism (19.0% vs 42.4%, p = 0.027). Of 38 women of age 60–74 years with one comorbidity, 12 were in plasma group and 26 in the no plasma group. Only one of these (8.3%) died in the plasma group and 13 (50.0%) in the no plasma group (p = 0.013).

Out of a total of 694 patients with severe COVID-19 in ICU, 101 (14.6%) patients worsened on non-invasive ventilation (NIV) and needed to be shifted to invasive ventilator. Fifty-four (53.46%) of these patients were given CP. There were 316 (45.5%) patients, who remained on NIV only and out of these 157 (49.6%) received CP. Overall, CP did not reduce the chances of being put on invasive ventilator from NIV (p = 0.508).

Patients on ventilator had significantly lower mortality in plasma arm (37.2% vs 49.3%, p=0.009) (Table 4). This was particularly so for patients on invasive ventilator (IV) with mortality 63.9% vs 82.9% (p = 0.014), respectively in plasma vs no plasma group. Patients on an invasive ventilator and on vasopressor had high (almost 90%) mortality in both the groups (Table 4).

Twenty-six out of 333 (7.8%) received second unit of CP, as per the physician's decision. Ten of these patients (38%) died.

Safety of CPT

Convalescent plasma infusion was largely safe and no major adverse effects were observed in any of our patients. Two patients with minor allergic reactions (rashes) were reported to the Blood Bank Officer.

Discussion

The current study was undertaken to evaluate the effectiveness of CP in patients with moderate and severe COVID-19 disease. To date, this is the largest retrospective case control study from India, presently reporting world's second largest number of COVID-19 cases.

There are a number of reports comprising small number of patients treated with CP[21,22,23] from different countries across the world. Duan et al. were first to report benefit of CP in a small cohort of 10 patients with improvement in all 10 patients and undetectable viral load in 7/10 patients[21]. In contrast, Zeng et al. reported mortality in 5/6 patients who received CP[26]. Table 5

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

summarizes the literature review of relevant studies on CP, with more than 100 patients and / or RCTs.

The results of our study are quite different from that of the only other large-scale study from India - a multicentre prospective RCT PLACID trial, which included 464 patients of moderate severity COVID-19, from 39 different hospitals across India[17]. This study did not find any difference in mortality between plasma vs no plasma group (15% vs 14%), respectively. However, this study did not include very severe or life threatening COVID-19 patients. Even in our study, if we see the overall cohort of 1079 patients (moderate and severe), CP did not have any mortality benefit (22.4% vs 18.5%; p = 0.125). The benefit emerged only in more critically ill patients of COVID-19 who were in ICU (25.5% vs 33.2%; p = 0.026). This happened despite plasma group had more elderly males, where anyway the mortality is expected to be higher[27]. Also, the main hospital, which had maximum experience with the use of CP, showed a highly significant mortality benefit in severe COVID-19 (20.5% vs 36.9%; p = 0.0014).

A similar study involving moderately ill COVID-19 patients by Abolghasemi et. al, showed that significantly higher number of patients who received CP were discharged from the hospital versus control (98.2% vs 78.7%)[28]. They reported that CP significantly reduced need for mechanical ventilation in treatment versus control group (7% vs 20.3%). All-cause mortality in CP group was 14.8% versus 24.3% in control arm in the study but this was not statistically significant (p = 0.09). RCT by Ling Li et al. also showed no significant difference in time to clinical improvement or in 28-day mortality between patients who received CP vs control[18].

Study by Xia et al. also showed that there was less likelihood of patient who received CP to be transferred to ICU as compared to those who did not receive CP (2.4% vs 5.1%)[20]. Our study did not show any benefit with CP, in terms of reducing the chances of patients going onto invasive ventilation from NIV. The Indian PLACID trial also showed no benefit of CP in terms of total and post enrolment duration of respiratory support, and proportion of patients who had to be put on invasive ventilation and those needing vasopressor support[17]. In the study by Altuntas et al., the duration of stay in ICU, rate of mechanical ventilation and vasopressor requirement were lower in the CP group versus control (p = 0.001, p = 0.02, p = 0.001 respectively)[29]. They however, found no statistically significant difference in the fatality rate between the CP and control groups (24.7% vs 27.7%, p = 0.150). In our study, however patients on ventilator had significantly lower mortality in plasma arm as compared to no plasma arm (37.2% vs 49.3%, p = 0.009). This was particularly so for patients on invasive ventilator with mortality 63.9% and 82.9% (p = 0.014) in plasma and no plasma arm, respectively.

The patient outcome in the current study was quite similar to the study by Salazar et al. where they found significant mortality reduction in severe and life threatening COVID-19 patients (p = 0.047) especially when CP was given within 72 hours of admission[30].

In our study, we found maximum benefit of CP in ICU patients, in the age group 60-74 years, where the mortality in the plasma group was 26.7% versus 43% in the no plasma group (p=

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

0.004). Similar findings were reported by Rogers et al. wherein a subgroup analysis of patients above 65-years-old or greater who received CP demonstrated a significantly increased hospital discharge rate among these patients (RR 1.86, 95% CI 1.03-3.36)[31].

Significant difference in mortality between plasma and no plasma group was also observed in patients in our study with one comorbidity largely driven by females. This finding has not been reported in literature so far. The mortality in patients with specific comorbidity such as HTN, DM and CAD was not different (minimum p = 0.099) but was significantly different in patients with hypothyroidism (19% vs 42.4%, p = 0.027). This needs further investigation.

Klassen et al. aggregated patient outcome data from various RCTs, matched-control, case series and case report studies and found that CP exhibited a 51% reduction in mortality rate compared to patients receiving standard treatments (19% vs. 29% mortality; OR:0.49, 95% CI: 0.37, 0.64, p< 0.001)[32].

Our study showed mortality benefit of CP in severely ill COVID-19 patients requiring some form of ventilation and in the age group >60 years, especially women with 1-2 medical comorbidities. We do not know the exact mechanism of action of CP in COVID-19 but it seems that plasma therapy played a significant role in reduction of mortality in the highly vulnerable patient population of elderly and on ventilator. Perhaps a little push by convalescent plasma in this segment of patients was able to tilt the balance towards recovery.

Limitations of the study

It is a retrospective study. During the study duration, patients received several treatments such as HCQs, remdesevir, ivermectin, azithromycin, steroids (dexamethasone or methylprednisolone), tociluzimab depending on prevailing guidelines at those time points and at treating physician's discretion. Majority of patients in plasma arm were recruited at one centre while no plasma arm patients were at other hubs. We also do not have information if some of the patients had already developed adequate antibodies when CP was performed. These limitations notwithstanding, we are able to identify a subset of patients with COVID-19 who are likely to benefit from CP.

Conclusions

The use of convalescent plasma reduced mortality in severe COVID-19 elderly patients, above 60 years of age, particularly females, those with comorbidities and especially those who require some form of ventilation. This beneficial effect was lost when the entire cohort of patients across varying severity of illness was compared. Plasma did not seem to offer any mortality benefit in patients of moderate severity or those who were terminally ill. Further research into the mechanism of actions of CP in COVID-19 may help predict the good responders.

CAD	24	47.1%	11	44.0%	0.802
Hypothyroidism	14	42.4%	8	19.0%	0.027

*Deaths out of cases mentioned in Table 1 for the respective subgroups
HTN: Hypertension; DM: Diabetes mellitus; CAD: Coronary artery disease

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

Table 4. Comparative Mortality of patients on ventilation & vasopressor between Best Supportive Care Only Group & Plasma with Best Supportive Care Group

Characteristic	Best Supportive Care Only (*n* = 361)		Plasma with Best Supportive Care (*n* = 333)		p-value
	Deaths*	Mortality	Deaths*	Mortality	
No Ventilator	7	5.3%	4	3.5%	0.488
Any Ventilator	113	49.3%	81	37.2%	0.009
Non-Invasive (NIV)	55	34.6%	42	26.8%	0.131
Invasive (IV)	58	82.9%	39	63.9%	0.014
Vasopressor with invasive ventilation (IV)	33	91.7%	21	87.5%	0.675

*Deaths out of cases mentioned in Table 2 in the respective rows

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

Table 5. Review of various studies (larger RCTs and/or > 100 matched cases) on effectiveness of Convalescent Plasma in COVID-19

Ref	Number of patients	Study	Patient population	Antibody titre used	Results	Adverse Effects	Author Conclusions	Our comments
Ling Li et al.[18]	103	Open label RCT, multicentre	23 vs 22 Severe 29 vs 29 Life-threatening COVID-19	1:640	No significant difference in time to clinical improvement or in 28 days mortality between patients who received CP versus control	Chills and rashes -1 shortness of breath, cyanosis, and severe dyspnea -1	CP not effective	Not powered to predict the difference
Abolghasemi H et al.[28]	189 115 in plasma group and 74 in control group	Multicentre nonrandomized clinical study	Moderate severity	Antibody titer cut off > 1.1 using semi quantitative ELISA and Rapid strip test	CP reduced all cause mortality in treatment group compared with control group (14.8% vs 24.3%); however this was not statistically significant (p=0.09). it had a significant impact of length of stay (p=0.002) and need for intubation (p=0.006)		CP effective	Control group was much smaller and had milder cases
Salazar E et al.[30]	136 cases and 251 controls	Prospective propensity matched study	Severe and/or life threatening COVID-19	Anti-RBD IgG titre of 1:1350	Significant reduction (p= 0.047) in mortality within 28 days, specifically in patients transfused within 72 hours of admission with CP with anti-RBD IgG titre of > 1:1350		Transfusion of high anti-RBD IgG titre CP early in hospitalisation reduces mortality	
Xia X et al.[20]	138 cases and 1568 controls	Retrospective observational study	Severe or critical COVID-19		Mortality in CP group was 2.2% as compared to 4.1% in non CP group also from CP group, only 2.4% got shifted to ICU whereas in non CP group, 5.1% patients got ICU transfer	3 patients had minor allergic reactions (pruritus or erythema) during transfusion	Patients with SCSS > 5 before therapy showed no improvement after CP.	Authors classified patients who were given CP into responders, partial responders and nonresponders.
Altuntas F et al.[29]	Cases 888 Control 888	Retrospective case control study	Severe and critically ill COVID-19	IgG antibody not routinely done	Duration in ICU, rate of mechanical ventilation support and vasopressor support were lower in CP group (p = 0.001, p = 0.02, p = 0.001, respectively).	Not available		Antibody titres of plasma donors were not available

This preprint research paper has not been peer reviewed. Electronic copy available at: https://ssrn.com/abstract=3726179

					CFR was 24.7 in CP group and 27.7 in control group (p = 0.15)			
Agarwal A et al & PLACID trial collaborators[17]	Cases: 235 Controls: 229	Open label parallel are phase II Multicentre randomized controlled trial	Moderately ill COVID- 19 patients	Nearly 2 / 3rd of donor had NAb titre > 1:20 with a median titre of 1:40	Mortality in intervention arm was 14.5% vs 13.5% in control arm (odd ratios was 1.06). There was no difference in the 2 arms with respect to duration of respiratory support, proportion of patient requiring invasive ventilation and vasopressor support	Minor adverse event of pain, chills, nausea in one patient; fever and tachycardia in 3 patients; dyspnoea and IV catheter blockage in 2 patients each. Mortality was assessed as possibly related to CP in 3 patients (1.3%).	CP not effective	Three reported cases of mortality related to CP raised a significant concern regarding safety profile of CP.
OUR STUDY	1079 (total cases in ward and ICU) In ICU : 694 Plasma group in ICU :333 No plasma group in ICU : 361	Retrospective case control observational study	Moderate and Severe COVID-19	Quantitative IgG antibody assay with cut off 15 AU/ml equivalent to 1:40 plaque neutralization antibody	Overall no statistically significant difference in mortality between CP and non CP group (22.4% vs 18.5%; p=0.125. However, significantly reduced mortality in COVID-19 patients admitted in ICU (25.5% vs 33.2%; p=0.026)especially in age group 60-74 (26.7% vs 43%; p=0.004), females (23.1% vs 53.5%; p=0.013), those with one comorbid medical condition(22.3% vs 36.5%; p=0.004) and on invasive mechanical ventilation (63.9%vs 82.9%; p =0.014)	2 patients had mild allergic reaction (rashes) during plasma transfusion	Highest mortality benefit with CP seen in COVID-19 patients above 60 years of age, admitted in ICU, especially females and those on ventilator and having medical comorbid conditions.

NIBSC

Calibration of secondary standards to WHO International Standards

Peter Rigsby, Analytical & Biological Sciences, NIBSC

Medicines & Healthcare products Regulatory Agency

WHO International Standards (IS)

- World Health Organization International Standards: highest order standards used to enable biological & immunological assay results to be expressed in the same way worldwide
- WHO Expert Committee on Biological Standardization (ECBS) establishes and assigns a value to an IS
- “An international collaborative study must be carried out before any candidate biological reference standard can be considered for establishment by the WHO ECBS” *(WHO Technical Report Series, No. 932, 2006)*

WHO International Standards (IS)

- Most IS define International Units (IU) of biological activity
  - Arbitrary units representing content of ampoule or vial; no uncertainty assigned
  - Often not dependent on assay method used
- Often lyophilized, giving highly stable preparations

- Not intended for routine use
  - Secondary standards calibrated directly against (and traceable to) the relevant IS are required

Guidance documents

World Health Organization

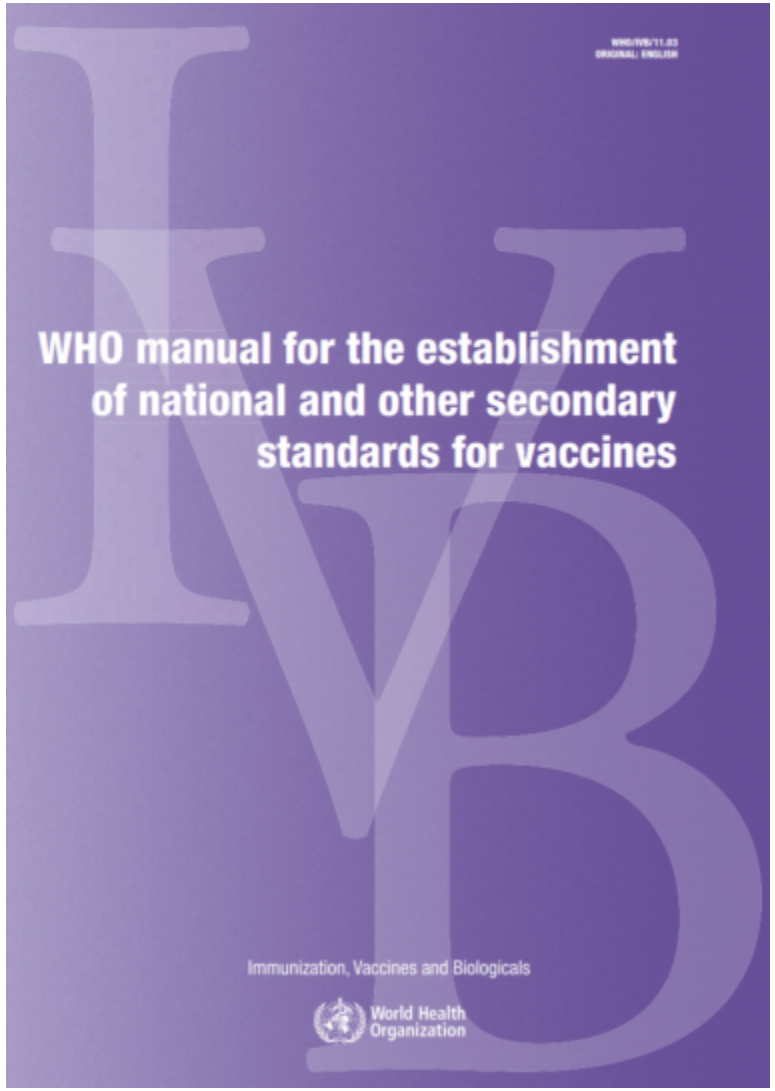
Post ECBS version

ENGLISH ONLY

MANUAL FOR THE PREPARATION OF SECONDARY REFERENCE MATERIALS FOR IN VITRO DIAGNOSTIC ASSAYS DESIGNED FOR INFECTIOUS DISEASE NUCLEIC ACID OR ANTIGEN DETECTION:

CALIBRATION TO WHO INTERNATIONAL STANDARDS

© World Health Organization 2016



Key properties of different standards

	WHO International Standard	Secondary standard	Tertiary standard
Alternate names	Highest order, International calibrator	Regional or national working reference materials, working reagents, manufacturer's working calibrator	Working reagents, in-house calibrators, in-house controls, manufacturer's product calibrator
Calibration	Established by WHO international collaborative study	Calibrated against the WHO International Standard	Calibrated against the secondary standard
Unitage	IU/mL	IU/mL	IU/mL
Traceability	N/A	Yes	Yes
Uncertainty of measurement	No	Yes (assay specific)	Yes (assay specific)
Final format	Lyophilised (generally)	Lyophilised or liquid	Liquid (generally)
Usage	Calibration of secondary standards, Initial validation of new assay/platform	Calibration of tertiary standards, working reagent, limited use as run control or calibrator	Working reagent, run control, calibrator
Establishment of standard	International agreement through WHO international collaborative study including laboratories worldwide, different assays, different types of test laboratories (approximately 15-30 participants)	May be calibrated in several ways: • In parallel with a study to establish the International Standard • Regional or national collaborative study similar to the WHO collaborative study but with fewer participants from regional laboratories • Small study by a single or limited number of laboratories with a single or limited number of different assays/platforms	Assay-specific study, normally by a single laboratory for use with a specific test/platform Small study by a single or limited number of laboratories with a single or limited number of different assays/platforms

(WHO Technical Report Series, No. 1004, Annex 6, 2017)

Calibration principles

- Test secondary standard multiple times on different occasions in parallel with the WHO IS under exact same test conditions
- Assess validity of individual assays e.g. linearity and parallelism
- Estimate potency (IU/mL) for secondary standard in all valid assays
- Combine estimates and assign combined estimate as potency

Notes on calibration

- Use optimal test system (e.g. commercial assay, validated laboratory test)
- Use only qualified operators, equipment etc.
- No general guidance regarding number of assay runs to perform
  - Decision will depend on various factors
  - E.g. sufficient testing may be performed to give Uncertainty of Measurement (UoM) that is negligible in comparison to the expected precision of the routine assay

Slide 7 Notes

Assuming appropriate assay conditions, UoM can be expressed as 95% Confidence Interval (CI) for combined estimate.
In such cases, this will account for imprecision but not any inherent bias so care should be taken with assay design etc.

Calibration example

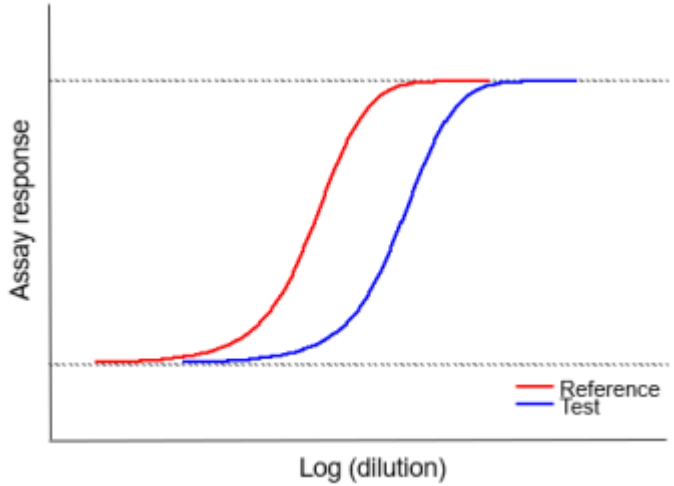
- Samples tested:
  - WHO IS for anti-SARS-CoV-2 immunoglobulin (20/136)
    Potency 250 IU/ampoule for neutralising antibody assays
    Reconstituted to concentration of 1000 IU/mL
  - In-House Standard (IHS)
- Aim: Calibrate IHS in IU/mL using IS
- Samples initially tested in 3 independent assay runs

Calibration example – assay 1

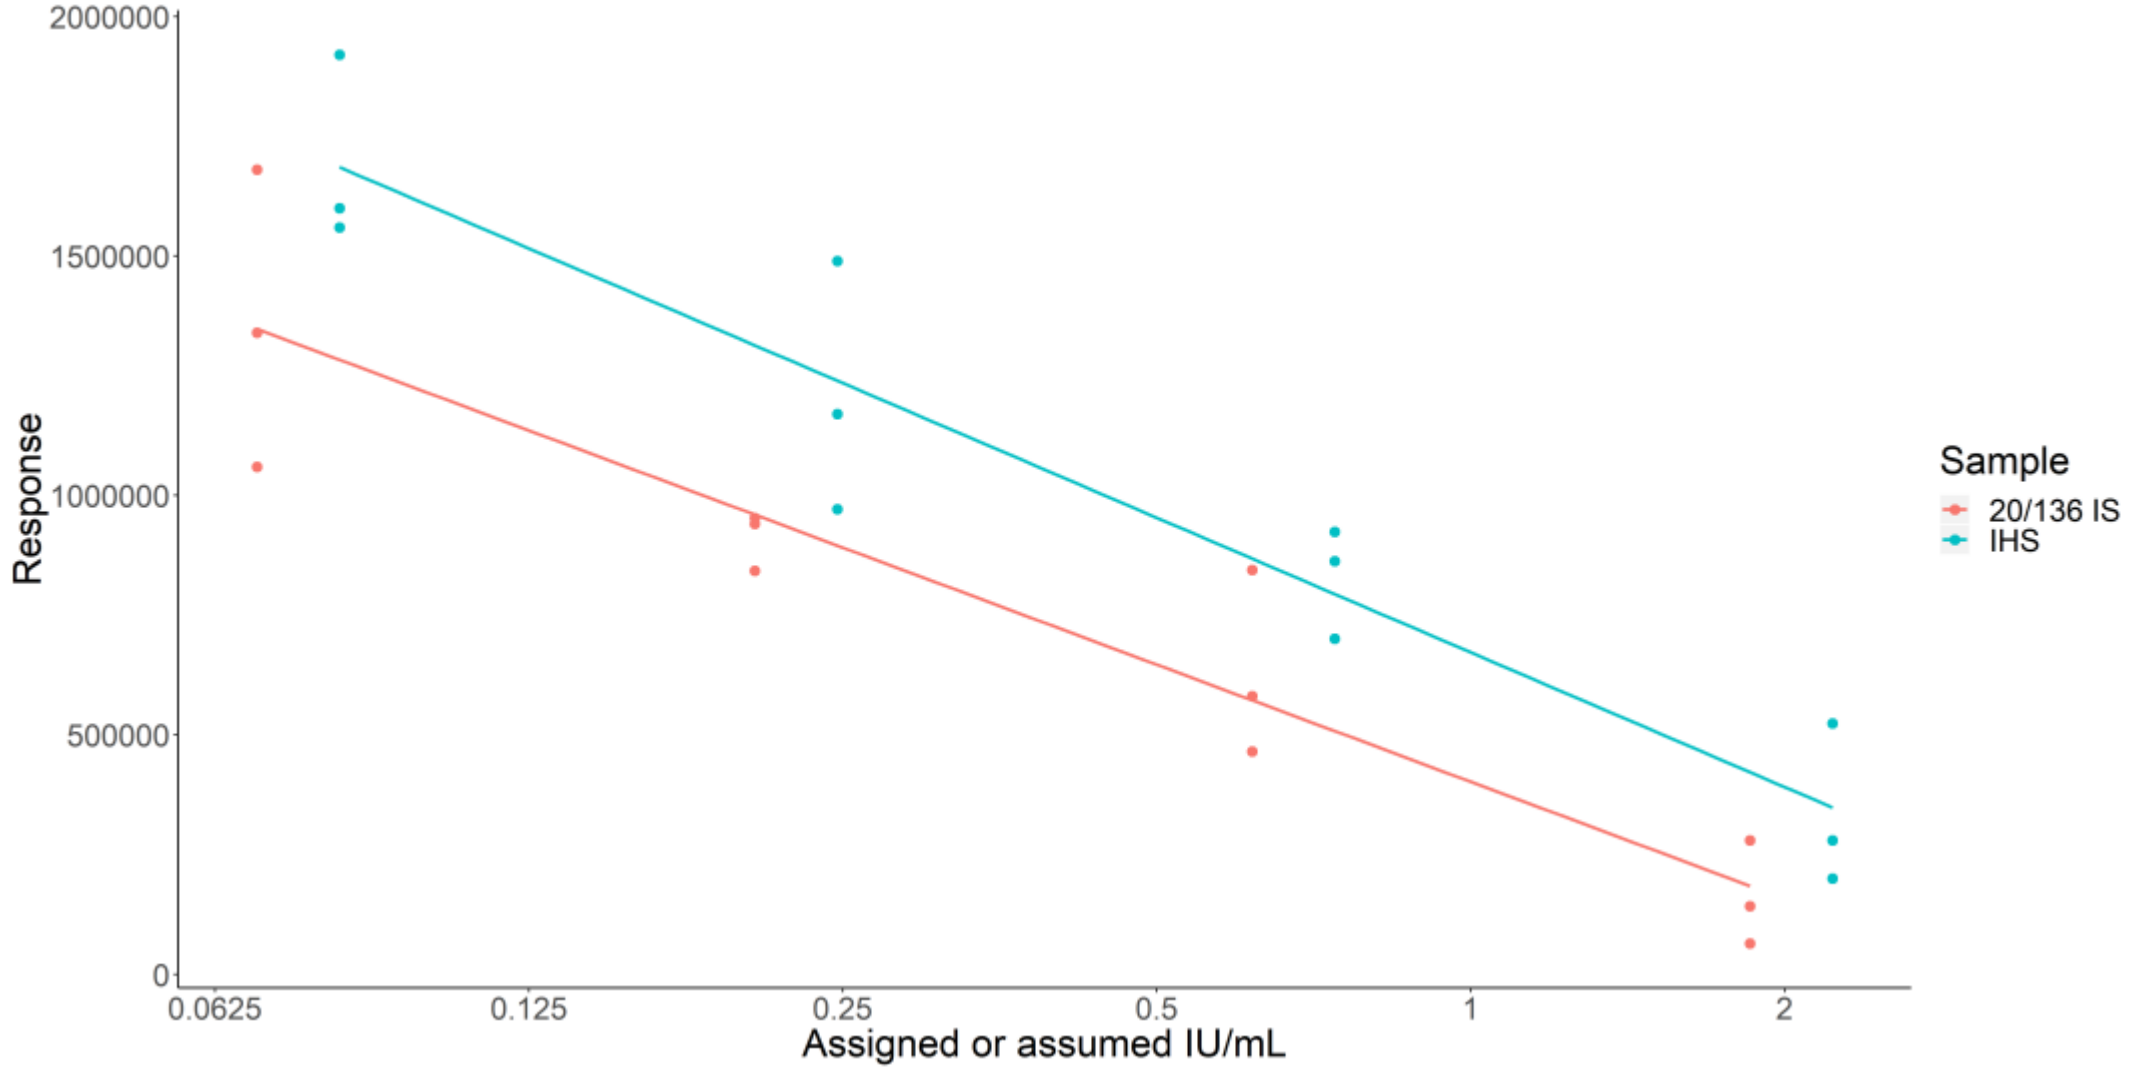
IS 20/136				IHS			
1000 IU/mL				20 IU/mL (assumed)			
Dilution	Responses			Dilution	Responses		
1/60	30	80	360	1/1	40	30	30
1/180	70800	92400	2510	1/3	580	2730	71600
1/540	142000	280000	64700	1/9	280000	200000	524000
1/1620	465000	844000	581000	1/27	863000	701000	924000
1/4860	953000	941000	843000	1/81	1170000	1490000	971000
1/14580	1060000	1680000	1340000	1/243	1560000	1920000	1600000
1/43740	870000	1480000	1290000	1/729	1210000	1410000	1310000

Data analysis

- Objectives of dose-response data analysis:
  - Assess assay validity e.g. linearity/parallelism for linear model
  - Estimate potency of IHS relative to WHO IS
- Various possible analysis methods, including:
  - Parallel line (parallel curve) analysis [recommended]
  - Interpolation from fitted dose-response curve for WHO IS
- Software options will depend on analysis method:
  - Specialised software for bioassay analysis
  - General statistical software packages, Excel



Calibration example – assay 1



Calibration example – assay 1 analysis

- Analysis output for assay 1:

Source	Df	Sum of Sq	Mean Sq	F-ratio	P-Value
Treatments	7	5.63597E+12	8.05139E+11	21.549	<0.001 ***

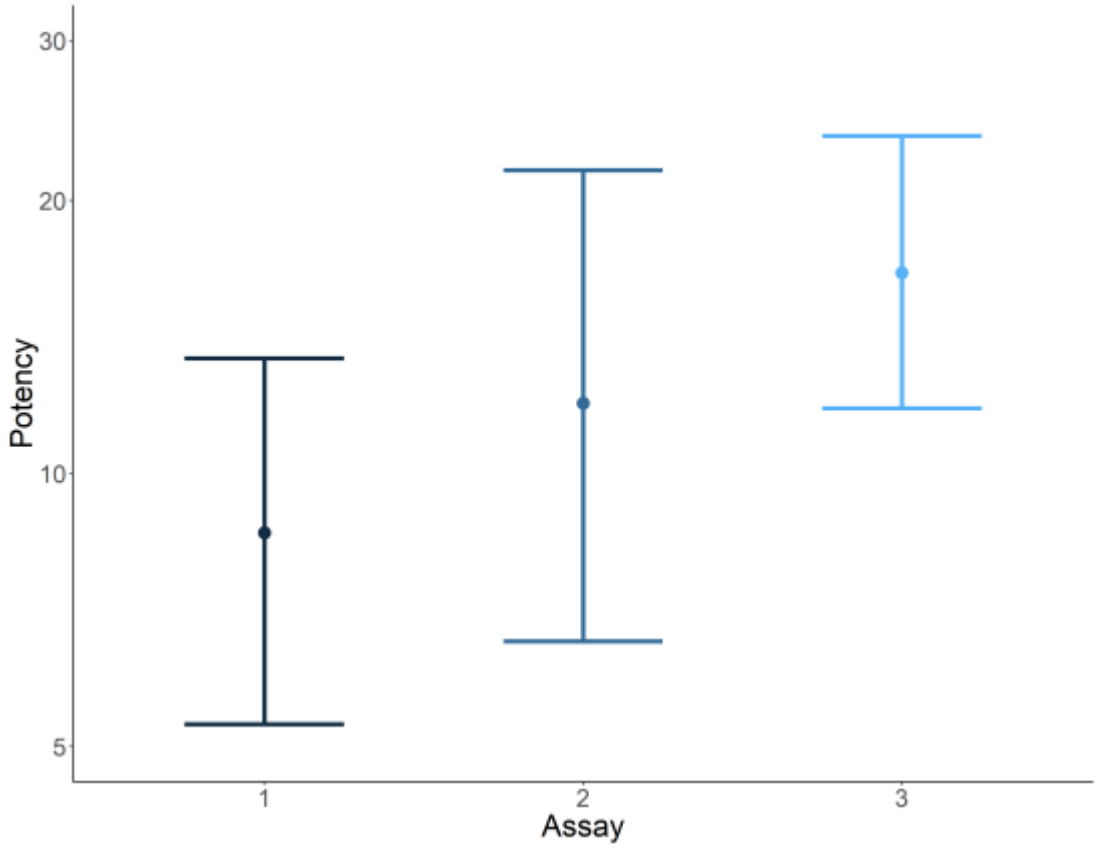
- Combined estimate (IU/mL) from assays 1-3:

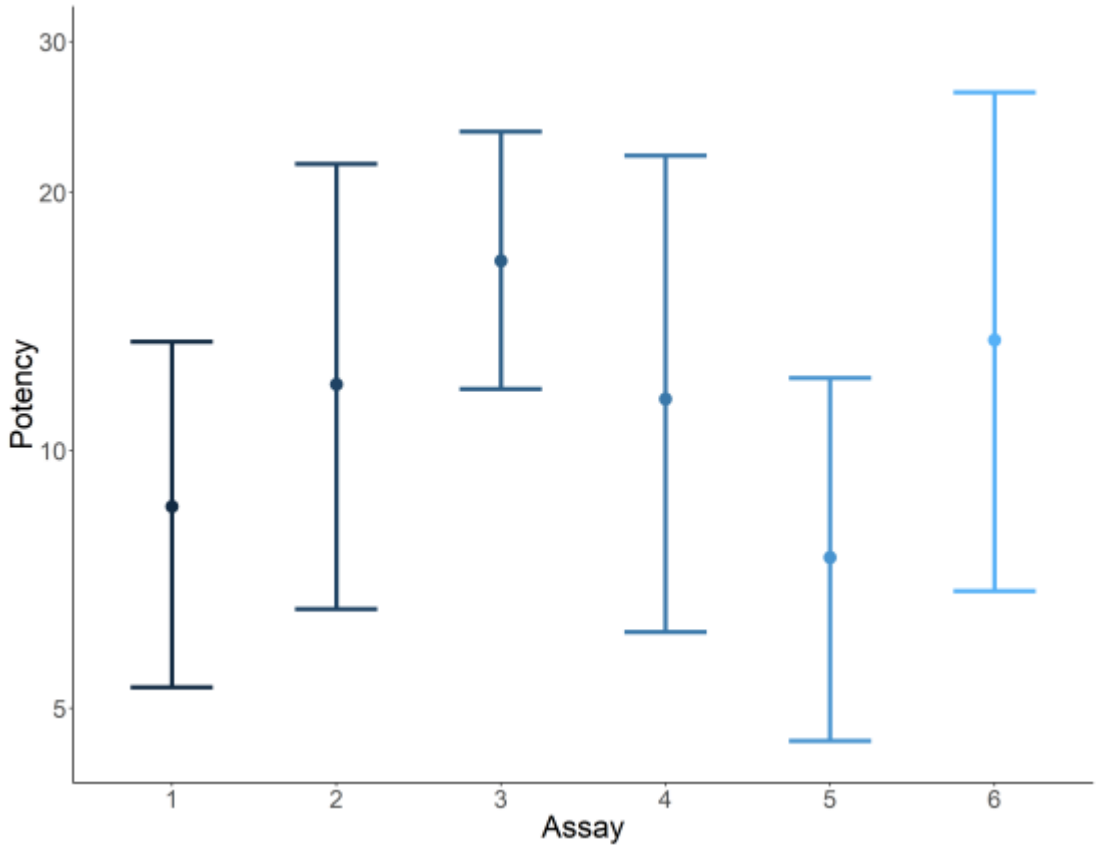
Estimate	95% LCL	95% UCL	LCL as %	UCL as %
12.3	8.5	17.9	68.9%	145.2%



Calibration example – after additional assays

- Combined estimate (IU/mL) from assays 1-6:

Estimate	95% LCL	95% UCL	LCL as %	UCL as %
11.5	9.2	14.4	79.9%	125.1%



Calibration example – conclusions

- Assigned value to internal standard = 11.5 IU/mL

- Assay currently states µg/mL unitage for internal standard

➢ Neat concentration used is 5 µg/mL

➢ Calibration exercise estimated neat concentration as 11.5 IU/mL

➢ Any existing results reported in µg/mL (from this assay platform, using this internal standard) can now be converted to IU/mL

Summary

- Expression of assay results in International Units (IU) requires use of the WHO International Standard (IS) directly, or the use of a secondary standard calibrated using the IS
- A calibration exercise can be performed to assign an IU value to the secondary standard
- Existing assay results already reported relative to a secondary standard (in µg, EU, relative titre etc.), can then be reported as IU
  - In most cases, existing assay analysis methods are unaffected

WHO standards for COVID-19: update from WHO ECBS

Dr Ivana Knezevic, Norms and Standards for Biologicals (WHO/MHP/HPS)

20 Jan 2021, WG on COVID-19 assays

WHO norms and standards for biologicals

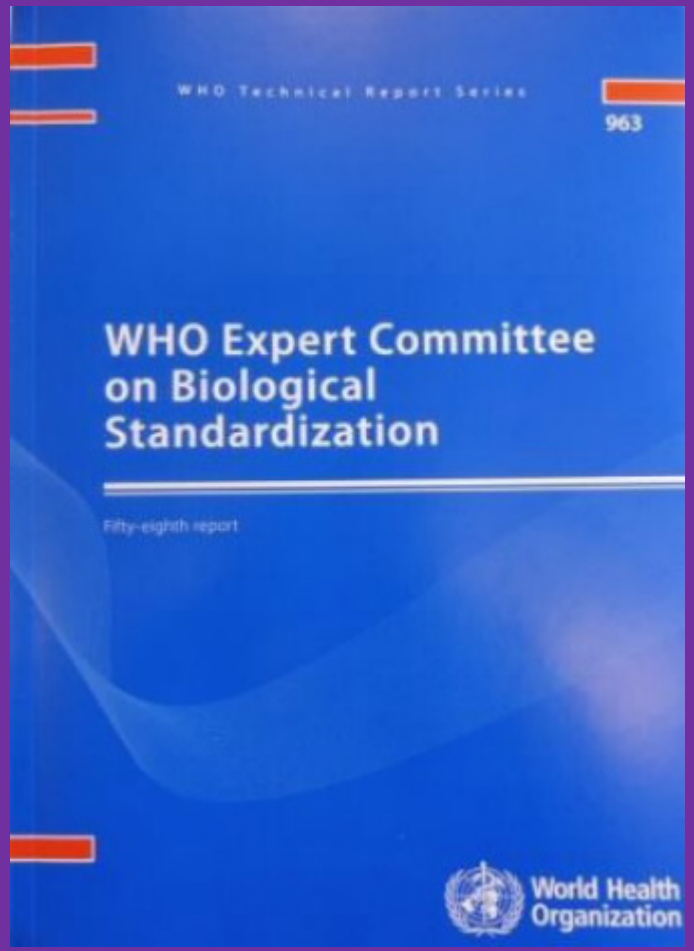
https://www.who.int/groups/expert-committee-on-biological-standardization

Global written standards

Total 103 docs (Recommendations/ Guidelines)
General docs that apply to vaccines & biologicals: 10
General documents that apply to all vaccines: 12
Vaccine specific: 71
BTP specific: 9

Scientific evidence

1) Standardization of assays
2) Further development and refinement of QC tests
3) Scientific basis for setting specifications



Global measurement standards

Measurement standards:
essential elements for development, licensing and lot release

Main outcomes of 73rd ECBS meeting in 2020

World Health Organization

1. ECBS meeting on 9-10 Dec 2020 (focused on COVID-19): published on WHO web site: https://www.who.int/groups/expert-committee-on-biological-standardization:

- Executive Summary posted on WHO web site on 16 Dec 2020:

https://www.who.int/groups/expert-committee-on-biological-standardization

3 new WHO International reference preparations established

Standards for use in public health emergencies		
SARS-CoV-2 RNA for NAT-based assays	7.40 $\log_{10}$ IU/ampoule	First WHO International Standard
Anti-SARS-CoV-2 immunoglobulin	250 IU/ampoule (neutralizing antibody activity)	First WHO International Standard
Anti-SARS-CoV-2 immunoglobulin panel	[no assigned units]	First WHO International Reference Panel

- Proposal to develop a standard for SARS-CoV-2 antigens to support the development, assessment and comparability of antigen-based rapid diagnostic tests.

- Update on written standards provided

Measurement standards for COVID-19

World Health Organization

Aim: to facilitate the development, validation and assessment of molecular and antibody assays. This will facilitate the comparability of results from different assays/labs and help harmonize the evaluation of diagnostics, vaccines and other products. Expression of the results of neutralization assays in the International Units would also contribute to the establishment of the correlates of protection.

Timeline: Feb to Dec 2020 is the absolute record for developing and establishing WHO International Standards in 9 months instead of 2-3 years.

Antibody standards during the COVID-19 pandemic: research reagents and WHO International Standards: joint effort by CEPI, NIBSC and WHO

WHO International Antibody Standards:

- **help interpreting results from vaccine CTs by providing the basis for the expression of the antibody titers in the International Units, particularly results from efficacy trials for various vaccine candidates. For instance, correlate of protection can be defined as IU/mL**
- **IS permits datasets across a range of assays to be compared by reference to the IU. This is especially important with the large number of vaccine candidates**

Uptake of WHO Ab standards – way forward

World Health Organization

1. **Why WHO Ab standards have not been used as expected?**

- Lack of information on the existence of these standards
- Misunderstandings regarding the intended use
- Labour intense calibration of secondary standards
- Lack of expertise for the use of standards and for the assays in CTs
- Other reasons?

2. **Need for secondary standards calibrated against WHO IS**

- Several initiatives ongoing
- How many vaccine developers plan to express results of neutralization assays in IU?

How can we help users of standards to express CT results in the International Units?

World Health Organization

1. ECBS – Executive Summary and report in WHO TRS

2. Collaborative study report provides lots of information about the standards but also about the assays

3. Instruction for use

4. WHO EUL: "Considerations for the Assessment of COVID-19 Vaccines for Listing by WHO" (https://www.who.int/teams/regulation-prequalification/eul/covid-19):

4.1. The assays used for immunogenicity evaluation should be validated for their intended purpose and calibrated against WHO international standards, where available (section 3.2)

4.2. Assay results should be reported in international units wherever possible (section 3.3.8)

5. Webinars

6. Case studies with the examples

7. Manual for secondary standards for vaccines – Update and/or specific advice for COVID-19 standards

8. Other opportunities?

NIBSC

Roles and Importance of Standards in Assays

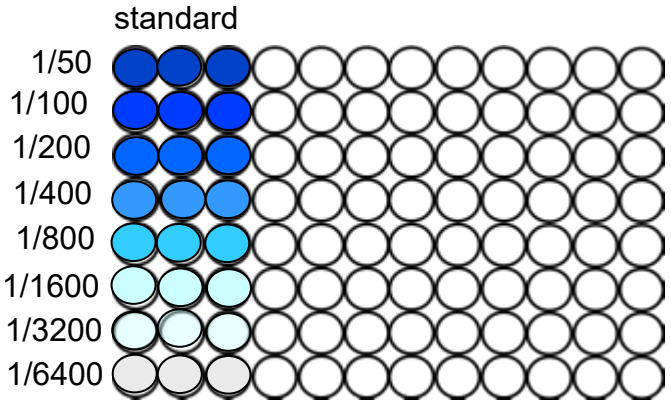
Giada Mattiuzzo

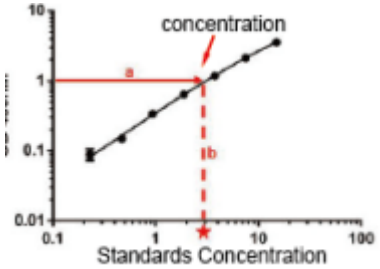
20th January 2021

Standards in assays

- 44 laboratories participated to the CS establishment of WHO IS for anti-SARS-CoV-2 immunoglobulin;
- 8 laboratories did not use an assay internal standard – results reported based on dilution factor
- Difficult to compare with other assays

- Internal calibrator/standard;
- run control;
- working reagent
- Secondary or tertiary reagent





Slide 2 Notes

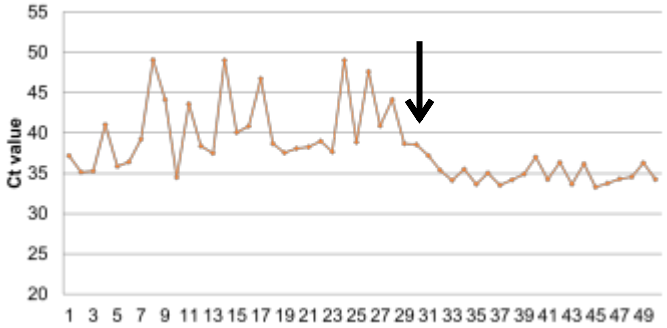
Most commercial assays have a calibrant

External controls

Allow to check for performance drifting of the assay over time/between operators

Monitoring data from diagnostic lab starting using NIBSC Working Reagent for Norovirus GII (⇩)

Kindly provided by NIBSC Diagnostics Group, IDD



Examples are: national standards, commercially available secondary reagents

Can be used to compare assay between laboratory

Primary calibrant

- WHO International Standard – established by the WHO ECBS
- Define the common language to expressed potency of the samples

Slide 4 Notes

Common language already reduces the difference between labs

Why International units? A bit of history

- 1890's First Biological: Diphtheria antitoxin
  No reliably produced. Lot to lot variation as biological activity differed from physical property
- Paul Ehrlich: STANDARD ANTITOXIN PREPARATION – calibrated in Units and used to calibrate future batches
- Henry Dale applied concept to insulin and other biologics (1920s) and on International level – appearance of International Units (IUs) as measure of strength or activity of a product

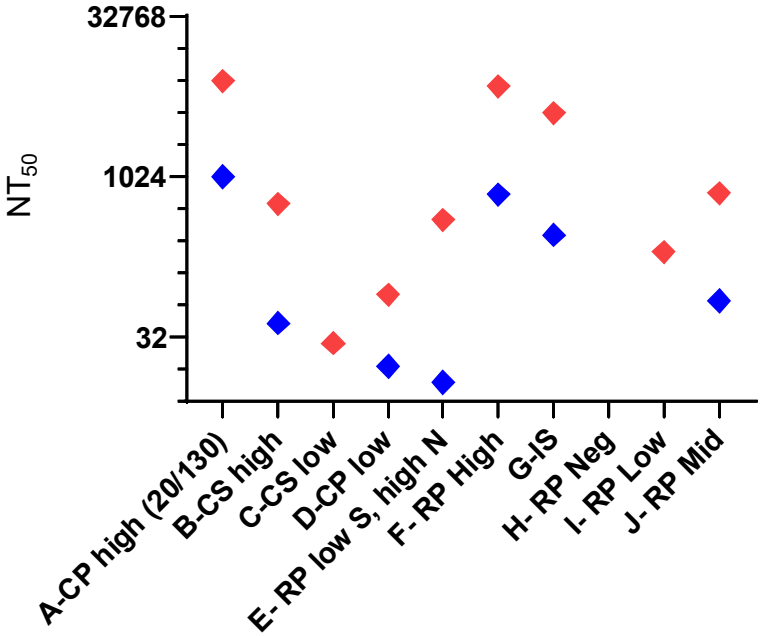
https://www.who.int/bloodproducts/ref_materials/en/

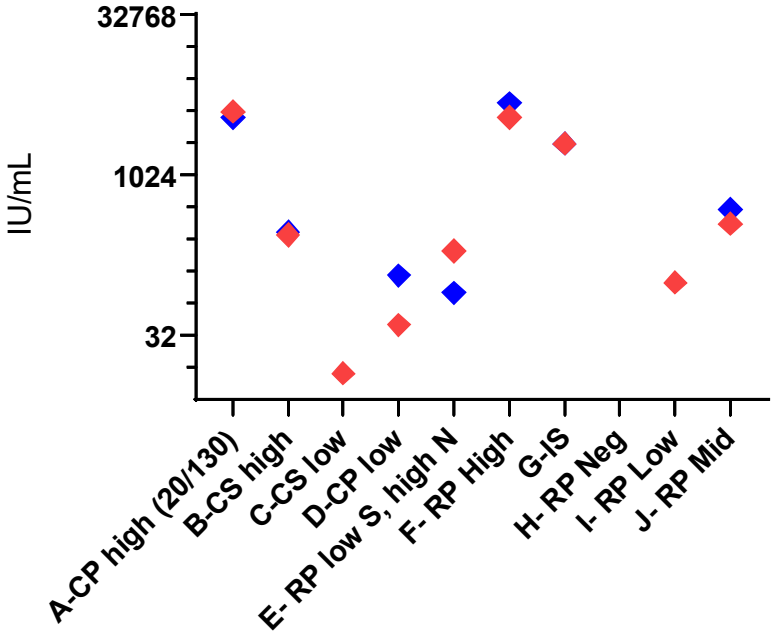
Slide 5 Notes

This is to answer the popular question on what’s the conversion factor to ng/mL

A recent example: SARS-CoV-2 antibody

Foci reduction neutralisation assay





Binding antibody assay- Spike ELISA

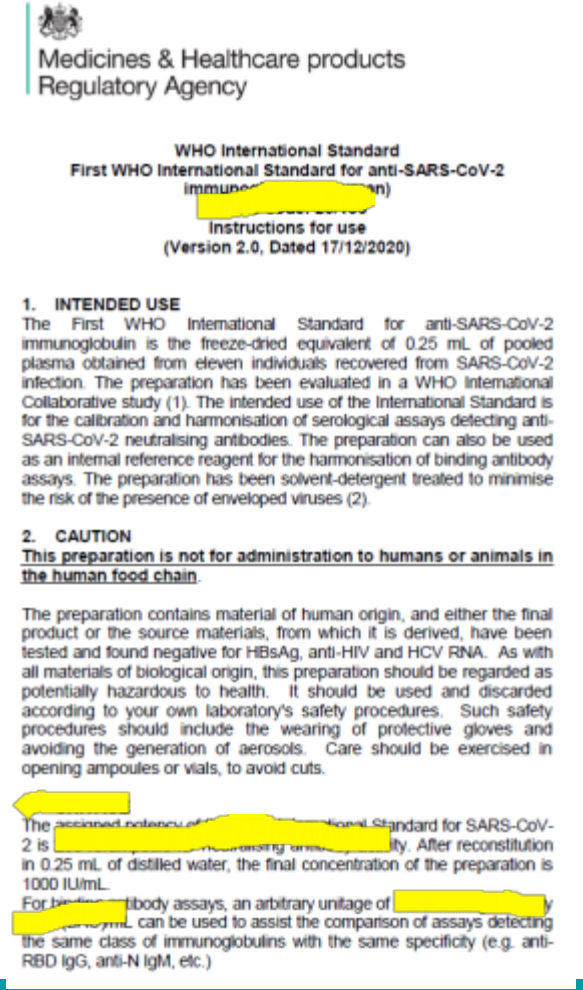
Slide 7 Notes

2000 fold difference when expressed with different unitage vs less than 5 fold when expressed relative to IU

Unitage assign to the International Standard

- WHO IS established by WHO ECBS on 10th December 2020;
- Available in NIBSC catalogue on 18th December 2020;
- On 18th January 2021, approximately 50 end users have acquired the IS (tot shipped ampoules 162)



Medicines & Healthcare products Regulatory Agency

WHO International Standard
First WHO International Standard for anti-SARS-CoV-2 immunoglobulin (human)
Instructions for use
(Version 2.0, Dated 17/12/2020)

1. INTENDED USE

The First WHO International Standard for anti-SARS-CoV-2 immunoglobulin is the freeze-dried equivalent of 0.25 mL of pooled plasma obtained from eleven individuals recovered from SARS-CoV-2 infection. The preparation has been evaluated in a WHO International Collaborative study (1). The intended use of the International Standard is for the calibration and harmonisation of serological assays detecting anti-SARS-CoV-2 neutralising antibodies. The preparation can also be used as an internal reference reagent for the harmonisation of binding antibody assays. The preparation has been solvent-detergent treated to minimise the risk of the presence of enveloped viruses (2).

2. CAUTION

This preparation is not for administration to humans or animals in the human food chain.

The preparation contains material of human origin, and either the final product or the source materials, from which it is derived, have been tested and found negative for HBsAg, anti-HIV and HCV RNA. As with all materials of biological origin, this preparation should be regarded as potentially hazardous to health. It should be used and discarded according to your own laboratory's safety procedures. Such safety procedures should include the wearing of protective gloves and avoiding the generation of aerosols. Care should be exercised in opening ampoules or vials, to avoid cuts.

The assigned potency of [redacted] International Standard for SARS-CoV-2 is [redacted] ity. After reconstitution in 0.25 mL of distilled water, the final concentration of the preparation is 1000 IU/mL.

For binding antibody assays, an arbitrary unitage of [redacted] /mL can be used to assist the comparison of assays detecting the same class of immunoglobulins with the same specificity (e.g. anti-RBD IgG, anti-N IgM, etc.)

First WHO International Reference Panel for anti-SARS-CoV-2 immunoglobulin (20/268)

Reference Panel will comprise 4 pools of COVID-19 convalescent plasma and a negative; freeze-dried equivalent of 0.25 mL

High (NIBSC code 20/150)

Mid (NIBSC code 20/148)

Low S, high N (NIBSC code 20/144)

Low (NIBSC code 20/140)

Negative (NIBSC code 20/142)

Representative data

	High 20/150	Mid 20/148	low S, high N 20/144	low 20/140	
Neut Ab	1473	210	95	44	**IU/mL**
anti-RBD IgG	817	205	66	45	**BAU/mL**
anti-S1 IgG	766	246	50	46	**BAU/mL**
anti-Spike IgG	832	241	86	53	**BAU/mL**
anti-N IgG	713	295	146	12	**BAU/mL**

The candidate Reference Panel samples were ranked similarly in almost all the assays used with very few exceptions

No unitage will be assigned for the Reference Panel, but representative data from CS include in IFU

Reseach Reagent 20/130

- Made available end April 2020 for the development of assay for the detection of SARS-CoV-2 antibody
- Secondary standard which allows assay to report data in IU/mL, retrospectively
- Calibrated to the WHO IS as part of the CS

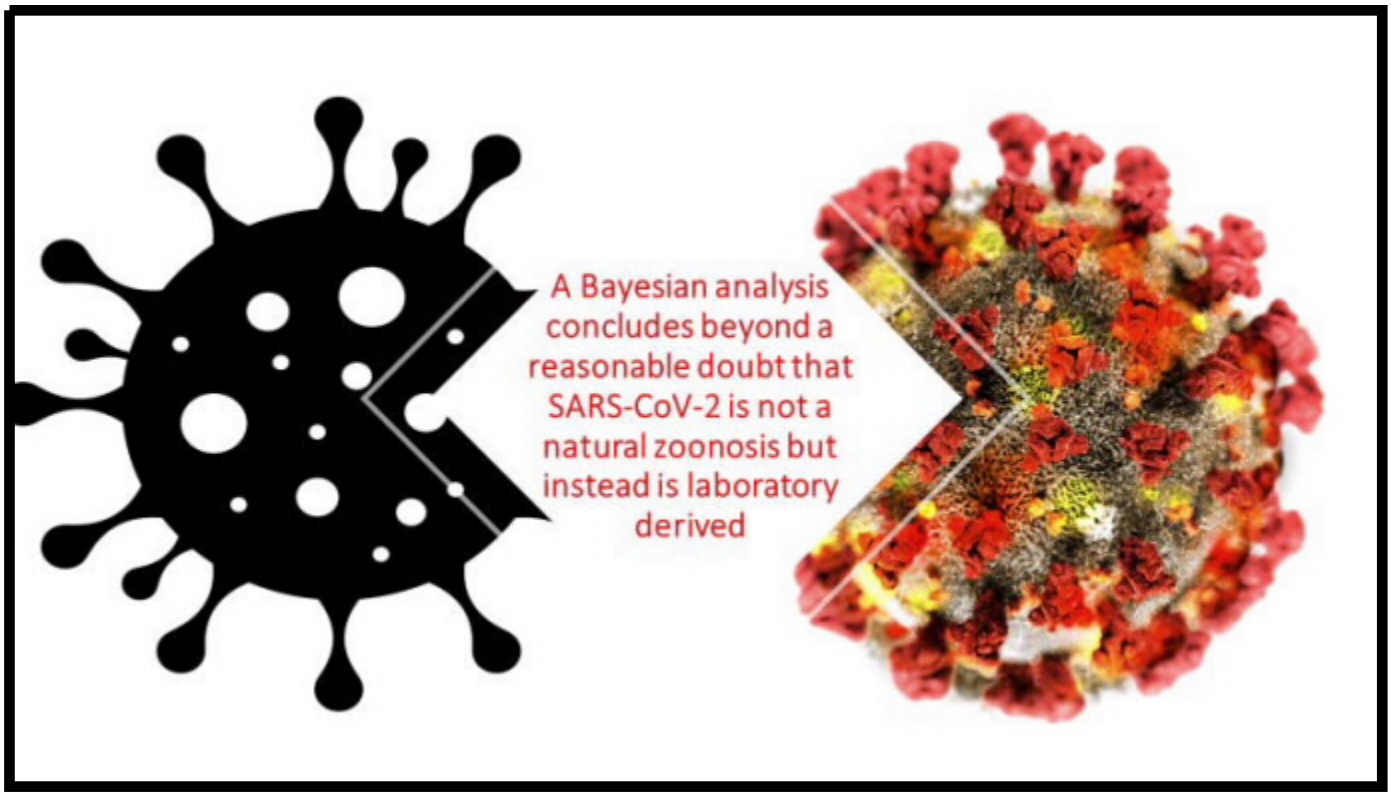
	GM	95% CI	
Neut Ab	1300	981-1719	**IU/mL**
anti-RBD IgG	502	382-660	**BAU/mL**
anti-S1 IgG	588	398-870	**BAU/mL**
anti-Spike IgG	476	418-542	**BAU/mL**
anti-N IgG	747	214-2606	**BAU/mL**

Slide 10 Notes

Slides available, however this data are also included in the revised Datasheet available in our website; less than 130 vials left- cannot be used as run control

Intended use the standards

- WHO International Standard 20/136 is primary calibrant; distribution restricted to 5 ampoules per end user per year
- Availability of secondary reagents- 20/130 is almost depleted; few example of national standards;
- other secondary standard (?)
- Internal Standard/run control can be calibrated to the IS or to secondary reagents- no need for a CS
- How?



By

Steven C. Quay, MD, PhD

A Bayesian analysis concludes beyond a reasonable doubt that SARS-CoV-2 is not a natural zoonosis but instead is laboratory derived

Executive Summary. The one-year anniversary of the COVID-19 pandemic records 2.1 million deaths, 99.7 million confirmed cases,[1] and trillions of dollars of economic damage. Although there is universal agreement that a coronavirus identified as Severe Acute Respiratory Syndrome Coronavirus 2 or SARS-CoV-2 (abbreviated CoV-2 henceforth) causes the disease COVID-19, there is no understanding or consensus on the origin of the disease.

The Chinese government, WHO, media, and many academic virologists have stated with strong conviction that the coronavirus came from nature, either directly from bats or indirectly from bats through another species. Transmission of a virus from animals to humans is called a zoonosis.

A small but growing number of scientists have considered another hypothesis: that an ancestral bat coronavirus was collected in the wild, genetically manipulated in a laboratory to make it more infectious, training it to infect human cells, and ultimately released, probably by accident, in Wuhan, China. For most of 2019 this theory was considered a crackpot idea, but in the last few weeks, more media attention has been given to the possibility that the Wuhan Institute of Virology, located in central Wuhan, may have been the source of the field specimen collection effort, laboratory genetic manipulation, and subsequent leak. On January 15, 2021, the U.S. Department of State issued a statement requesting the WHO investigation of the origin of COVID-19 include specific assertions related to a laboratory origin of the pandemic.[2]

Given the strong sentiment in the scientific community in favor of a zoonosis and the massive effort undertaken by China to find the natural animal source, one can assume that any evidence in favor of a natural origin, no matter how trivial, would become widely disseminated and known. This provides a potential evidence bias within the scientific community in favor of a natural origin which isn't quantifiable but should be kept in mind.

This becomes especially important background when evidence that could support a laboratory origin has been directly provided by leading Chinese scientists themselves, like Dr. Zhengli Shi, head of coronavirus research at the Wuhan Institute of Virology and Gao Fu (George Fu Gao), Director of Chinese CDC; by the Chinese government, as well as by powerful and vocal, pro-natural origin scientists, like Dr. Peter Daszak, of the NYC-based NGO, EcoHealth Alliance.

This report uses Bayesian inference, a common statistical tool in which Bayes' theorem, a well-known statistical equation, is used to update the likelihood for a particular hypothesis as more evidence or information becomes available. It is widely used in the sciences and medicine and has begun to be used in the law.

[1] https://www.worldometers.info/coronavirus/?
[2] https://www.state.gov/ensuring-a-transparent-thorough-investigation-of-covid-19s-origin/

The starting probability for origin of SARS-CoV-2 was set with the zoonotic or natural hypothesis at 98.8% likelihood with the laboratory origin hypothesis set at 1.2%. The initial state was biased as much as possible towards a zoonotic origin, with the starting point selected as the upper bounds of the 95% confidence interval for the mean and standard deviation of three independent estimates, including one by Daszak and colleagues. Each piece of new evidence for or against each hypothesis was then used to adjust the probabilities. If evidence favored a natural origin the math adjusts upward the probability of a natural origin, and so on.

The outcome of this report is the conclusion that the probability of a laboratory origin for CoV-2 is 99.8% with a corresponding probability of a zoonotic origin of 0.2%. This exceeds most academic law school discussions of how to quantify 'beyond a reasonable doubt,' the threshold for finding guilt in a criminal case. The report contains the detailed analysis and quantitative basis for the statistics and conclusion. It should be noted that because of the commutative property of the collected adjustments to the probabilities, the order in which they are used in the overall calculation is immaterial and the same end likelihoods will be reached regardless of the order of input.

The following Text-Table summarizes the evidence examined and the changes in probabilities:

Evidence	Zoonotic Origin	Laboratory Origin
Initial State	98.8%	1.2%
International committees to determine CoV-2 origin may not be impartial	98.8%	1.2%
Three key zoonotic papers: pros and cons	98.8%	1.2%
SARS-like infections among employees of the Wuhan Institute of Virology in the fall of 2019 reported by US Government	98.8%	1.2%
Location of first cases near Wuhan Institute of Virology	95.1%	4.9%
Lack of evidence of seroconversion in Wuhan and Shanghai	80.9%	19.1%
Lack of posterior diversity	30.8%	69.2%
Opportunity: The Wuhan Institute of Virology has publicly disclosed that by 2017 it had developed the techniques to collect novel coronaviruses, systematically modify the receptor binding domain to improve binding or alter zoonotic tropism and transmission, insert a furin site to permit human cell infection, make chimera and synthetic viruses, perform experiments in humanized mice, and optimize the ORF8 gene to increase human cell death.	30.8%	69.2%
Lack of furin cleavage sites in any other sarbecovirus	4.7%	95.3%
Rare usage of -CGG- single codons & no CGG-CGG pairs	0.5%	99.5%
Routine use of CGG in laboratory codon optimization, including Daszak & Shi	0.2%	99.8%
Spike Protein receptor binding region (200 amino acids) optimized for humans	0.2%	99.8%
Whole genome analysis shows pre-adaption of CoV-2	0.2%	99.8%
The finding of CoV-2 in Barcelona wastewater in early 2019 was an artifact	0.2%	99.8%
Shi and the WHO comment early on that CoV-2 seemed to begin with a single patient	0.2%	99.8%
Mammalian biodiversity between Yunnan and Hubei is significantly different, limiting a potential common intermediate host	0.2%	99.8%
The ancestor of CoV-2 can only obtain a furin site from other subgenera viruses but recombination is limited/non-existent between subgenera	0.2%	99.8%
Canvas of 410 animals shows humans and primates are the best, bats are the worst, for ACE2-Spike Protein interaction	0.2%	99.8%
A government requested review of samples collected from a mineshaft may have caused the COVID-19 pandemic	0.2%	99.8%
The Hunan Seafood Market and farmed animals in Hubei province are not the source of CoV-2	0.2%	99.8%
Line 2 of the Wuhan Metro System is the likely conduit of the pandemic and is the closest subway line to the WIV	0.2%	99.8%
Feral and domestic cats are not the intermediate host	0.2%	99.8%
Extraodinary pre-adaption for the use of human tRNA is observed	0.2%	99.8%
Evidence of lax operations and disregard of laboratory safety protocols and regulations in China	0.2%	99.8%
Previous SARS-CoV-1 laboratory accidents	0.2%	99.8%
Shi and Daszak use Wuhan residents as negative control for zoonotic coronavirus exposure	0.2%	99.8%
RaTG13 could be CoV-2 precursor using the synthetic biology 'No See 'Em' technique	0.2%	99.8%
Location, location, location: Based on the distance between known SARS-CoV-1 laboratory-acquired infections and the hospital of admission of the infected personnel, the WIV is within the expected hospital catchment for a CoV-2 LAI	0.2%	99.8%

The summary which follows will simply be a review and discussion of the evidence in the context of the two hypotheses.

Zoonosis Hypothesis

A viral zoonosis has at least three elements, a host, a virus, and the human population. With some viruses there are often two hosts. One is a 'reservoir host' where the virus can live for years or even decades in a relatively stable relationship. The reservoir host is never decimated by the virus, and the virus is never burned out by the reservoir host, disappearing completely. For coronaviruses the reservoir host is always one or more bat species. If there is a reservoir host that some viruses that cannot jump directly into the human population, there is a need for an second host, an intermediate host. In this case the virus spends time jumping into the intermediate host, 'practicing' adaption through random mutation and Darwinian selection for fitness to reproduce, infect, and transmit in the intermediate host. This process is then repeated between the intermediate host and the human population. Alternatively, the virus can jump directly between the bat reservoir and humans, without the need for an intermediate host.

For two prior human coronavirus epidemics, an intermediate or proximate host was identified. For SARS-CoV-1 in 2003-4 it was the civet cat while for Middle Eastern Respiratory Syndrome (MERS) in 2012-4 it was the camel. In both of these human epidemics, the intermediate host was identified within four to ten months of the first clinically identified human infection. With CoV-2 we are at 12 months since the pandemic began and still waiting for evidence of, despite a much larger effort inside China to find an intermediate host. For both of these previous pandemics, a bat species reservoir host was also identified, but not in the case of SARS-CoV-2.[3]

Based on the genome sequence of CoV-2, Drs. Shi and Daszak have proposed that the reservoir host for CoV-2 is the intermediate horseshoe bat (*Rhinolophus affinis*), which is found in Yunnan Province. Yunnan Province is in southern, rural China and about 1900 km from the north central province of Hubei, where the 11 million people of Wuhan live. In the US this would be equivalent in distance, climate change, and human population density difference to going from the Everglades in Florida to Manhattan, in New York City. The intermediate horseshow bat isn't found at all in Hubei province, making a direct bat-to-human transmission improbable.[4] Experiments in three independent laboratories also demonstrate that CoV-2 has changed genetically so much that it can no longer infect any bat species cell culture tested. So, while the leading US coronavirus expert, Dr. Ralph Baric of The University of North Carolina suggested in early 2020 that CoV-2 may have jumped into the human population directly from bats without an intermediate host, this hypothesis seems to no longer be viable.

For the zoonosis hypothesis to be advanced, it is now necessary to find an intermediate host. In January 2020 a theory was proposed that CoV-2 arose in the Huanan Seafood Market, a

[3] I am distinguishing here the difference between SARS-CoV-2 being a descendent of a bat coronavirus (with 3.8% or 1100 nucleotide (nt) differences between them) and the finding of the immediate precursor of SARS-CoV-2 in a bat colony population somewhere in the wild, which usually is <100 nt differences.

[4] "We have done bat virus surveillance in Hubei Province for many years but have not found that bats in Wuhan or even the wider Hubei Province carry any coronaviruses that are closely related to SARS-CoV-2. I don't think the spillover from bats to humans occurred in Wuhan or in Hubei Province," said Dr. Shi. Science, July 2020

traditional Chinese "wet market" where live animals are butchered and sold for food. The market theory was based on the observation that about 40% of early patients worked or shopped there. This was reminiscent of the wet market sources for civet cats infected with SARS-CoV-1 or the camel markets for the MERS coronavirus. The Chinese authorities closed the market on December 31, 2019 after performing extensive environmental sampling and sanitation.

But by May 2020 Dr. Gao Fu, Director of the Chinese CDC, announced that the market was not the source of CoV-2, as all of the animal specimens tested negative for CoV-2. And while SARS-CoV-1 was found in 100% of local farmed civets when tested, CoV-2 was different. In July 2020 Dr. Shi reported that extensive testing of farmed animals throughout Hubei Province failed to find CoV-2 in any animals.

For about six months, the pangolin, a scaly anteater, was suspected to be the intermediate host but finally Dr. Daszak reported that CoV-2 was not found in pangolins in the wild or from the (illegal) market trade.[5] Domestic and feral cats also were ruled out as a possible source. A comprehensive computer-based screen of 410 different animals reported the remarkable finding that the best ACE2 receptor matches to CoV-2 were human and other primates (or primate cells in the laboratory), including the favorite laboratory coronavirus host, the VERO monkey cell culture, and that all bat species were the worst host. At the time of this writing, there is not even a working hypothesis for the species of an intermediate host.

A typical zoonosis has a number of characteristic properties that can allow identification of a zoonotic infection, even in the absence of identifying an intermediate host. None of these properties are found for CoV-2.

All zoonotic infections have in common the principle that when a virus in nature uses evolution to move from, for example, a bat host to a camel host and then to a human host, it is a hit and miss, slow process. After all, evolution is the result of random genetic changes, mutations, and then enrichment of the ones that are helpful by amplification during reproduction. With both SARS-CoV-1 and MERS, the coronavirus spent months and years jumping from the intermediate host into humans, not having all of the necessary mutations needed to be aggressive, grow, and then spread, but spending enough time in humans to cause an infection and leaving behind a corresponding immune response.

The hallmark evidence of this 'practice' in abortive host jumping is in stored, archived human blood specimens taken from before the epidemic, where one can find evidence of pre-epidemic, usually sub-clinical, community spread from the antibodies to the eventual epidemic virus. For SARS-CoV-1 and MERS, about 0.6% of people in the region where the epidemic began showed signs of an infection in archived blood. With CoV-2, this seroconversion, as it is called, has never been observed, including in 540 specimens collected from 'fever clinics' in Wuhan between October 2019 and January 2020, reported by the WHO. Because this is such a potent signal of a zoonosis, and because I believe that China has over 100,000 stored specimens from

[5] https://link.springer.com/article/10.1007/s10393-020-01503-x

Wuhan taken in the fall of 2019, the lack of reports of seroconversion, the silence from China on this evidence, speaks volumes.

Another hallmark of a slow, natural zoonosis can be found in the virus. In SARS-CoV-1 and MERS, the coronavirus spent years in the intermediate host, passing back and forth among populations of hosts, the civets or camels, that were living in close proximity. During this time, they would accumulate a background of genetic mistakes, i.e., mutations- usually about one mistake every two weeks. When the final chip falls, and a mutation(s) happens allowing the jump into humans, the virus with that new mutation(s) also jumps around within the intermediate host population. The consequence of this latter behavior for a true zoonosis is that the genome sequences found in humans don't all descend from a single jump into a single human but show jumps from viruses that are only cousins of each other, not direct lineal descendants.

In a true zoonosis, the family tree of virus genome sequences doesn't pass back through the first patient but instead tracks all the way back to an ancestor months or years earlier. This is called posterior diversity, and it is an easy genetic test to perform. With CoV-2, every one of the more than 294,000 virus genomes sequenced can be traced back to the first genomic cluster and in the first patient in that cluster, a 39-year-old man who was seen at the People's Liberation Army (PLA) Hospital about one mile from the Wuhan Institute of Virology. The CoV-2 pandemic has the phylogenetic signature of one pure virus sequence infecting one human, with human-to-human spread thereafter; there is just the one and only jump into the human population ever seen. This lack of posterior diversity has been alluded to by Dr. Shi, by the WHO, and by other prominent virologists; they just never take that critical piece of the evidence to the next the proper inference.

The virus in a true zoonosis also contains the signature record of the gradual changes and adaptions it made in the protein key, the Spike Protein, it uses to unlock human cells and cause infection. With SARS-CoV-1 the Spike Protein had fewer than one-third of all the changes it would later develop by the time it became an epidemic. With CoV-2 the Spike Protein was almost perfectly adapted to the human lock, using 99.5% of the best amino acids possible.

Since with CoV-2 we have no evidence from stored blood that it was quietly practicing on humans in the community of Wuhan, it is surprising that when it finds its first patient, it has perfected to 99.5% the spike protein amino acid sequence, its ability to attack and infect humans. If this adaption couldn't have happened in the community, the only place it could have happened is in a laboratory, by what is called serial passage, a common laboratory process that repeatedly gives the virus a chance to practice on humanized mice or VERO monkey cells.[6] A related study showing human adaption right from the start of the pandemic looked at which of the dozens of protein manufacturing tools that CoV-2 uses (called tRNAs). It showed the same uncanny adaptation to the human tools with no evidence that the tools from other potential intermediate hosts would be suitable.

[6] It is noteworthy that the furin cleavage site is actually unstable in passage in VERO cells and is often deleted within a few passages. A laboratory origin theory needs to account for this observation. On the other hand, mutations in the furin site among the human CoV-2 genomes are exceedingly rare.

This evidence presented makes a strong case that CoV-2 did not come from nature. But is there affirmative evidence that it could have come from a laboratory? The answer is yes.

Laboratory Origin Hypothesis

The spike protein that gives the coronavirus its name, corona or crown, is the key to match with the lock found in host cells. But before it can inject its genetic material in the host cell, the spike protein needs to be cut, to loosen it in preparation for infection. The host cell has the scissors or enzymes that do the cutting. The singular, unique feature of CoV-2 is that it requires a host enzyme called furin to activate it at a spot called the S1/S2 junction. No other coronavirus in the same subgenera has a furin cleavage site, as it is called. The other coronaviruses are cleaved at a site downstream from the S1/S2 site, called the S' site.

This is of course a major problem for the zoonosis theory, but it gets worse.

Since 1992 the virology community has known that the one sure way to make a virus deadlier is to give it a furin cleavage site at the S1/S2 junction in the laboratory. At least eleven gain-of-function experiments, adding a furin site to make a virus more infective, are published in the open literature, including Dr. Zhengli Shi, head of coronavirus research at the WIV. This has caused a flurry of Chinese papers since the pandemic began trying to show a natural furin site in a related virus (this one example was later shown to be an error in interpretation) or to show that furin sites from distant cousins of CoV-2 might be the source through a process called recombination, where two different viruses infect the same host and then make a mistake in copying their genetic material, and swap sequences.

These convoluted, hypothetical methods each fail, however. It turns out that it is Daszak himself who has shown that the subgenera of coronaviruses that have furin sites are found in different bat hosts, which live in different regions of China, than the sarbecovirus subgenera of which CoV-2 is a member. And even with these barriers, they apparently are too far apart to recombine. "For the three focal subgenera, *Sarbecoviruses, Merbecoviruses and Embevoviruses*…none of the three focal subgenera recombines with one another."[7] As noted previously[2] Dr. Shi also does not believe the bats of Hubei province are capable of being a host for CoV-2-related coronaviruses.

But it gets worse still for the zoonosis theory. The gene sequence for the amino acids in the furin site in CoV-2 uses a very rare set of two codons, three letter words so six letters in a row, that are rarely used individually and have never been seen together in tandem in any coronaviruses in nature. But these same 'rare in nature' codons turn out to be the very ones that are always used by scientists in the laboratory when researchers want to add the amino acid arginine, the ones that are found in the furin site. When scientists add a dimer of arginine codons to a coronavirus, they invariably use the word, CGG-CGG, but coronaviruses in nature rarely (<1%) use this codon pair. For example, in the 580,000 codons of 58 Sarbecoviruses the only CGG pair is CoV-2; none of the other 57 sarbecoviruses have such a pair.[8]

[7] CoV-2 is in the subgenera Sarbecoviruses.
https://journals.plos.org/plosgenetics/article?id=10.1371/journal.pgen.1009272
[8] https://virological.org/t/alignment-of-58-sarbecovirus-genomes-for-conservation-analysis-of-sars-cov-2/430

So, there is no natural example of a furin protein site in nature that could be introduced into CoV-2 by recombination, there is no natural example of the particular gene sequence for the furin protein site contained in CoV-2 being used to code for anything in nature, but this particular coding is exactly what Dr. Shi, Baric, and others have used previously in published experiments to insert or optimize arginine codons.

It is telling that when Dr. Shi introduced the world to CoV-2 for the first time in January 2020 she showed hundreds of gene sequences of this novel virus but stopped just short of showing the furin site, the one she is purported to have introduced, seemingly not wanting to call attention to her handywork. She apparently failed to realize that an accomplished but innocent virologist, finding the first furin site ever seen in this class of viruses apparently coming from nature, would have featured the presence of the furin site prominently, and also would have used its presence and her experience with furin sites in other viruses to predict what it would foretell for the world due to its aggressive nature.

She could have perhaps saved many lives just by telling the world that she saw a furin site in the virus sequence. It would be left to a French and Canadian team to later identify the furin site in a paper.[9] They would write: "This furin-like cleavage site…may provide a **gain-of-function** to the 2019-nCoV for efficient spreading in the human population compared to other lineage b betacoronaviruses." [Emphasis added.]

Dr. Shi has denied the virus came from her lab, but she has created such a record of multiple examples of obfuscation, half-truths, contrived specimens, genetic sequences taken from thin air but published in premier journals and US NIH databases, etc. that her veracity is deeply damaged. Perhaps her words and actions on December 30, 2019 show the truth. Her very first response when told there was an unknown outbreak in Wuhan and to return back quickly from a meeting she was attending in Shanghai was to say, "Could this have come from our lab?"[10]

"I wondered if [the municipal health authority] got it wrong," she says. "I had never expected this kind of thing to happen in Wuhan, in central China." Her studies had shown that the southern, subtropical provinces of Guangdong, Guangxi and Yunnan have the greatest risk of coronaviruses jumping to humans from animals—particularly bats, a known reservoir. After all, the US equivalent of the distance, climate change, and human population density change between Yunnan and Wuhan is comparing the Everglades National Park in Florida and New York City.

Her other action on December 30 was to alter WIV computer databases of novel coronaviruses used by the world's virologists for research to make it more difficult to search for which coronaviruses she had in her building. In short, the day she was asked to address the pandemic in Wuhan, she chose to spend time to make unavailable to her fellow scientists of the world her decades of coronavirus work.

[9] https://www.sciencedirect.com/science/article/pii/S0166354220300528?via%3Dihub
[10] https://www.scientificamerican.com/index.cfm/_api/render/file/?method=inline&fileID=E1FDF8DE-9E22-4CE5-AD8B2E4682F52A86

The notion that CoV-2 was a laboratory creation, designed for maximum virulence, that escaped the laboratory accidentally has additional rings of evidence. From President Xi announcing in February new laws about laboratory security, to abundant evidence that the WIV was closed in October with few personnel inside, to the top military medical research doctor, General Chen Wei, being placed in charge of the WIV, to many more clues, it is clear an event occurred in Wuhan sometime in late 2019 that is most consistent with a laboratory escape.

The Asian region has a two-decade record of a little less than one laboratory-acquired infection per year. After the first SARS-CoV-1 epidemic was ended, SARS-CoV-2 jumped four more times into the human population, all from laboratories, with two in China. The last smallpox death in the entire world was a secretary who worked two floors above a research lab in England and contracted it through the ventilation system. The head of that laboratory committed suicide over his anguish for causing her death.

Over and over again. there is a long history and record of laboratory acquired infections that provides the background for considering what happened here.

Lab-made Bio-Weapon Hypothesis

But was SARS-CoV-2 more than just a gain-of-function experiment that escaped a laboratory? Could it have been one part of a two-part novel virus-vaccine bioweapons program?

General Chen Wei has been involved in vaccine research since joining the People's Liberation Army after college. In a 2017 internal speech at the AMMS (Academy of Military Medical Sciences) she said: "只要有矛. 才能研究盾." which translates roughly as, "you need to have an arrow to study a shield."I believe a Rubicon has been crossed by the world with this pandemic and framing the proper understanding of how we got here, and the proper response will be the critical next steps.

When Oppenheimer saw the application of Einstein's physics in the embodiment of the atomic bomb, he is said to have quoted a line from the Hindu scripture, the Bhagavad Gita, which reads: 'Now I am become Death, the destroyer of worlds.' The contribution of physics' research to human killing would total less than 300,000 people in two ten-square mile zones in Japan, and the horrors of those events led the world to regulate the raw materials of such bombs and to sanction sovereign nations who attempted to violate the rules.

This had followed the contribution of chemistry to human killing in the form of chemical warfare during World War I, in which 100,000 were killed, and led the nations of the world to an historic agreement to never use chemical warfare again. It is now only 'rogue' operators who violate the norms civilized nations have agreed to.

It seems to be biology's turn to show its dark arts. If it is generally understood that biology/biotechnology has been harnessed to create a pandemic that has killed more people than physics and chemistry research combined, and to be a weapon where no place on earth is safe from its effects (SARS-CoV-2 has been detected in the deepest Amazon jungles and at research stations in Antarctica), there needs to be developed a new set of regulations, rules, etc. to both honor the 1.8 million innocent people who died from COVID-19 and to protect the world so this

never happens again. It is also urgent to gather further data to support or refute if this was a Chinese bioweapons program, as the consequences of that would be significant.

Pre-publication input has been sought. The following individuals were sent a copy of this unpublished manuscript by email and asked to provide comments, criticisms, or improvements.

No response has been received at the time of this publication. An update will be made at such time as useful comments are received.

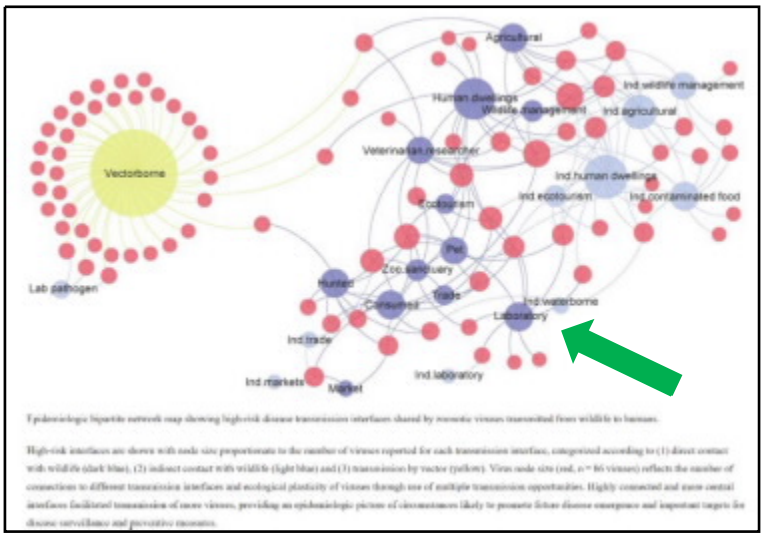
A Bayesian analysis concludes beyond a reasonable doubt that SARS-CoV-2 is not a natural zoonosis but instead is laboratory derived

Introduction. A two-hypothesis, Bayesian analysis was conducted to determine the origin of the SARS-CoV-2 pandemic. The conclusion was that it was created in a laboratory with synthetic biology tools from a bat beta coronavirus, subgenera sarbecovirus backbone (98.9% probability) and not from a natural, zoonotic transmission (1.1%).

There is no direct evidence of whether the release was accidental, or deliberate but circumstantial evidence makes it is highly likely it was accidental.

At the one-year anniversary of the first cases of COVID-19, the coronavirus pandemic caused by the SARS-CoV-2 virus, the origin of the virus remains unknown. While leading institutions and experts have been consistently adamant that it is a zoonotic disease which jumped from a bat reservoir host to humans directly or through an intermediate host the alternative possibility that it escaped from a laboratory conducting research remains a viable option.

In fact, in 2015 Peter Daszak, a leading zoonotic proponent of CoV-2 origin, wrote in, "Spillover and pandemic properties of zoonotic viruses with high host plasticity,"[11] that transmission from laboratories was a major source of zoonotic disease. The Figure below from the Daszak paper shows this important relationship (green arrow):

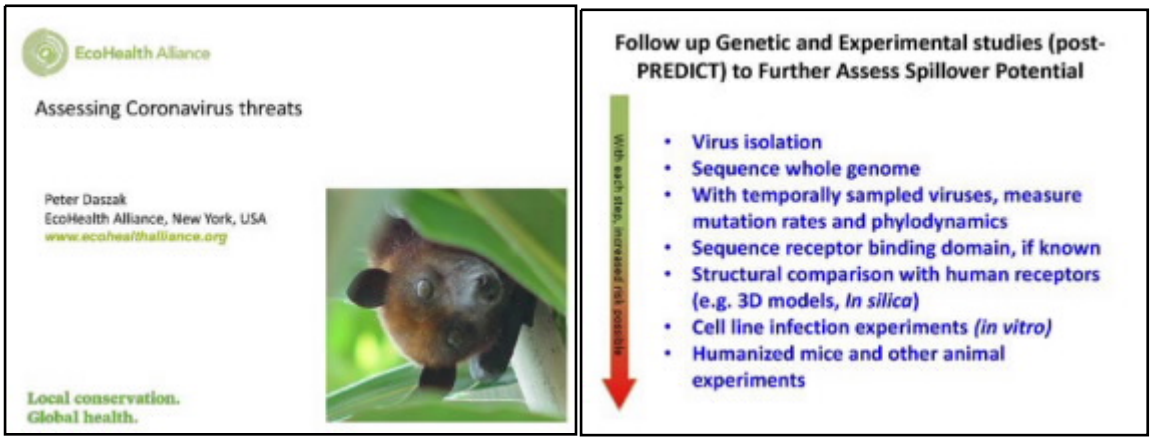


Daszak et al. also writes: "**Zoonotic virus spillover** from wildlife was most frequent in and around human dwellings and in agricultural fields, as well as **at interfaces with occupational exposure to animals** (hunters, **laboratory workers**, veterinarians, **researchers**, wildlife management, zoo and sanctuary staff). **Primate hosts were most frequently cited as the source of viruses transmitted by direct contact** during hunting (exact P = 0.051) and **in laboratories**

[11] https://www.nature.com/articles/srep14830

(exact P = 0.009).” [Emphasis added]. Primate “hosts” can presumably include monkey cell culture, such as the ubiquitous VERO cell used in all virology laboratories, including the WIV.

In 2015 Dr. Daszak spoke of the spillover danger of certain types of laboratory research:



He writes: “with each step, increased risk possible” with “Humanized mice and other animal experiments” the highest risk work.

In a prescient Twitter post in November 2019, he highlights the work he is doing using recombinant viruses with humanized mice and making viruses that “**don’t respond to MAbs, vaccines…**” in response to criticism his work is of limited value:

Clearly, before the beginning of the pandemic, Daszak, now a member of both the WHO and Lancet teams being sent to China to explore the origin of CoV-2, could entertain the eal possibility of a laboratory created virus escaping into the human population/community.

The purpose of this analysis is to use a Bayesian Inference Network approach to the collected circumstantial evidence that is available to provide likelihoods of the alternative hypotheses as to the origin of SARS-CoV-2. The analysis also will include certain prior probabilistic conclusions to help set the initial state before the proprietary evidence is used.

Origin hypotheses: Initial States to establish the posterior probabilities.

Two published Bayesian analyses and two independent studies of zoonotic spillover from nature and laboratory-acquired infections in Asia will be used to establish the posterior probabilities for this analysis.

Zoonotic spillover frequency versus laboratory acquired infection frequency based on two published papers, one by Daszak et al.

In 2015 Daszak et al. published a paper entitled, "Spillover and pandemic properties of zoonotic viruses with high host plasticity,"[1] in which they identified 162 zoonotic viruses with naturally occurring animal-to-human transmission from 1990-2010. This is a frequency of 162/20 = 8.1 events per year.

They also note: "The majority (94%) of zoonotic viruses described to date (n = 162) are RNA viruses, which is 28 times higher (95% CI 13.9–62.5, exact P < 0.001) than the proportion of RNA viruses among all vertebrate viruses recognized, indicating that RNA viruses are far more likely to be zoonotic than DNA viruses." CoV-2 is an RNA virus.

Finally, they note that: "In general, wild animals were suggested as the source of zoonotic transmission for 91% (86/95) of zoonotic viruses compared to 34% (32/95) of viruses transmitted from domestic animals and 25% (24/95) with transmission described from both wild and domestic animals."

One of the caveats of the Daszak data is that it categorizes a laboratory-acquired infection (LAI) from an animal collected from the wild as a zoonotic spillover. There is no data in the paper to assess this issue and leaving it uncorrected is a conservative approach since it only inflates the natural zoonotic frequency.

In 2018 a paper by Siengsanan-Lamont entitled, "A Review of Laboratory-Acquired Infections in the Asia-Pacific: Understanding Risk and the Need for Improved Biosafety for Veterinary and Zoonotic Diseases," was published.[12] They reported 27 LAIs between 1982 and 2016, a frequency of 27/(2016 – 1982) = 0.8 events per year.

Using these historical frequencies of zoonotic spillover versus LAI to predict a future event can be calculated in the following manner:

Evidence	ZoonoticOrigin	LaboratoryOrigin
Frequency per year from Daszak paper	8.1	NA
Frequency per year from Siengsanan-Lamont paper	NA	0.8
Total events per year	8.1 + 0.8 = 8.9	8.1 + 0.8 = 8.9
Likelihood of future event based on historical frequency	8.1/8.9 X 100 = 0.91	0.8/8.9 X 100 = 0.9

Daszak's initial state analysis. This evidence sets the likelihood that CoV-2 was a zoonotic origin event at 91% and a laboratory origin event at 9%.

[12] https://www.ncbi.nlm.nih.gov/pmc/articles/PMC6073996/

Independent prior analyses: Rootclaim.

The next data that will be used is a recent analysis published on the Rootclaim website.[13] Three hypotheses below were analyzed through a series of evidence statements and the probabilities that each was the origin of SARS-CoV-2 determined:

Hypothesis	Calculated Probability
Lab escape: The virus was the subject of genetic research, including gain-of-function, and was released by accident	81%
Zoonotic: The virus evolved in nature and was transmitted to humans from a non-human vertebrate animal	16%
Bioweapon: The virus was genetically engineered as a bioweapon and was deliberately released	3%

As can be seen, the highest likelihood probability is an accidental lab escape, the lowest a bioweapon. The details of the evidence used to arrive at this conclusion is contained in Appendix 1. A summary of the changes in probability at each level of evidence analysis is shown in this table:

Evidence	Laboratory	Zoonosis	Bioweapon
Starting point	1.2%	82%	16%
Contagion and mortality	1.4%	97%	1.9%
Outbreak location: Wuhan	42%	56%	2.8%
Virus sources near Wuhan	16%	83%	1.0%
Chimera	37%	60%	2.5%
Furin cleavage	72%	23%	4.8%
WIV lab procedures	80%	17%	3.5%
WIV disassociation	89%	9%	2.0%
Chinese response	90%	8%	1.7%
No reported infections at WIV	86%	11%	2.4%
No whistleblowers	81%	16%	2.8%

As can be seen, the starting point assumed an 82% probability of a zoonotic origin. This starting point is a reasonable value and will be used here. Since some of the evidence in the above analysis will be used here, only the starting point will be used and not the probability changes from there.

For purposes of this analysis only the Rootclaim initial state will be used since much of their evidence is also covered in the analysis here.

[13] https://www.rootclaim.com/analysis/what-is-the-source-of-covid-19-sars-cov-2

In a paper by Daszak and colleagues it states: "In general, wild animals were suggested as the source of zoonotic transmission for 91% (86/95) of zoonotic viruses compared to 34% (32/95) of viruses transmitted from domestic animals and 25% (24/95) with transmission described from both wild and domestic animals."[1]

On the other hand, domestic animals seem to have been ruled out for SARS-CoV-2. In an interview for *Science* in July 2020, Dr. Zhengli Shi, head of coronavirus research at the Wuhan Institute of Virology, stated: "Under the deployment of the Hubei Provincial Government, our team and researchers from Huazhong Agricultural University collected samples of farmed animals and livestock from farms around Wuhan and in other places in Hubei Province. We did not detect any SARS-CoV-2 nucleic acids in these samples."[14]

Reanalysis of Rootclaim initial state to remove Bioweapons option.

The US government uses the following definitions:

"Gain-of-function (GOF) studies, or research that improves the ability of a pathogen to cause disease, help define the fundamental nature of human-pathogen interactions, thereby enabling assessment of the pandemic potential of emerging infectious agents, informing public health and preparedness efforts, and furthering medical countermeasure development.

Gain-of-function studies may entail biosafety and biosecurity risks; therefore, the risks and benefits of gain-of function research must be evaluated, both in the context of recent U.S. biosafety incidents and to keep pace with new technological developments, in order to determine which types of studies should go forward and under what conditions."[15]

"Dual use research of concern (DURC) is life sciences research that, based on current understanding, can be reasonably anticipated to provide knowledge, information, products, or technologies that could be directly misapplied to pose a significant threat with broad potential consequences to public health and safety, agricultural crops, and other plants, animals, the environment, materiel, or national security. "[16]

For this analysis, the assumption is made that GOF and DURC are largely the same processes and techniques in the laboratory and thus can only be distinguished by direct, documentary evidence of the intent of the research from administers in the facilities conducting the work.

In the absence of any such documentary evidence that bioweapon research was being conducted or that SARS-CoV-2 is a bioweapon and to take the least inflammatory posture, the initial state for the above prior analysis will be recalculated by eliminating the hypothesis, and its accompanying probability, that SARS-CoV-2 was created as a bioweapon. The revised initial state calculation is shown in this table:[17]

[14] https://www.sciencemag.org/sites/default/files/Shi%20Zhengli%20Q%26A.pdf
[15] https://www.phe.gov/s3/dualuse/Pages/GainOfFunction.aspx
[16] https://www.phe.gov/s3/dualuse/Pages/default.aspx
[17] For clarity, the 3% bioweapon probability was simply dropped and the remaining likelihoods, 81% and 16%, were normalized.

Evidence	ZoonoticOrigin	LaboratoryOrigin	BioweaponsOrigin
Rootclaiminitial state	0.86	0.012	0.16
Remove bioweapons	NA	NA	0
Normalizeremaining hypotheses	0.86/(0.86+0.012) = 0.986	0.012/(0.86+0.012) = 0.014	NA

Rootclaim Initial state analysis, adjusted. This evidence sets the likelihood that CoV-2 was a zoonotic origin event at 98.6% and a laboratory origin event at 1.4%.

Additional Prior Evidence by Demaneuf and De Maistre. A second prior Bayesian analysis was performed by professionally educated risk assessment personnel and Chinese-language speaking professionals[18] and is included herein in its entirety. For the sake of brevity, the zoonotic origin evidence was based primarily on population size, distribution, and geographic distribution of bat populations relative to Wuhan. With respect to a lab accident, they separately analyze probabilities of a virus escape during collection, transport, and direct lab accidents and then separately the probability of a community outbreak following a lab escape. They also use primary Mandarin-language sources for Chinese estimates of the same events, showing corroboration of the probabilities. Their conclusion is that the probability of a lab escape ranges from 6% to 55% with a zoonotic origin a zoonotic origin probability being 45% to 94%.

Second Bayesian analysis. Using the most conservative probabilities, this evidence sets the likelihood that CoV-2 was a zoonotic origin event at 94% and a laboratory origin event at 6%.

Selection of initial state for Bayesian analysis.

The Text-Table below summarizes the three approaches to an initial state as to the origin of CoV-2. While the Demaneuf and De Maistre analyses set a range for the zoonotic origin of 45% to 94%, I have used the top of the range of their probability of a zoonotic origin to be conservative.

Prior Analysis	Zoonotic Origin	Laboratory Origin
Daszak et al. paper	91%	9%
Rootclaim Bayesian analysis	98.6%	1.4%
Demaneuf and De Maistre Bayesian analysis	94%	6%

Using a simple online calculator[19] the mean of these three value sets is 94.5%, the standard deviation is ± 3.8%, and the 95% confidence interval is ± 4.3%. Using these data, the upper bound of the 95% confidence interval is 98.8% and, to be most conservative, this will be used as the starting probability of a zoonotic origin.

Initial state for this analysis. The likelihood that SARS-CoV-2 began as a zoonotic event is 98.8% and the likelihood it began as a laboratory event is 1.2%.

[18] https://zenodo.org/record/4067919#.X-qIm9gzbOj . For reference purposes, this paper comes with a spreadsheet listing 112 individual BSL-3 labs in China across 62 lab-complexes.
[19] https://www.calculator.net/standard-deviation-calculator.html?numberinputs=91%2C+94%2C+98.6&ctype=s&x=48&y=19

1. General approach of this analysis[20]

This analysis is intended to examine two competing and mutually exclusive theories of the origin of the coronavirus, SARS-CoV-2 (CoV-2), and the pandemic it has caused, COVID-19.

At the time of this writing there have been 83 million confirmed cases and 1.8 million deaths.[21] Some sources place the economic damage at $21 trillion USD.

Bayes Theorem

This brief description of the Bayes Theorem was taken from the work of Jon Seymour: [22]

"The eponymously named Bayes Theorem was discovered by the Reverend Thomas Bayes in the 1700's and saved for posteriority by an archivist of his papers who discovered the work posthumously. In common language, it provides a rational technique for revising a prior belief in light of new evidence. The equation for Bayes Theorem is given below:

$$P(H|E) = \frac{P(E|H).P(H)}{P(E)}$$

where:

- H is the statement of the hypothesis of interest
- P(H) is the prior probability that the hypothesis is true, independent of the evidence.
- E is the evidence being used to revise the belief in hypothesis
- P(E) is the marginal likelihood of the evidence, independent of the hypothesis
- P(E|H) is the likelihood the evidence, given that the hypothesis is true
- P(H|E) is the posterior probability of the hypothesis, given the evidence.

P(E) is sometimes difficult to estimate, but the following identity must hold:

$$P(E) = P(E|H).P(H) + P(E|\hat{H}).P(\hat{H})$$

Here P(E|^H) is the probability of the evidence, assuming the hypothesis is false and P(^H) is the probability the hypothesis is false which is the same as 1-P(H). Estimating the two conditional probabilities P(E|H) and P(E|^H) is generally easier than estimating the unconditional probability, P(E)."

---

[20] The statistical approach and many of the individual statistical analyses were performed by Dr. Martin Lee, PhD, Adjunct Professor of Biostatistics, UCLA. https://ph.ucla.edu/faculty/lee The likelihood adjustments to the Bayesian analysis, which you can see are routine math, were conducted by the author.
[21] https://www.worldometers.info/coronavirus/coronavirus-cases/
[22] https://jonseymour.medium.com/a-bayesian-analysis-of-one-aspect-of-the-sars-cov-2-origin-story-where-the-first-recorded-1fbdcbea0a2b

Theory One. The zoonotic theory is that a vertebrate animal was infected with CoV-2 or an ancestor (Index Host) and that a human was infected with contact to that Index Host in some manner. Human-to-human spread then followed.

Theory Two. The laboratory origin theory is that CoV-2 or an ancestor was being used in laboratory experiments and that it 'escaped' from the lab via an infected person, lab animal, experimental waste, etc.

I have found no evidence of a deliberate release and early firsthand accounts of local officials and scientists suggest surprise and consternation. If this was a deliberate release, such evidence would be extremely local, limited in distribution, and highly compartmentalized. It is beyond the scope of this analysis.

Weight of the evidence. For purposes of the calculation of posterior probabilities in the Bayesian analysis, evidence which has a statistical basis will be used directly to adjust the probabilities.

Statistically significant evidence. Since some of the probability calculations have astronomical values which would make a single such evidence statement, if inputted directly, swamp any further calculation and make their later contribution mute, a decision was made to simply treat quantitative probabilities as significant at the $p = 0.05$ level, no matter how much 'more significant' the calculation suggested.

So, for example, a probability of certain codon usage coming from nature may be one in 440 or $p = 0.002$, the contribution of this evidence to the input to the posterior probability adjustment would be set at a p-value of 0.05. In such cases the adjustment would be to change the 'winning' hypothesis by multiplying by 19, since a $p = 0.05$ is the same as a 19 out of 20 likelihood event. This is a conservative treatment of what would be highly significant data.

Other quantitative evidence. If a piece of evidence can be quantified but it does not reach a significance of $p = 0.05$ it will be used directly in the likelihood adjustment.

Non-quantitative evidence. For evidence that cannot be quantified, the decision was made to treat these as quantitative outcomes with a 51% to 49% likelihood value with respect to the 'winning' hypothesis. This has the effect of increasing the probability of that hypothesis for that step in the Bayesian analysis by 1.04. This 51%/49% concept is related to the legal standard of the 'preponderance of the evidence' used in civil litigation.

Independence. An important qualitative assessment that must be made is whether or not two pieces of evidence are independent of each other. If they are independent, they can each be used in determining a new likelihood calculation. If they are dependent on each other then they must be combined and only a single new likelihood analysis can be made. Where ever possible, evidence statements that could be considered as dependent are called out and this rule is followed on their contribution to the analysis.

Subjective Discount Factor. The impact of each piece of evidence was adjusted further by a subjective discount factor. This is a qualitative assessment of the overall veracity of a particular

piece of evidence when all factors, samples, methods, data sources, etc. are taken into context. It varies from 60% to 100% and is used as a fraction to reduce the impact of a single piece of evidence even further.

Hearsay. Just as in a court of law, evidence, usually attributed to a given person or persons, that is not directly available but instead relies on statements of others is usually not allowed in a court trial and will accordingly not be used here to adjust the Bayesian analysis. It may be recorded and preserved as a placeholder and reminder for further research. If new, direct evidence can be found than the bar of using it is lifted and it can be used for adjustment.

Significant figures. Because of the overall nature of the analyses here, all math calculations related to likelihoods are performed and carried forward at the 'one significant figure' level, with standard rounding rules applied. This has the effect, near the end of the cumulative evidence, of failing to change the relative probabilities as the small adjustments are reversed in the rounding process.

Evidence. International committees to investigate the origin of SARS-CoV-2 may not be impartial.

At the time of the writing of this manuscript there are two committees charged with examining the evidence and determining the origin of the SARS-CoV-2 virus. One committee is commissioned by the World Health Organization (WHO) and the other is an ad hoc committee established by the British medical journal, *The Lancet.*

The composition of the two committees is shown in the Text-Table below:

	Lancet Commission of CoV-2	WHO Commission on CoV-2 origin
	Dr. Peter Daszak, Chair	**Dr. Peter Daszak, Ph.D (EcoHealth Alliance, USA)**
	Dr. John Amuasi	Prof. John Watson (Public Health England, United Kingdom)

	Co-author with Daszak	

There are a number of potential conflicts of interest:

Fully half of The Lancet's team had already suggested that any lab-leak hypothesis was a "conspiracy theory" in a January 2020 paper that has been shown elsewhere within to have been orchestrated behind the scenes to appear spontaneous.

Origin and cross-species transmission of bat coronaviruses in China

Alice Latinne[1,6,7], Ben Hu[2,7], Kevin J. Olival[1], Guangjian Zhu[3], Libiao Zhang[3], Hongying Li[1], Aleksei A. Chmura[1], Hume E. Field[1,4], Carlos Zambrana-Torrelio[1], Jonathan H. Epstein[1], Bei Li[2], Wei Zhang[2], Lin-Fa Wang[5], Zheng-Li Shi[2✉] & Peter Daszak[1✉]

Bats are presumed reservoirs of diverse coronaviruses (CoVs) including progenitors of Severe Acute Respiratory Syndrome (SARS)-CoV and SARS-CoV-2, the causative agent of COVID-19. However, the evolution and diversification of these coronaviruses remains poorly understood. Here we use a Bayesian statistical framework and a large sequence data set from bat-CoVs (including 630 novel CoV sequences) in China to study their macroevolution, cross-species transmission and dispersal. We find that host-switching occurs more frequently and across more distantly related host taxa in alpha- than beta-CoVs, and is more highly constrained by phylogenetic distance for beta-CoVs. We show that inter-family and -genus switching is most common in Rhinolophidae and the genus *Rhinolophus*. Our analyses identify the host taxa and geographic regions that define hotspots of CoV evolutionary diversity in China that could help target bat-CoV discovery for proactive zoonotic disease surveillance. Finally, we present a phylogenetic analysis suggesting a likely origin for SARS-CoV-2 in *Rhinolophus* spp. bats.

The above paper published in August 2020 has as co-authors Drs. Hume, Daszak, and Shi. Having two of these scientists be asked to investigate a third co-author is a clear conflict of interest.

A newspaper piece about Peter Daszak entitled, "The doctor who denied COVID-19 was leaked from a lab had this major bias,"[23] questions his ability to be unbiased due to a deep, long history of work with Dr. Zhengli Shi of the WIV.

A lengthy piece in Wired was subtitled, "The two major investigations into the origins of the pandemic are compromised by potential conflicts of interest."[24]

Since the purpose of this manuscript is to evaluate the scientific evidence concerning the origin of SARS-CoV-2 no further effort will be put into these matters. If and when a report is prepared from either committee there will be time to analysis the work in the reports and compare it to prior publications and statements from the committee members to look for bias.

Likelihood from initial state is unchanged following this evidence analysis:

Zoonotic origin (98.8%) and laboratory origin (1.2%)

[23] https://nypost.com/2021/01/16/doctor-who-denied-covid-was-leaked-from-a-lab-had-this-major-bias/
[24] https://www.wired.com/story/if-covid-19-did-start-with-a-lab-leak-would-we-ever-know/?utm_source=twitter&utm_medium=social&utm_campaign=onsite-share&utm_brand=wired&utm_social-type=earned

Evidence. Three high visibility papers grounded the zoonotic origin hypothesis in the public conversation from February to May 2020: a pros and cons analysis.

Introduction. The two key data points from December 2019 concerning the origin of the SARS-CoV-2 coronavirus infection, the cause of COVID-19, are the observation that a large number of the earliest patients worked or had visited the Hunan Seafood Market in Wuhan, China and that the hospitals where the first patients were admitted were a short distance from the Wuhan Institute of Virology (WIV), the only high security, BSL-4 laboratory in all of China, and arguably the leading research institute in the world studying coronaviruses of the type causing COVID-19.

The first data point is reminiscent of the origin of SARS-CoV-1, a zoonosis with interspecies transmission from bats to civet cats and then to humans, identified in wet markets in southern China. The second data point is reminiscent of the four SARS-CoV-1 human spillovers that occurred after the 2003 epidemic ended and were each a laboratory-acquired infection (LAI) by a scientist working in a government research laboratory, much like the WIV, and then local human-to-human spread and nearby hospital admission.

To be clear in this paper, the term zoonosis will only be used to describe a interspecies transmission outside of a laboratory. This point seems important to clarify since Dr. Zhengli Shi, head of coronavirus research at the WIV, has previously reported: "An outbreak of hemorrhagic fever with renal syndrome occurred among students in a college (College A) in Kunming, Yunnan province, China in 2003. Subsequent investigations revealed the presence of hantavirus antibodies and antigens in laboratory rats at College A and two other institutions. Hantavirus antibodies were detected in 15 additional individuals other than the index case in these three locations. Epidemiologic data indicated that the human infections were a result of **zoonotic transmission** of the virus from laboratory rats."[25] [emphasis added.] The author has found no other support for the use of the term zoonotic transmission with respect to an LAI and its dual use could be confusing, and so will be avoided.

While the two initial data points would suggest that a balanced approach should be taken with respect to investigations of the origin of SARS-CoV-2, three high visibility publications that argued the laboratory origin idea was a "conspiracy theory" and strongly argued that it was of zoonotic origin foreclosed legitimate debate for much of 2019. The purpose of this evidence analysis is to examine these papers and weigh the strength of the evidence.

Paper 1: The February 3, 2020 paper by WIV scientist Dr. Shi et al. entitled: "A pneumonia outbreak associated with a new coronavirus of probable bat origin."

This seminal paper set the stage for the zoonotic origin of SARS-CoV-2 and has been accessed over one million times. According to *Nature*, this article is in the 99th percentile (ranked 24th) of the 326,159 tracked articles of a similar age in all journals and the 99th percentile (ranked 2nd) of the 783 tracked articles of a similar age in Nature.

[25] https://pubmed.ncbi.nlm.nih.gov/20380897/

However, a careful analysis of it shows serious issues which suggest it is unreliable. The following analysis is in the form of an independent manuscript:

The seminal paper from the Wuhan Institute of Virology claiming SARS-CoV-2 probably originated in bats appears to contain a contrived specimen, an incomplete and inaccurate genomic assembly, and the signature of laboratory-derived synthetic biology

The coronavirus RaTG13 was purportedly identified in a bat "fecal" specimen that is probably not feces, has significant unresolved method-dependent genome sequence errors and an incomplete assembly with significant gaps, and has an anomalous base substitution pattern that has never been seen in nature but is routinely used in codon-optimized synthetic genome constructions performed in the laboratory

Abstract. The species of origin for the SARS-CoV-2 coronavirus that has caused the COVID-19 pandemic remains unknown after over six months of intense research by investigators around the world. The current consensus theory among the scientific community is that it originated in bats and transferred to humans either directly or through an intermediate species; no credible intermediate species exists at this time. The suggested origin early on from a Wuhan "wet market" has been determined to be a red herring and the pangolin is no longer considered a likely intermediate by the virology community.

The basis for the hypothesis that SARS-CoV-2 probably evolved from bats initially came from a February 2020 paper[26] from Dr. Zheng-Li Shi's laboratory at the Wuhan Institute of Virology (WIV). In that paper the Wuhan laboratory made two claims: 1), "a bat fecal sample collected from Tongguan town, Mojiang county in Yunnan province in 2013" contained a coronavirus, originally designated "Rhinolophus bat coronavirus BtCoV/4991[27]" in 2016 but renamed in their paper, RaTG13; and 2), the genomes of RaTG13 and SARS-CoV-2 had an overall identity of 96.2%, making it the closest match to SARS-CoV-2 of any coronavirus identified at that time. RaTG13 remains the closest match to SARS-CoV-2 at the current time.

In this paper I document that:

1) The RaTG13 specimen was not a bat fecal specimen, based on a comparison of the relative bacterial and eukaryotic genetic material in the purported fecal specimen to nine authentic bat fecal specimens collected in the same field visits as RaTG13 was collected by the Wuhan laboratory, run on the same Illumina instrument (id ST-J00123), and published in a second paper in February 2020.[15] While the authentic bat fecal

[26] Zhou, P., Yang, X., Wang, X. *et al.* A pneumonia outbreak associated with a new coronavirus of probable bat origin. *Nature* **579,** 270–273 (2020). https://doi.org/10.1038/s41586-020-2012-7 .

[27] A Coronavirus BtCoV/4991 Genbank entry by Dr. Shi records: organism="Rhinolophus bat coronavirus BtCoV/4991." In July 2020 she wrote: "Ra4991 is the ID for a bat sample while RaTG13 is the ID for the coronavirus detected in the sample. We changed the name as we wanted it to reflect the time and location for the sample collection. 13 means it was collected in 2013, and TG is the abbreviation of Tongguan town, the location where the sample was collected."

samples were, as expected, largely bacterial (specifically, 65% bacteria and 12% eukaryotic genetic sequences), the purported RaTG13 specimen had a reversed composition, with mostly eukaryotic genes and almost no bacterial genetic material (0.7% bacteria and 68% eukaryotic). The RaTG13 specimen was also only 0.01% virus genes compared to an average of 1.4% for authentic bat fecal specimens. A Krona analysis identified 3% primate sequences consistent with VERO cell contamination, the standard monkey cell culture used for coronavirus research, including at the Wuhan laboratory. Based on using the mean and standard deviation of the nine authentic bat fecal specimens from the Wuhan laboratory, the probability that RaTG13 came from a true fecal sample but had the composition reported by the Wuhan laboratory is one in thirteen million;

2) According to multiple references, RaTG13 was identified via Sanger dideoxy sequencing before 2016, partially sequenced by amplicon sequencing in 2017 and 2018, and then complete sequencing and assembly by RNA-Seq in 2020, although some reports from WIV suggest the timing of the RNA-Seq experiments may have been performed earlier than 2020. In any case, a Blast analysis of sequences from the amplicon and RNA-Seq experiments indicates an approximate 5% nucleotide difference, 50-fold higher than the technical error rate for RNA-Seq of about 0.1%. At least two gaps of over 60 base-pairs, with no coverage in the RNA-Seq data, were easily identified. The incomplete assembly and anomalous, method-dependent sequence divergence for RaTG13 is troublesome;

3) The pattern of synonymous to non-synonymous (S/NS) sequence differences between RaTG13 and SARS-CoV-2 in a 2201 nucleotide region flanking the S1/S2 junction of the Spike Protein records 112 synonymous mutation differences with only three non-synonymous changes. Based on the S/NS mutational frequencies elsewhere in these two genomes and generally in other coronaviruses the probability that this mutation pattern arose naturally is approximately one in ten million. A similar pattern of unnatural S/SN substitutions was seen in a 10,818 nt region of the pp1ab gene. This pp1ab gene pattern has a probability of occurring naturally of less than one in 100 billion. A total of four regions of the RaTG13 genome, coding for 7,938 nt and about one-quarter of the entire genome, contain over 200 synonymous mutations without a single non-synonymous mutation. This has a probability of one in 10^{-17}. A possible explanation, the absolute criticality of the specific amino acid sequence in the regions which might make a non-synonymous change non-infective, is ruled out by the rapid appearance of an abundance of non-synonymous mutations in these very regions when examining the over 80,000 human SARS-CoV-2 specimens sequenced to date. An alternative hypothesis, that this arose by codon substitution is examined. It is demonstrated, by example from a published codon-optimized SARS-Cov-2 Spike Protein experiment, that the anomalous S/SN pattern is precisely the pattern which is produced, by design, when synthetic biology is used and represents a signature of laboratory construction.

Based on the findings concerning the RaTG13 data, including anomalies and inconsistent statements about RaTG13, its origin, renaming, and sequencing timing; the finding that the specimen it is purported to have come from is not bat feces and has a signature of cell culture contamination; the unexplained method-dependent 5% sequence difference for RaTG13; and the S/SN mutation pattern reported, which to my knowledge has never been seen in nature, it can be concluded that RaTG13 is not a pristine biological entity but shows evidence of genetic manipulation in the laboratory.

Until a satisfactory explanation of the findings in this paper have been offered by the Wuhan laboratory, all hypotheses of the proximal origin of the entry of SARS-CoV-2 into the human population should now include the likelihood that the seminal paper contains contrived data. For example, the hypothesis that SARS-CoV-2 was the subject of laboratory research and at some point escaped the laboratory should be included in the narrative of the origin of SARS-CoV-2 research.

Introduction. Since the first reported patient on December 1, 2019 with a SARS-CoV-2 infection, the virus has caused a pandemic that has led to twenty-five million cases worldwide and over 840,000 deaths as of August 30, 2020. To make progress on treating this disease and preventing the next viral outbreak, knowing the origin of the virus and how it entered the human population is critical.

On February 3, 2020 a paper was published from the Wuhan Institute of Virology that identified a bat coronavirus, RaTG13, as having a 96.2% identity to SARS-CoV-2, quickly providing support for a zoonotic origin, either from bats directly or from bats to humans through an unknown intermediary species. If true, this would replicate the model of SARS-CoV 2003 in which the transmission was from bats to civets to humans and for MERS in which the transmission was from bats to camels to humans. At the time of this paper and through August 30, 2020, no other virus has been identified with a closer sequence homology to SARS-CoV-2 than RaTG13. The publication containing the RaTG13 sequence has been cited over 1600 times in the six months since publication. None of these studies contain research on the isolated virus itself since the virus has never been isolated or cultured. It was apparently found in only one sample from 2013 and that sample has been exhausted.[28]

An examination of the raw data associated with RaTG13 immediately identified serious anomalies, bringing into question the existence of RaTG13 as a biological entity of completely nature origin.

Below is a screen shot of the GenBank entry for the purported specimen from which RaTG13 was identified and upon which RNA-Seq was performed. While the title claims it is a "Rhinolophus affinis fecal swab" specimen it also records in the design of work entry that "(t)otal RNA was extracted from bronchoalveolar lavage fluid." These descriptions are clearly inconsistent.

SRX7724752: **RNA-Seq of Rhinolophus affinis:Fecal swab**
1 ILLUMINA (Illumina HiSeq 3000) run: 11.6M spots, 3.3G bases, 1.7Gb downloads

Design: Total RNA was extracted from bronchoalveolar lavage fluid using the QIAamp Viral RNA Mini Kit following the manufacturers instructions. An RNA library was then constructed using the TruSeq Stranded mRNA Library Preparation Kit (Illumina, USA). Paired-end (150 bp) sequencing of the RNA library was performed on the HiSeq 3000 platform (Illumina).

Apparent missing amplicon reads for RaTG13 in GenBank.

There are 33 amplicon reads in GenBank for RaTG13 from experiments recorded as having been performed in 2017 and 2018. A file naming pattern was noticed among the data sets which suggests there may be amplicon runs that were not deposited in GenBank. These files, if related to RaTG13, may contain useful sequence data and an effort should be made to retrieve them and, if appropriate, upload them to GenBank. A Table with the apparently missing data (yellow) is shown here.

Relationship of *Rhinolophus* bat coronavirus BtCoV/4991 and Bat coronavirus RaTG13.

The Wuhan laboratory has reported on the bat coronaviruses, BtCoV/4991 and RaTG13, in two peer-reviewed publications, one in 2016 and one in February 2020.[29] They have submitted three entries to GenBank for these two viruses, in 2016, February 2020, and May 2020.[30] The GenBank entries confirm sequencing experiments using Sanger dideoxy sequencing in 2016, PCR-generated amplicon sequencing performed on an AB 310 Genetic Analyzer in 2017 and 2018, and RNA-seq performed on an Illumina HiSeq 3000 (instrument id ST-J00123) in 2020. A single GISAID entry records that the RNA-seq data was obtained from an original specimen without passage.[31] This is an important detail since evidence of primate sequences, consistent with VERO cell contamination, is found in this specimen, as reported below, which would suggest laboratory passage.

None of these disclosures report that BtCoV/4991 and RaTG13 are the same coronavirus, simply renamed. This information was only disclosed in a written Question and Answer publication from *Science* magazine by Dr. Shi on July 31, 2020.[4, 32] Given this disclosure months after the original publication concerning RaTG13 in *Nature* it is possible that the omission of the original publication and sequence data concerning BtCoV/4991 violated the "Reporting

[29] 2016 Virologica Sinica paper and February 2020 Nature paper
[30] RaTG13 complete genome Feb 2020, Raw sequence reads for RaTG13 published Feb 2020, Amplicon reads for RaTG13 from 2017 and 2018 published in May 2020.
[31] The GISAID entry is EPI_ISL_402131.
[32] Dr. Shi wrote: "Ra4991 is the ID for a bat sample while RaTG13 is the ID for the coronavirus detected in the sample. We changed the name as we wanted it to reflect the time and location for the sample collection. 13 means it was collected in 2013, and TG is the abbreviation of Tongguan town, the location where the sample was collected."

standards and availability of data, materials, code and protocols" required for *Nature* publications.[33]

The February 2020 papers uses the RNA-Seq data for RaTG13 genome determination but fails to disclose the previous data obtained by Sanger dideoxy sequencing in 2016 and by amplicon sequencing in 2017 and 2018. Since these unrecorded data establish method-dependent sequencing differences of up to 4% the failure to disclose this data or to reconcile these differences is troubling.

In addition, the raw assembly accession data for RaTG13 are not described or linked to the Genbank entry, MN669532, and also no assembly method is specified in the raw data SRX7724752 12 and the Illumina run. And the amplicon sequencing data has sequence gaps of approximately 20% of the genome. Therefore, no primary assembly data has been made available by the WIV for the RaTG13 genome. This is contrary to the *Nature* Reporting Standards[9] as they state: "When publishing reference genomes, the assembly must be made available in addition to the sequence reads."

Relationship of RaTG13 and SARS-CoV-2.

There have been two descriptions of the process by which the RaTG13 genome was identified as closely homologous to SARS-CoV-2. These seem to be inconsistent with each other.

In the February 2020 *Nature* paper[5] it states:

"We then found that a short region of RNA-dependent RNA polymerase (RdRp) from a bat coronavirus (BatCoV RaTG13)—which was previously detected in Rhinolophus affinis from Yunnan province—showed high sequence identity to 2019-nCoV. We carried out full-length sequencing on this RNA sample (GISAID accession number EPI_ISL_402131). Simplot analysis showed that 2019-nCoV was highly similar throughout the genome to RaTG13, with an overall genome sequence identity of 96.2%."

In a July 2020 interview the process was described:

"We detected the virus by pan-coronavirus RT-PCR in a bat fecal sample collected from Tongguan town, Mojiang county in Yunnan province in 2013, and obtained its partial RdRp sequence. Because the low similarity of this virus to SARS-CoV, we did not pay special attention to this sequence. In 2018, as the NGS sequencing technology and capability in our lab was improved, we did further sequencing of the virus using our remaining samples, and obtained the full-length genome sequence of RaTG13 except the 15 nucleotides at the 5' end. As the sample was used many times for the purpose of viral nucleic acid extraction, there was no more sample after we finished genome sequencing, and we did not do virus isolation and other studies on it. Among all the bat samples we collected, the RaTG13 virus was detected in only one single sample. In 2020, we compared the sequence of SARS-CoV-2 and our unpublished bat

[33] Nature research reporting standards for availability of data

coronavirus sequences and found it shared a 96.2% identity with RaTG13. RaTG13 has never been isolated or cultured."

If the full-length genome of RaTG13 was available by 2018 it is unclear why a database search within the WIV for coronaviruses that resembled SARS-CoV-2 would lead to identifying the 370-nt segment representing the RdRp gene (as stated in the February paper) but not the full length RaTG13 genome (which was stated to have been sequenced by 2018). In addition, an assembly of all available amplicon data for RaTG13 from 2017 and 2018 contains gaps of approximately 20% of the genome. If the sample was completely consumed during the 2017-8 sequencing it is unclear how RNA-Seq was conducted in 2020 to permit the full-length genome to be determined.

Analytical methods. Taxonomy of specimens was determined in the NCBI Sequence Read Archive and KRONA.[34] Blast was used for sequence alignment and comparisons.[35]

To evaluate the data from the bat species relative to the RaTG13 fecal sample analysis, the latter was treated as a fixed result with the comparison to the taxonomy results of the nine bat feces specimens. It also was noted that the data were clearly right skewed (and descriptively both mean/median and standard deviation/interquartile range were used). Therefore, a non-parametric procedure, the Wilcoxon signed-rank test was used with the p-value calculated by an exact procedure because of the small sample size. Considering the synonymous to non-synonymous mutation frequency and how to evaluate that for the various protein coding regions of the virus, it was noted that for all of the genes pooled, the ratio of the synonymous to non-synonymous regions was approximately 0.83. To analyze the corresponding distribution for each gene, we assumed that each mutation was an independent observation from a Bernoulli random variable and, therefore the number of synonymous mutations in the gene would have a binomial distribution (with probability 0.83). A probability was then computed for the actual number of synonymous mutations on this basis (the probability was determined on a one-sided basis, i.e. excess mutations, and was calculated as a strict inequality).

Results.

Original characterization of RaBtCoV/4991 (RaTG13) and related bat fecal specimen.

In 2016 Dr. Shi and colleagues published a paper entitled, "Coexistence of multiple coronaviruses in several bat colonies in an abandoned mineshaft[36]" in which a number of novel bat coronaviruses were isolated from bat fecal specimens collected during 2012 and 2013. The viruses were named, according to the paper, in the following fashion:

[34] NCBI Sequence Archive
[35] Blast alignment
[36] Xing-Yi Ge, et. al., Coexistence of multiple coronaviruses in several bat colonies in an abandoned mineshaft, Virologica Sinica, 2016, 31 (1): 31–40. DOI: 10.1007/s12250-016-3713-9

> "The positive samples detected in this study were named using the abbreviated bat species name plus the bat sample number abbreviation. For example, a virus detected from *Rhinolophus sinicus* in sample number 4017 was named RsBtCoV/4017. If the bat was co-infected by two different coronaviruses, numbers were appended to the sample names, such as RsBtCoV/4017-1 and RsBtCoV/4017-2."

In the July 2020 interview Dr. Shi wrote:

> "Ra4991 is the ID for a bat sample while RaTG13 is the ID for the coronavirus detected in the sample. We changed the name as we wanted it to reflect the time and location for the sample collection. 13 means it was collected in 2013, and TG is the abbreviation of Tongguan town, the location where the sample was collected."

The 2016 and 2020 statements about the naming of virus RsBtCoV/4991 appear inconsistent with each other.

Of the 152 coronaviruses identified, 150 were classified as alphacoronaviruses while only two were classified as betacoronaviruses, HiBtCoV/3740-2 and RaBtCoV/4991. The naming convention from the paper means this latter coronavirus was identified in a fecal specimen from a *Rhinolophus affinis* bat and was sample number 4991.

The latter virus was described in the paper as follows:

> "Virus RaBtCoV/4991 was detected in a R. affinis sample and was related to SL-CoV. The conserved 440-bp RdRp fragment of RaBtCoV/4991 had 89% nt identity and 95% aa identity with SL-CoV Rs672. In the phylogenetic tree, RaBtCoV/4991 showed more divergence from human SARS-CoV than other bat SL-CoVs and could be considered as a new strain of this virus lineage."

The Genbank accession number for RaBtCoV/4991 is MN KP876546.1 and in Genbank it is identified as having been collected in July 2013 as a "feces/swabs" specimen.

The RATG13 genome sequence was assembled from low coverage RNA-Seq data.

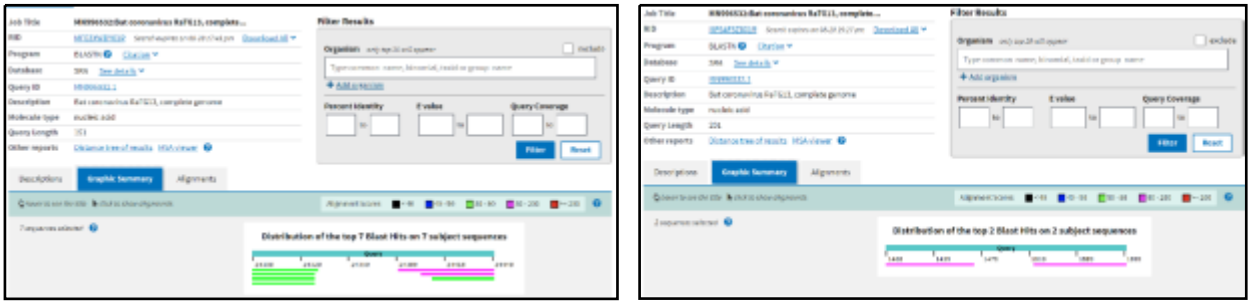
A Blast analysis of the RaTG13 genome against SRR11085797 retrieved about 1700 reads which covers only about 252,000 nt of the total reads of 3.3 Gb. Since the genome size of RaTG13 is known to be about 30,000 nt this represents an 8-fold coverage, typically insufficient for a definitive assembly. For example, some have suggested a 30-fold coverage is necessary to create high quality assemblies.[37]

[37] Sims, D. *et al.* Sequencing depth and coverage: key considerations in genomic analyses. Nature Reviews – Genetics. (2014) 15: 121-132. doi:10.1038/nrg3642.

At an eight-fold coverage and based on the typical practice of having four or more reads to call a SNP,[38] the 8-fold coverage of RaTG13 would have 4.2% bases or about 1260 calls of less than 4 reads and about 10 bases would be missed completely, with no calls at all.

A Blast of the RaTG13 published genome onto the RNA-Seq data documents at least two 60 base-pair gaps with no coverage, precluding a complete assembly.

Given the low coverage in the RNA-Seq data, an exploratory, non-exhaustive Blast search was conducted against the published RaTG13 sequence. Two gaps of over 60 nt, shown below, were easily found:

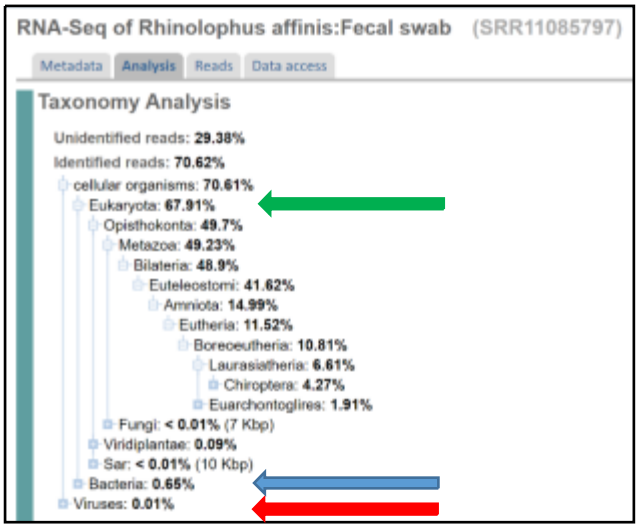


It is conceivable there are additional gaps but the above two are sufficient to document that the complete RaTG13 genome sequence could not have been assembled solely from the RNA-Seq data, as stated.[2]

Taxonomy analysis of the RaTG13 specimen is inconsistent with being from bat feces and shows evidence of laboratory cell culture contamination.

According to the Wuhan laboratory, the RaTG13 coronavirus was a fecal swab specimen collected from a *Rhinolophus affinis* bat in 2013. Unexpectedly, (Text-Figure below) the taxonomy analysis is primarily eukaryotic (green arrow; 67.91%) with only traces of bacteria (blue arrow; 0.65%). The viral genomes also make only a trace contribution (red arrow; 0.01%):

[38] Illumina Technical Bulletin Call Coverage



Taxonomy analysis for RaTG13 data SRR11085797

To compare this specimen composition to bat fecal specimens collected by Dr. Shi and her WIV colleagues and analyzed in other studies, a paper from Dr. Shi's laboratory, also published in February 2020, was identified. In this paper, entitled, "Discovery of Bat Coronaviruses through Surveillance and Probe Capture-Based Next-Generation Sequencing,"[39] a total of nine specimens "collected during previous bat CoV surveillance projects, (were) extracted from bat rectal swabs." According to the Methods section in this paper, the "previous bat CoV surveillance projects" include the field work in 2013 when the RaTG13 was said to have been collected. The comparison below is thus the same specimens collected on the same field surveillance projects by the same investigators from the Wuhan laboratory and sequenced on the same Illumina instrument. These nine specimens will be referred to as "reference fecal specimens" henceforth.

The following Text-Table compares the taxonomical analysis of the RaTG13 and reference fecal specimens. The reference fecal specimens have an average eukaryotic genome content of about 12% while RaTG13's eukaryotic content was 68%. On the other hand, the most abundant genes in the reference fecal specimens were bacterial, with an average of 65%; RaTG13 had less than 1% bacterial genes. And finally, the reference fecal specimens had 1.57% virus genes compared to the 0.01% virus genes of RaTG13.

[39] Discovery of bat coronaviruses through surveillance and probe capture-based next-generation sequencing

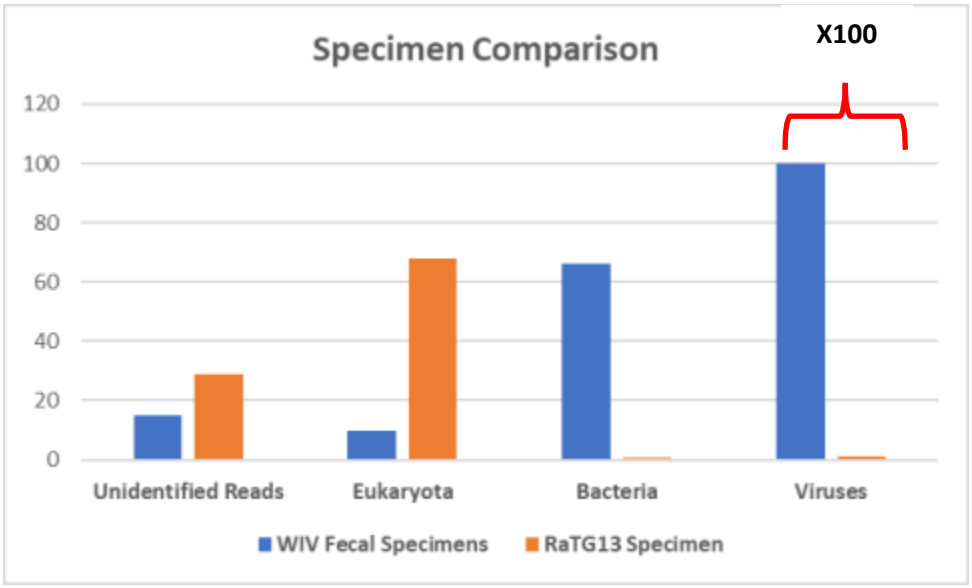
As shown in the Text-Table above the RaTG13 specimen is significantly different from the reference fecal specimens in composition. The probabilities for each category, eukaryote, bacteria, and virus, are individually highly statistically significant. They are also independent of each other and therefore the overall probability that RaTG13 has the composition of eukaryote, bacteria, and virus genes that was reported by the Wuhan laboratory but is actually from an authentic bat fecal specimen is less than one in 13 million.

The alternative conclusion is that this sample was not a fecal specimen but was contrived. The data cannot, however, distinguish between a non-fecal specimen that came from true field work on the one hand and a specimen created *de novo* in the laboratory on the other hand.

A graphical comparison of the above data is shown below and visually shows the significant differences between the WIV fecal specimens and the RaTG13 specimen, despite the claim they were collected in the same field surveillance trips:



Another comparison can be made between the reference fecal specimens and the RaTG13 specimen by looking at the taxonomy of the nine to twelve "strong signals" identified on the NCBI Sequence Read Archive. The following Text-Table is a summary of these findings.

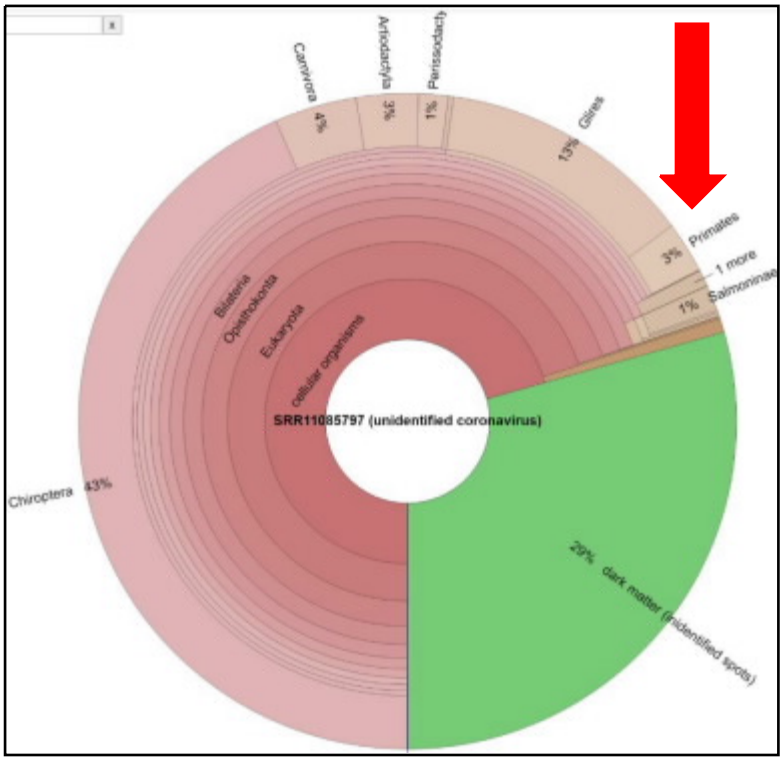
Specimen	The identity of the Strong Signals in the Specimens		
	Bacteria	Eukaryotes	Viruses
Rhinolophus affinis anal swab (SRR11085736)	92%	One magnaorder of placental mammals, includes bat	None
Miniopterus schreibersii anal swab (SRR11085734)	88%	**One bat**, the host bat, Miniopterus sp.	None
Scotophilus kuhlii anal swab (SRR11085737)	56%	**Two bats**, mouse-eared and big brown bats.	Two viruses, kobuvirus (host includes bats) and a Scotophilus kuhlii coronavirus
Hipposideros larvatus anal swab (SRR11085733)	56%	**One bat,** the host bat, Hipposideros sp. and one rodent.	Hipposideros pomona bat coronavirus
Hipposideros pomona: Anal swab (SRR11085735)	78%	**One bat**, the host bat, Hipposideros sp.	None
Pipistrellus abramus: Anal swab (SRR11085738)	73%	**Two bats**, the big brown bat and the mouse-eared bat.	Pipistrellus abramus bat coronavirus
Tylonycteris pachypus: Anal swab (SRR11085739)	67%	**Three bat**s, the microbat, the great roundleaf bat, and a superorder of mammals, which includes bats.	None
Miniopterus pusillus: Anal swab (SRR11085740)	89%	**One bat**, the Natal long-fingered bat.	None
Rousettus aegyptiacus: Anal swab (SRR11085741)	91%	One magnaorder of placental mammals, includes bats.	None
Average	77%		
RaTG13 Rhinolophus affinis:Fecal swab (SRR11085797)	None	All nine strong signals are eukaryotes. **Five bats**, the Great Roundleaf bat, resident of China, the Egyptian fruit bat, which is not found in China, a megabat, mouse-eared bat, and bent-winged bat. Two marmots, the Alpine marmot from Europe and the Yellow-bellied marmot of North America.The paraorder of whales. The red fox.	None

As can be seen, while the strong signals in the authentic specimens contain 56% to 92% (average 77%) bacterial signals, the RaTG13 specimen has no bacteria among the nine strong signals. Most specimens do not have virus strong signals but the three that do are host-related coronaviruses (four) or one host-related kobuvirus.

RaTG13 has no viral strong signals. Among the reference specimens with eukaryotic strong signals, they are either bat-related genes (eleven) or higher order taxonomy signals that include bats (three). There is one anomalous rodent-related signal among the reference specimens.

The RaTG13 specimen is again an outlier with all nine strong signals arising from eukaryotic genes. Five of the nine signals are bats, some resident to China and some with non-Chinese host ranges. Surprisingly, unlike three of the reference bat signals which are identified as host-related, the RaTG13 specimen did not contain *Rhinolophus* sp. host-related strong signals. The remaining four strong signals are marmot-related genes (two), whale-related gene (one), and red fox-related gene (one).

Finally, a Krona analysis (below) identifies 3% primate sequences (red arrow) in the RaTG13 sequence data. This is consistent with contamination by the standard laboratory coronavirus cell culture system, the VERO monkey kidney cell line.



Source: [Krona analysis of RaTG13 specimen]

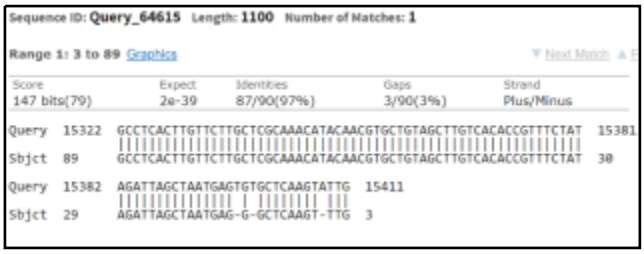
It is unclear why these obviously anomalous findings were not detected during the peer-review process prior to publication of this important work. At this point, an explanation is needed from the WIV to refute the conclusion that the specimen identified as the source of RaTG13 is **not** a bat fecal/anal specimen and that the primate genetic material is consistent with a VERO cell contaminated specimen.

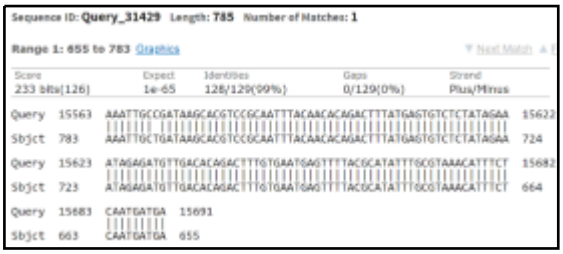
Method-related nt base substitutions in RaTG13.

The original Sanger dideoxy RdRp sequence reported in 2016 is homologous to RNA-seq data from 2020 but is non-homologous to amplicon sequencing data from 2017 and 2018.

As expected, a comparison of the 2016 RdRp GenBank sequence for BtCoV/4991 obtained by Sanger dideoxy sequencing with the RNA-seq sequencing of RaTG13 reported in *Nature* shows 100% identity over the 370 nt segment.

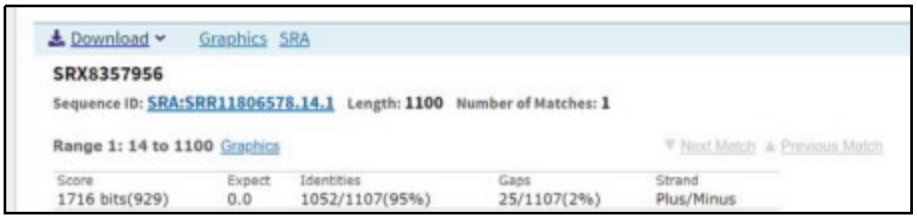
Surprisingly, the two amplicon sequences from 2017 that partially cover the 370 nt RdRp region have four base substitutions or gaps over a total segment of 219 nt (2% divergence).





RaTG13 Spike Protein gene has 5% substitutions when comparing 2020 RNA-Seq and 2017 amplicon sequencing data.

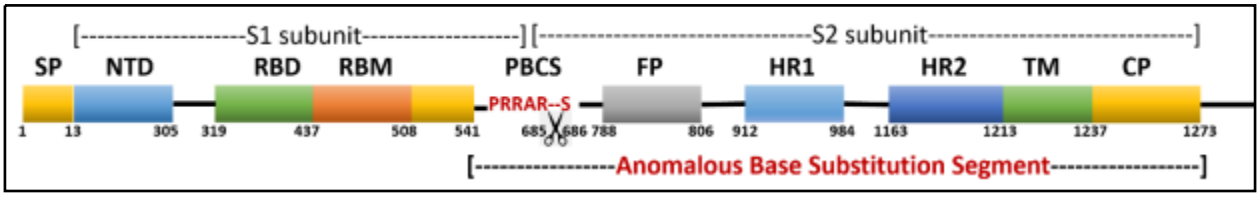
The segment of RaTG13 which shows the greatest sequence divergence between the RNA-seq and amplicon sequencing methods spans from A8886 to A9987 and is shown here below. It contains 80 base substitutions/indels in a 1107 nt sequence (5% substitution and 2% gaps).



No explanation has been offered in publications from the WIV for the method-dependent sequencing differences identified here, which are twenty- to 50-fold higher than the 0.1% technical error rate sometimes attributed to RNA-Seq data.

The Spike Protein gene sequence substitution divergence between RaTG13 and SARS-CoV-2 contains an improbable synonymous/non-synonymous pattern.

The functional structure of the SARS-CoV-2 Spike Protein is shown here:



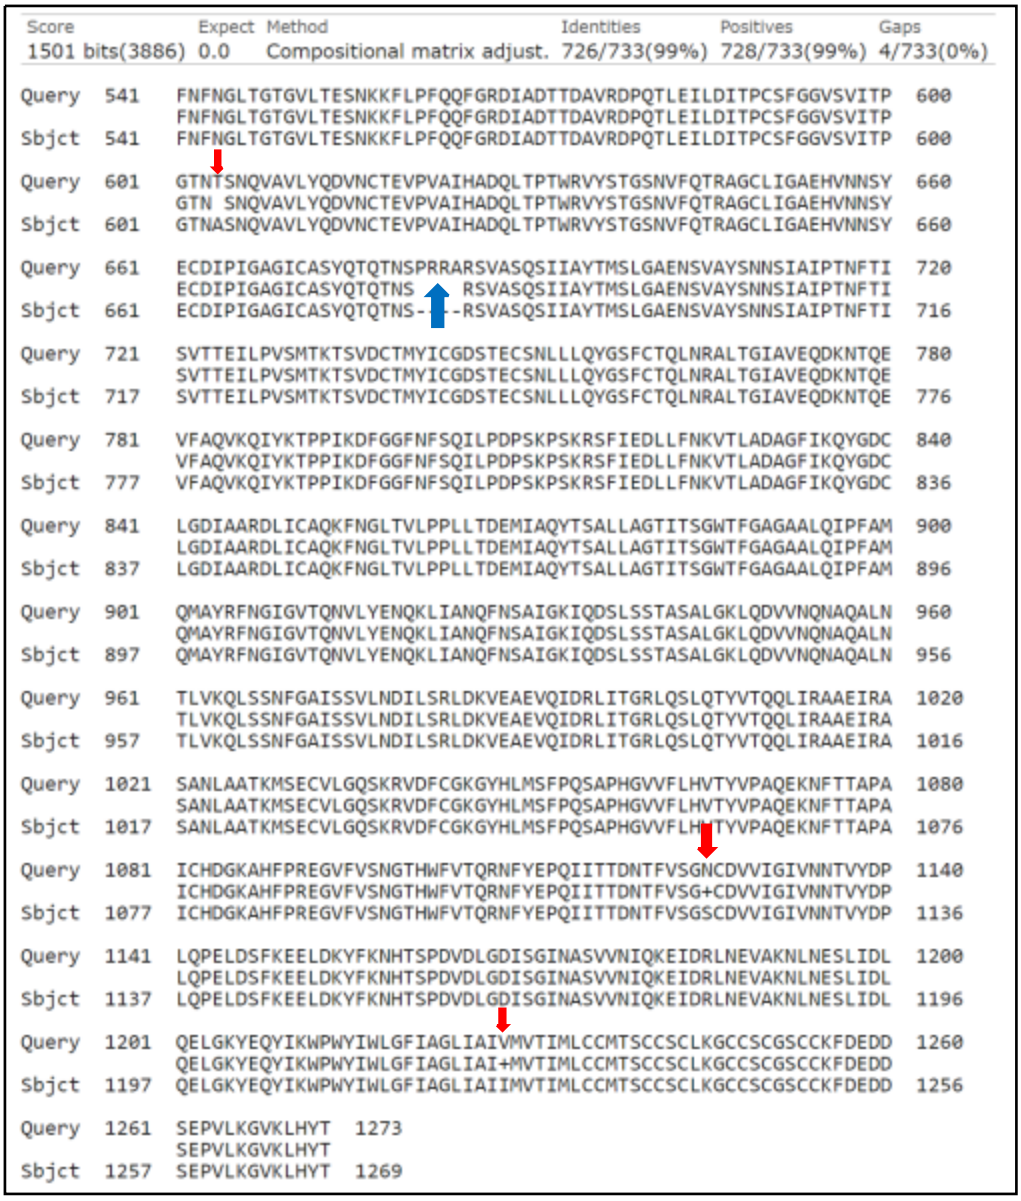
The SARS-CoV-2 Spike protein (above) contains an S1 subunit and S2 subunit with the Polybasic Cleavage Site (PBCS) between R685 and S686. This cleavage is performed by a host cell surface protease, furin, and is an important attribute in explaining the virulence of SARS-CoV-2 compared to other human coronaviruses, which do not have a furin cleavage site. The PBCS also contains the unusual PRRA insertion that has not been previously seen in Clade B coronaviruses and for which no natural mechanism for its appearance has been offered.[40]

The S1 subunit is located within the N-terminal 14–685 amino acids of S protein, containing N-terminal domain (NTD), receptor binding domain (RBD), and receptor binding motif (RBM). The S2 subunit contains a fusion peptide (FP), heptad repeat 1 (HR1), heptad repeat 2 (HR2), transmembrane domain (TM) and cytoplasmic domain (CP).

The base substitution pattern of synonymous and non-synonymous substitutions when comparing RaTG13 and the reference sequence of SARS-CoV-2 demonstrated an anomalous pattern for the coding region for aa 541 to 1273, a 733 aa protein segment representing over 60% of the SP gene.

As shown in the Text-Figure below, there are only three substitutions (red arrow) and the PBCS insertion (blue arrow) when comparing this segment of the RaTG13 and SARS-CoV-2 SP. Excluding the PBCS, the amino acid sequences are 99.6% identical.

[40] The proximal origin of SARS-CoV-2.



Score	Expect	Method	Identities	Positives	Gaps

Given the high amino acid identity of this 733 amino acid sequence (except for the PBCS insertion) and the typical coronavirus synonymous to non-synonymous mutation frequency of between three and five synonymous mutations for each non-synonymous mutation,[41] it was expected that a comparison of the nucleotide sequence for this region between SARS-CoV-2 and RaTG13 would show an almost identical sequence as well.

In fact, when the SARS-CoV-2 nt sequence 23,183-25,384 was compared to the RaTG13 nt sequence 23,165-25,354, the corresponding genome sequence to the 99.6% identical protein sequence above, the nucleotide identity was only 94.2% identical, with 122 synonymous substitutions and only the three non-synonymous substitutions.

[41] Comparative genomic analysis

To put this in context a comparison of thirteen other protein coding regions of SARS-CoV-2 and RaTG13 (Text-Table below) shows that the overall synonymous to non-synonymous mutation frequency is 549 synonymous to 109 non-synonymous or a ratio of about 5.0.

Gene	Region of Genome	Total Nucleotides	Synonymous mutations	Non-Synonymous mutations	S/NS	Probability of more than the number of synonymous mutations given the probability of a synonymous mutation is 0.83 (based on all genes pooled)
pp1ab	1-21,239	21,239	659	102	6.5	0.003
pp1ab ABSS	**7448-18266**	**10,818**	**283**	**13**	**21.8**	**5.73 x 10^-12**
Spike Protein RBD	1-1814	1814	131	27	4.9	0.48
Anomalous Base Substitution Segment	**23,183-25,384**	**2201**	**112**	**3**	**37.3**	**< 1.0 x 10^-7**
Entire Spike Protein	1-3810	3808	231	41	5.6	0.18
ORF1a polyprotein	1-13,215	13215	440	86	5.2	0.33
ORF3a protein	1-828	828	25	6	4.2	0.56
E Protein	1-228	228	1	0	Infinite	0.83

ORF7b Protein	1-132	132	0	1	0	0.83
ORF8 Protein	1-366	366	5	6	0.8	0.99
Nucleocapsid Phosphoprotein	1-1260	1260	35	4	8.75	0.083

With the exception of the anomalous base substitution segment (ABSS) in the Spike Protein gene and the pp1ab gene, the remainder of the S/SN substitution ratios are consistent with the literature values for coronaviruses. Only two genes or gene regions have a higher S/SN ratio than the ABSS because they have no non-synonymous mutations: the E protein gene with 228 nucleotides and the ORF6 protein gene with 186 nucleotides. Because of the short length of these two genes, the probabilities of the results for the E and ORF6 genes were not significant, with p-values of 0.86 and 0.17, respectively.

The p-value for the ABSS, on the other hand, was highly significant, with a p-value of <0.0000001. This strongly suggests a non-natural cause for this base substitution pattern, barring some unknown biological mechanism for such a result.

A second highly anomalous sequence was found in the pp1ab gene. This is about five-times larger than the Spike Protein region and is even more unlikely to have happened naturally, a chance of about one in 100 billion times.

Are there only synonymous mutations in these regions because non-synonymous mutations lead to non-replicative viruses?

A simple explanation for these results would be an extreme criticality for the specific sequences of these regions with respect to infectivity. If a single amino acid change yielded a non-transmissible viral particle that strong negative purification process could explain the above results.

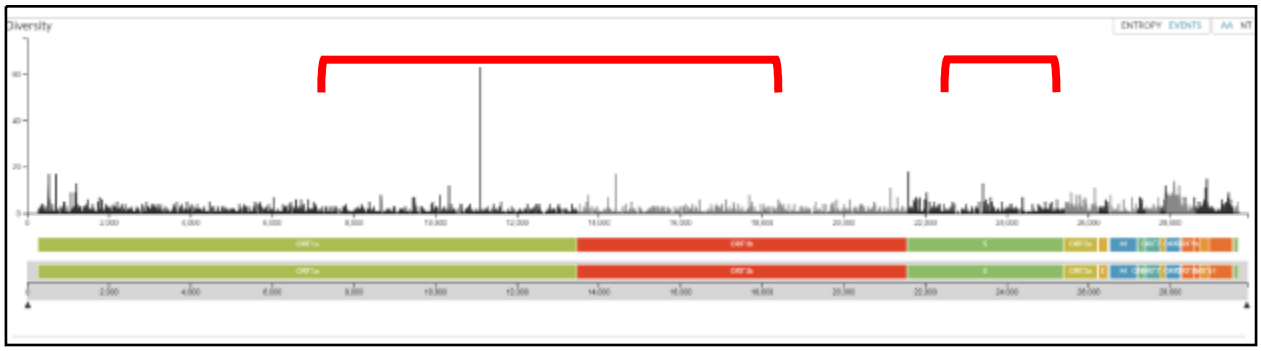
@2021. Steven C. Quay, MD, PhD

This hypothesis can be immediately rejected based on two observations.

In an examination of over 80,000 SARS-CoV-2 genome sequences, the most common Spike Protein non-synonymous mutation is within the ABSS (D614G) which was identified within weeks of the outbreak in January 2020 and which has become "the dominant virus…in every geographical region."[42] Specifically, as of August 28, 2020, GISAID reports that 65,738 full length SARS-CoV-2 genomes of a total of 83,387, or 79%, and comprising the G, GH, and GR clades, contain the D614G SNV. Under real world biological conditions, the ABSSN region has in fact, not a strong negative purification process in operation but in fact a strong positive selection process ongoing.

Secondly, in an analysis of mutations in 63,421 SARS-CoV-2 genomes the Spike Protein amino acid 605 to 1120 region had a total of 7,149 mutations. Fully 5,936 of these mutations (83%) are the above noted D614G non-synonymous change. Of the remaining 1213 mutations, 452 were non-synonymous while 755 were synonymous, a ratio of 1.7. There were also four indels and two stop codon mutations.

The following Text-Figure contains a map of the SARS-CoV-2 genome with the location of amino acid changes that have been found during the worldwide spread noted, with the frequency related to the height of the mark. The two ABSS in pp1ab and SP are marked with red brackets and clearly demonstrate an abundance of non-synonymous mutations in these regions during the human-to-human spread.



Nextstrain SARS-CoV-2 amino acid change events

Clearly, these regions can tolerate many non-synonymous mutations, rejecting the theory of a criticality for the amino acid sequence of this region. No other natural biological mechanism to explain these results has been identified.

Codon modification, enhancement, or optimization is an example from synthetic biology in which the S/SN ratio is, by design, an anomaly when looked at through the lens of nature

[42] Biswas NK, Majumder PP. Analysis of RNA sequences of 3636 SARS-CoV-2 collected from 55 countries reveals selective sweep of one virus type. Indian J Med Res. 2020;151(5):450-458. doi:10.4103/ijmr.IJMR_1125_20.

Synonymous codon substitution is a decades old, well known method of enhancing gene expression when cloning exogenous genes in a laboratory experiment. In a paper on the immunogenicity of the SARS-CoV-2 Spike Protein[43] the following synthetic biology methods were used:

"We used the following structure coordinates of the coronavirus spike proteins from the PDB to define the boundaries for the design of RBD expression constructs: SARS-CoV-2 (6VSB), SARS-CoV-1 (6CRV), HKU-1 (5I08), OC43 (6NZK), 229E (6U7H) NL63 (6SZS). Accordingly, a codon-optimized gene encoding for S1-RBD [SARS-CoV-1 (318 – 514 aa, P59594), SARS-CoV-2 (331 – 528 aa, QIS60558.1), OC43 (329 – 613 aa, P36334.1), HKU-1 (310 – 611 aa, Q0ZME7.1), 229E (295 – 433 aa, P15423.1) and NL63 (480 – 617 aa, Q6Q1S2.1)] containing human serum albumin secretion signal sequence, three purification tags (6xHistidine tag, Halo tag, and TwinStrep tag) and two TEV protease cleavage sites was cloned into the mammalian expression vector pαH. S1 RBDs were expressed in Expi293 cells (ThermoFisher) and purified from the culture supernatant by nickel-nitrilotriacetic acid agarose (Qiagen)."

The Genbank alignment (below) confirms that the authentic SARS-CoV-2 Spike Protein sequence (https://www.ncbi.nlm.nih.gov/nuccore/1798174254) and the Synthetic construct SARS CoV-2 spike protein receptor binding domain gene, complete cds are 100% homologous at the protein level:

But a comparison of the authentic nucleotide sequence of SARS-CoV-2 to the codon-optimized synthetic construct shows no match using the "highly similar Megablast" algorithm setting. When the alignment algorithm is run in a more relaxed mode the impact of codon optimization in this case can be seen, a 70% homology:

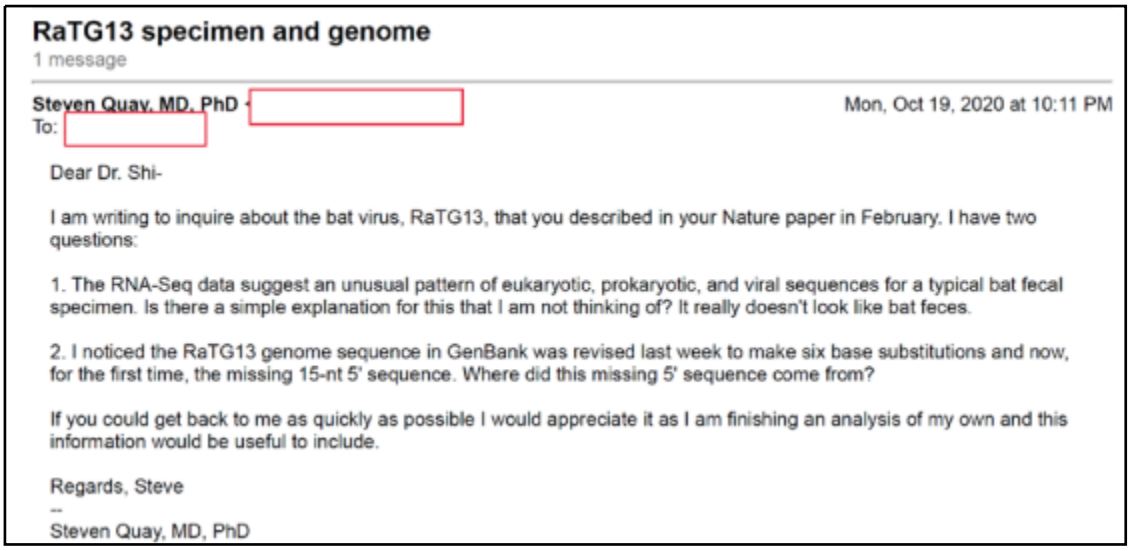
This is a situation in which there are 176 synonymous changes without a single non-synonymous change and is the genome signature of laboratory-derived synthetic biology. If these sequences were compared for phylogenetic divergence without the knowledge of their artificial construction, this synthetic laboratory experiment would create the impression that these two sequences had diverged in the wild from a common ancestor decades earlier.

The following Table identifies four regions of the RaTG13 and SARS-CoV-2 genomes in which there were a total of 220 synonymous mutations without a single non-synonymous change.

Protein/Gene	Protein Region	Total Nucleotides	Synonymous mutations	NS Mutations
S Protein	605-1124	1557	91	0
pp1ab	3607-4534	2781	66	0
pp1ab	4626-5111	1455	26	0
pp1ab	5113-5828	2145	37	0
	Total	7938	220	0

These regions represent over 26% of the entire genome and appear analogous to the outcome expected from the application of a synonymous codon modified, laboratory-derived synthetic biology project. They also represent about one-sixth of the 4% apparent phylogenetic divergence between RaTG13 and SARS-CoV-2.

October GenBank update. On October 13, 2020 the sequence for RaTG13 was updated. For the first time the first 15 nucleotides at the 5' end were present. However, these were not found in a blast of either the RNA-Seq raw reads or the Amplicons. The following email was sent to Dr. Shi asking for an explanation of the fecal specimen composition and the source for the 5' nt data.



RaTG13 specimen and genome
1 message

Steven Quay, MD, PhD [redacted] Mon, Oct 19, 2020 at 10:11 PM
To: [redacted]

Dear Dr. Shi-

I am writing to inquire about the bat virus, RaTG13, that you described in your Nature paper in February. I have two questions:

1. The RNA-Seq data suggest an unusual pattern of eukaryotic, prokaryotic, and viral sequences for a typical bat fecal specimen. Is there a simple explanation for this that I am not thinking of? It really doesn't look like bat feces.

2. I noticed the RaTG13 genome sequence in GenBank was revised last week to make six base substitutions and now, for the first time, the missing 15-nt 5' sequence. Where did this missing 5' sequence come from?

If you could get back to me as quickly as possible I would appreciate it as I am finishing an analysis of my own and this information would be useful to include.

Regards, Steve
--
Steven Quay, MD, PhD

At the time of this writing a response has not been received.

Discussion. The foundation of the working hypothesis that the COVID-19 pandemic arose via a natural zoonotic transfer from a non-human vertebrate host to man has been built on two publications: the February 3, 2020 *Nature* paper by Dr. Zheng-Li Shi and colleagues, in which the bat coronavirus RaTG13 is first identified as the closest sequence identity to SARS-CoV-2 at 96.2% and the March 17, 2020 *Nature Medicine* paper entitled, "The proximal origin of SARS-CoV-2," by Andersen *et al.,* in which the Shi *et al.* paper is cited as evidence for a bat origin for the pandemic. In the approximately six months since they were published, these two papers have been cited over 1600- and 200-times on PubMed, respectively.

However, research is beginning to question whether a bat species can be considered a natural reservoir for SARS-CoV-2. A recent paper performed an *in silico* simulation of the SARS-CoV-2 Spike Protein interaction with the cell surface receptor, ACE2, from 410 unique vertebrate species, including 252 mammals.[44] Among primates, 18/19 have an ACE2 receptor which is 100% homologous to the human protein in the 25 residues identified to be critical to infection,

[44] Broad host range of SARS-CoV-2 predicted by comparative and structural analysis of ACE2 in vertebrates Joana Damas, et al. Proc. of the Nat. Acad. of Sci. Aug 2020, 202010146; DOI: 10.1073/pnas.2010146117

including the *Chlorocebus sabaeus* (the Old World African Green monkey) and the rhesus macaques.

It is noteworthy that the laboratory workhorse of coronavirus research is the VERO cell, isolated from a female African Green monkey in 1962, and containing an ACE2 receptor that is 100% homologous to the human ACE2 in the 25 critical amino acids for infectivity.

This *in silico* work was confirmed in the laboratory with respect to rhesus macaques. Within weeks of the identification of SARS-CoV-2, the Wuhan laboratory had demonstrated that the pandemic virus would infect and produce a pneumonia in rhesus macaques.[45]

A surprising finding from the ACE2 *in silico* surveillance work was the very poor predicted affinity of the ACE2 receptors in both bats and pangolins. Of 37 bat species studied, 8 scored low and 29 scored very low. As expected by these predictions, cell lines derived from big brown bat (*Eptesicus fuscus*),[46] Lander's horseshoe bat (*Rhinolophus landeri*), and Daubenton's bat (*Myotis daubentonii*) could not be infected with SARS-CoV-2.[47]

It is unfortunate that growth of the RaTG13 specimen could not have been attempted in the *Rhinolophus sinicus* primary or immortalized cells generated and maintained in the Wuhan laboratory: kidney primary cells (RsKi9409), lung primary cells (RsLu4323), lung immortalized cells (RsLuT), brain immortalized cells (RsBrT) and heart immortalized cells (RsHeT).[48] However it should be noted that a synthetically created RaTG13 was reported not to infect human cells expressing *Rhinolophus sinicus* ACE2, providing evidence that RaTG13 may not be a viable coronavirus in a wild bat population.[49]

The other proposed intermediate host, the pangolin, also had predicted ACE-2 affinity that was either low or very low.

A recent paper that examined the high synonymous mutation difference between RaTG13 and SARS-CoV-2 used an *in silico* methodology to suggest that the difference could be largely attributed to the RNA modification system of hosts.[50] However, the authors do not "(t)he limitation of our study is that we were currently unable to provide experimental evidence for

[50] The divergence between SARS-CoV-2 and RaTG13 might be overestimated due to the extensive RNA modification

the modification on viral RNAs." The low S/SN ratio of 1.7 in the expansion of SARS-CoV-2 in the human population would argue against a robust host RNA modification mechanism.

In summary, the findings reported here are:

1. Inconsistences between published papers and interviews as to the source and sequencing history of the original specimen that was claimed to have been collected in 2013 (RaBtCoV/4991) and the specimen for the bat RaTG13 virus. For example, two explanations of the discovery of the close relationship between RaTG13 and SARS-Cov-2, a highly homologous match between the RdRp genes of the viruses noticed in 2020 followed by full genome sequencing, or identification in 2020 of a homologous match to full genome sequencing previously done in 2018. Current publicly available data for RaTG13 from 2017 and 2018 is a set of 33 amplicon sequencing runs but they cover only about 80% of the entire genome. In the *Science* interview Dr. Shi's says the specimen for RaTG was consumed during sequencing in 2018, but if this is true, the RNA-Seq referred to in the *Nature* paper could not have been performed in 2020. At this time, the Wuhan laboratory has not met the requirements of *Nature* with respect to the sharing of primary and sequence assembly data from their seminal paper[1] and this data should be provided immediately.
2. The specimen from which RaTG13 was reported to have been isolated and which has been repeatedly reported to have been a bat fecal specimen has a taxonomical composition of eukaryotes, bacteria, and viruses that is completely different from a set of nine bat fecal specimens collected in the same field visits by the same laboratory personnel from the Wuhan Institute of Virology. The probability that an authentic fecal specimen could have the composition reported is one in ten million, an impossibly low occurrence. Examination of the strong signals in the RaTG13 specimen identifies both a variety of bat genetic material, some that are not native to China, as well as unexpected species, such as marmots and a red fox. It also contains a telltale 3% primate sequence consistent with VERO cell contamination. I propose that this specimen is apparently either a mislabeled specimen (although I cannot conjure what the field source or specimen would be) or was artificially created in a laboratory.
3. The method-dependent sequence differences between the amplicon data and the RNA-Seq data are about 5% or about 50-times higher than expected as a technical error rate of 0.1%. This is an experimental quality issue that needs to be addressed; no explanation has been offered for this to date. In addition, no assembly methodology has been provided and at least two gaps, totaling over 60 nt, were easily identified.
4. The findings, reported here of a mutational drift of synonymous mutations only between SARS-CoV-2 and RaTG13 in the Spike Protein S1/S2 region and the pp1ab gene that has never been seen in nature before and which has a probability of having occurred by chance of less than one in ten million and one in one billion makes it more likely that, at least for these portions of the RaTG13 genome, comprising over one-quarter of the entire genome, another process is underway. With the demonstration

that codon-enhancement or optimization can produce this unnatural S/SN pattern, some form of laboratory-based synthetic biology was performed on RaTG13, SARS-CoV-2, or both.

Apparently, the entire specimen from which RaTG13 was purported to have been found has been consumed in previous sequencing experiments and the Principal Investigator has stated that no virus has ever been isolated or cultured from the specimen at any time in the past. Given the irregularities and anomalies identified in this paper it seems prudent to conclude that all data with respect to RaTG13 must be considered suspect. As such, reliance of the foundational papers of the origin of SARS-CoV-2 as having arisen from bats via a zoonotic mechanism must be reexamined and questioned.

Paper 2: The February 19, 2020 Lancet paper entitled: "Statement in support of the scientists, public health professionals, and medical professionals of China combatting COVID-19."

On February 19, 2020 *The Lancet* published a Correspondence entitled "Statement in support of the scientists, public health professionals, and medical professionals of China combatting COVID-19[51]" with 27 public health scientists from eight countries as authors. The statement seems to attempt to settle the question of the origin of SARS-CoV-2 and short circuit further debate, as the second sentence reads: "We stand together to strongly condemn conspiracy theories suggesting that COVID-19 does not have a natural origin." It goes on to state: "Conspiracy theories do nothing but create fear, rumors, and prejudice that jeopardize our global collaboration in the fight against this virus."

The letter provided an open solicitation for support and at this time has been signed by at over 20,300 people, as if to purport that science can be advanced through polling and the democratic process.[52] While it is a truism that conspiracy theories have no place in the academia, legitimate debate should not be foreclosed.

The statement itself provides a more nuanced discussion of the evidence for a zoonotic origin and contains 14 references, eight of which contain data about the COVID-19 pandemic and six of which are governmental policy statements without new data, background articles from 2003 and 2004 on zoonotic diseases, or a virus naming statement by the Coronavirus Study Group (CSG) of the International Committee on Taxonomy of Viruses, which is responsible for developing the official classification of viruses and taxa naming (taxonomy) of the Coronaviridae family. The eight articles with data were written at the end of January or early February, when there were fewer than 10,000 patients.

An analysis of the evidence for a zoonotic source given in support of the above Statement is contained in Text-Table here. The analysis shows there was very little actual data available at the

[51] https://www.thelancet.com/journals/lancet/article/PIIS0140-6736(20)30418-9/fulltext#back-bib1

[52] This is reminiscent of the story attributed to Albert Einstein by Stephen Hawkins in his *Brief History of Time.* According to Hawkins, a book was published in 1930 in pre-war Germany entitled, "One Hundred Authors Against Einstein." When he was asked about the book Einstein is reported to have retorted, "If I were wrong, then one would have been enough!"

time to permit reaching such a definitive conclusion. There was also the absence of data or discussion that could support a laboratory origin.

Reference	Statements concerning origin of SARS-CoV-2	Response to statements
1.Gorbalenya AE Baker SC Baric RS et al. Severe acute respiratory syndrome-related coronavirus: the species and its viruses—a statement of the Coronavirus Study Group. bioRxiv. 2020; (published online Feb 11. DOI: 2020.02.07.937862 (preprint).)	A naming statement about SARS-CoV-2. The emergence of SARS-CoV-2 as a human pathogen in December 2019 may thus be perceived as completely independent from the SARS-CoV outbreak in 2002–2003. With respect to novelty, SARS-CoV-2 differs from the two other zoonotic coronaviruses, SARS-CoV and MERS-CoV, introduced to humans earlier in the twenty-first century.	Does not provide data on a potential zoonotic source.
2.Zhou P Yang X-L Wang X-G et al. A pneumonia outbreak associated with a new coronavirus of probable bat origin. Nature. 2020; (published online Feb 3.)	The sequences of 2019-nCoV BetaCoV/Wuhan/WIV04/2019 among patient specimens are almost identical and share 79.6% sequence identity to SARS-CoV. Furthermore, we show that 2019-nCoV is 96% identical at the whole-genome level to a bat coronavirus. Pairwise protein sequence analysis of seven conserved non-structural proteins domains show that this virus belongs to the species of SARSr-CoV. The close phylogenetic relationship to RaTG13 provides evidence that 2019-nCoV may have originated in bats.	The bat genome identity of 96% described here, coupled with the known mutation rate of SARS-CoV-2 of about 26/year, implies a **lowest common ancestor about 44 years ago.**

3.Lu R Zhao X Li J et al. Genomic characterisation and epidemiology of 2019 novel coronavirus: implications for virus origins and receptor binding. Lancet. 2020; (published online Jan 30.)	Genome sequences of 2019-nCoV sampled from nine patients who were among the early cases of this severe infection are almost genetically identical, which suggests very recent emergence of this virus in humans and that the outbreak was detected relatively rapidly. 2019-nCoV is most closely related to other betacoronaviruses of bat origin, indicating that these animals are the likely reservoir hosts for this emerging viral pathogen.	Figure 1A shows 8 sequences and the concensus sequence. These 8 sequences show 3 with 0 mutations, 2 with 1 mutation, 3 with 2 mutations, and none with more than 2 mutations. Based on current estimates of 1 mutation per human passage, these are at most two human-to-human transfers apart. Importantly, there is no background diversity as would be seen in two or more resevoir-to-human events. Fig 2 states strain Bat-SL-CoVZC45 is 87.6% sequence identity to the human virus, which means a difference of about 3700 mutations or over 70 years from lowest common ancestor.
4.Zhu N Zhang D Wang W et al. A novel coronavirus from patients with pneumonia in China, 2019. NEJM. 2020; (published online Jan 24.)	"more than 85% identity with a bat SARS-like CoV (bat-SL-CoVZC45, MG772933.1) genome published previously. Since the sequence identity in conserved replicase domains (ORF 1ab) is less than 90% between 2019-nCoV and other members of betacoronavirus, the 2019-nCoV — the likely causative agent of the viral pneumonia in Wuhan — is a novel betacoronavirus belonging to the	A >85% identity with a bat coronavirus means the **human and bat virus have over 70 years to LCA.**

	sarbecovirus subgenus of Coronaviridae family."	
5.Ren L Wang Y-M Wu Z-Q et al. Identification of a novel coronavirus causing severe pneumonia in humans: a descriptive study. Chin Med J. 2020; (published online Feb 11.)	All five patients have sequence homology of 99.8% to 99.9%. These isolates showed 79.0% nucleotide identity with the sequence of SARS-CoV (GenBank NC_004718) and 51.8% identity with the sequence of MERS-CoV (GenBank NC_019843). The virus is closest to a bat SARS-like CoV (SL-ZC45, GenBank MG772933) with 87.7% identity, but is in a separate clade. **Surprisingly, RNA-dependent RNA polymerase (RdRp), which is the most highly conserved sequence among different CoVs, only showed 86.3% to 86.5% nt identities with bat SL-CoV ZC45.**	Similar to reference 3 comments. Lack of conserved sequencing of the most highly conserved sequence with bat coronavirus would **suggest a non-bat source.**
6.Paraskevis D Kostaki EG Magiorkinis G Panayiotakopoulos G Tsiodras S Full-genome evolutionary analysis of the novel corona virus (2019-nCoV) rejects the hypothesis of emergence as a result of a recent recombination event. Infect Genet Evol. 2020; (published online Jan 29.)	A BLAST search of 2019-nCoV middle fragment revealed no considerable similarity with any of the previously characterized corona viruses. Bat_SARS-like coronavirus sequences cluster in different positions in the tree, suggesting that they are recombinants, and thus that the 2019-nCoV and RaTG13 are not recombinants. Codon usage analyses can resolve	**The middle segment with no similarity to other corona viruses is about 40% of the entire genome. I agree SARS-CoV-2 is not a recombinant of RaTG13. I agree, codon usage analysis here supports the furin binding site insertion as having been invented de novo. A recent recombination event is not necessary for a**

	the origin of proteins with deep ancestry and insufficient phylogenetic signal or **invented de novo**. Our study rejects the hypothesis of emergence as a result of a recent recombination event. Notably, the new coronavirus provides a new lineage for almost half of its genome, with **no close genetic relationships to other viruses** within the subgenus of sarbecovirus. This genomic part comprises half of the spike region encoding a multifunctional protein responsible also for virus entry into host cells	**laboratory derived theory of origin. Statements do not advance a zoonotic origin.**
7.Benvenuto D Giovanetti M Ciccozzi A Spoto S Angeletti S Ciccozzi M The 2019-new coronavirus epidemic: evidence for virus evolution. J Med Virol. 2020; (published online Jan 29.)	The epidemic originated in Wuhan, China. A phylogenetic tree has been built using the 15 available whole genome sequences of 2019-nCoV, 12 whole genome sequences of 2019-nCoV, and 12 highly similar whole genome sequences available in gene bank (five from the severe acute respiratory syndrome, two from Middle East respiratory syndrome, and five from bat SARS-like coronavirus). >97% maximum likelihood match to Bat SARS-like virus 2015 (Fig 1) is noted. The SARS and MERS viruses are excluded as a source of SARS-CoV-2. These results do not	A 3% genome **distance from the noted bat virus to human is about 34 years** at 26 mutations per year, the in-human mutation rate. Predicted a future mutation like the D614G mutation which is more infective.

	exclude the fact that **further mutation due to positive selective pressure, led by the epidemic evolution, could favor an enhancement of pathogenicity and transmission of this novel virus.**	
8.Wan Y Shang J Graham R Baric RS Li F Receptor recognition by novel coronavirus from Wuhan: an analysis based on decade-long structural studies of SARS. J Virol. 2020; (published online Jan 29.)	Based on predicted RBD-host ACE2 receptor affinities, civet, mice, and rats are fuled out as source species. Pigs, ferrets, cats, and **nonhuman primates** contain largely favorable 2019-nCoV-contacting residues in their ACE2. SARS-CoV was isolated in wild palm civets near Wuhan in 2005, and its RBD had already been well adapted to civet ACE2.	The **potential nonhuman primate ACE2 usage is noted. Consistent with a laboratory origin from VERO cells**, a monkey kidney cell line. It expresses an ACE2 that permits SARS-CoV-2 infection, making it a possible source for the virus. A common tissue culture cell line forSARS virus research.
9.US Center for Disease Control and Prevention Coronavirus disease 2019 (COVID-19) situation summary. https://www.cdc.gov/coronavirus/2019-nCoV/summary.html Date: Feb 16, 2020 Date accessed: February 8, 2020	Rarely, animal coronaviruses can infect people and then spread between people such as with MERS-CoV, SARS-CoV, and now with this new virus, named SARS-CoV-2. The SARS-CoV-2 virus is a betacoronavirus, like MERS-CoV and SARS-CoV. All three of these viruses have their origins in bats. The sequences from U.S. patients are similar to the one that China initially posted, suggesting a likely single, recent emergence of this virus from an animal reservoir.	There are no data to support these statements about bats as the source for SARS-CoV-2.

10.Andersen KG Rambaut A Lipkin WI Holmes EC Garry RF The proximal origin of SARS-CoV-2. http://virological.org/t/the-proximal-origin-of-sars-cov-2/398 Date: Feb 16, 2020 Date accessed: February 17, 2020	See Table 2.	See Table 2.
11.Bengis R Leighton F Fischer J Artois M Morner T Tate C The role of wildlife in emerging and re-emerging zoonoses. Rev Sci Tech. 2004; 23: 497-512	In one pattern, actual transmission of the pathogen to humans is a rare event but, once it has occurred, human-to-human transmission maintains the infection for some period of time or permanently. Some examples of pathogens with this pattern of transmission are human immunodeficiency virus/acquired immune deficiency syndrome, influenza A, Ebola virus and severe acute respiratory syndrome.	This 2004 paper describes the pattern of rare animal-to-human transmission followed by human-to-human spread as an example of the SARS virus. It does not address the origin of SARS-CoV-2.
12.Woolhouse ME Gowtage-Sequeria S Host range and emerging and reemerging pathogens. Emerg Infect Dis. 2005; 11: 1842-1847	Emerging and reemerging pathogens are disproportionately viruses, with 37% being RNA viruses. Emerging and reemerging pathogens more often are those with broad host ranges that often encompass several mammalian orders and even nonmammals. For pathogens that are minimally transmissible within human populations (R0 close to 0), outbreak size is determined largely by the number of introductions from the reservoir. For pathogens that are highly transmissible within human populations	This 2005 article has good general information about looking broadly for the reservoir species(s), identifies RNA viruses as a major source of human epidemics, predicts a large outbreak size for a high Ro virus, but does address the origin of SARS-CoV-2 origin.

	(R0>>1), outbreak size is determined largely by the size of the susceptible population.

NAS, NAE, and NAM presidents' letter to the White House Office of Science and Technology Policy. https://www.nationalacademies.org/includes/NASEM%20Response%20to%20OSTP%20re%20Coronavirus_February%206,%202020.pdf Date: Feb 6, 2020 Date accessed: February 7, 2020	The closest known relative of 2019-nCoV appears to be a coronavirus identified from bat-derived samples collected in China.4 The experts informed us that additional genomic sequence data from geographically- and temporally-diverse viral samples are needed to determine the origin and evolution of the virus. Samples collected as early as possible in the outbreak in Wuhan and samples from wildlife would be particularly valuable. Understanding the driving forces behind viral evolution would help facilitate the development of more effective strategies for managing the 2019-nCoV outbreak and for preventing future outbreaks.	Agree. If additional genomic sequence data is available from geographically- and temporally-diverse viral samples are needed to determine the origin and evolution of the virus this should be made publicly available.
14.WHO Director-General's remarks at the media briefing on 2019 novel coronavirus on 8 February 2020. https://www.who.int/dg/speeches/detail/director-general-s-remarks-at-the-media-briefing-on-2019-novel-coronavirus---8-february-2020 Date: Feb 8, 2020 Date accessed: February 18, 2020	A general statement about the emerging pandemic without reference to the origin of SARS-CoV-2	There is no data about the origin of the pandemic.

In November 2020 the Watchdog group, US Right-to-Know, reported the following with respect to the *Lancet* article:[53]

"Emails obtained by U.S. Right to Know show that a statement in *The Lancet* authored by 27 prominent public health scientists condemning "conspiracy theories suggesting that COVID-19 does not have a natural origin" was organized by employees of EcoHealth Alliance, a non-profit group that has received millions of dollars of U.S. taxpayer funding to genetically manipulate coronaviruses with scientists at the Wuhan Institute of Virology."

"The emails obtained via public records requests show that EcoHealth Alliance President Peter Daszak drafted the Lancet statement, and that he intended it to "not be identifiable as coming from any one organization or person" but rather to be seen as "simply a letter from leading scientists". Daszak wrote that he wanted "to avoid the appearance of a political statement."

A separate, worrisome article entitled, "Peter Daszak's EcoHealth Alliance Has Hidden Almost $40 Million In Pentagon Funding And Militarized Pandemic Science,[54]" seems to indicate a serious conflict of interest with respect to Dr. Daszak's participation in any investigations on the origin of SARS-CoV-2.

Paper 3: The March 17, 2020 article in *Nature Medicine* entitled "The proximal origin of SARS-CoV-2" by Andersen et al.[55]

According to the journal, this article is in the 99th percentile (ranked 2nd) of the 312,683 tracked articles of a similar age in all journals and the 99th percentile (ranked 1st) of the 147 tracked articles of a similar age in *Nature Medicine.* The metrics also indicate it has been accessed over five million times. It is clearly the most cited paper and since its title and topic are the origin of the pandemic it clearly has an outsized influence on the topic.

The following statements form the evidence in the article of the natural origin of CoV-2:

- "While the analyses above suggest that SARS-CoV-2 may bind human ACE2 with high affinity, computational analyses **predict that the interaction is not ideal** and that the RBD sequence is different from those shown in SARS-CoV to be optimal for receptor binding. Thus, the high-affinity binding of the SARS-CoV-2 spike protein to human ACE2 is **most likely the result of natural selection on a human or human-like ACE2** that permits another optimal binding solution to arise. **This is strong evidence that SARS-CoV-2 is not the product of purposeful manipulation."** [emphasis added.]

    - A later analysis of over 3800 possible substitutions of amino acids in a 200 amino acid receptor binding region, much larger than the small, selective region referred to in this paper, shows that CoV-2 is 99.5% optimized for binding to the ACE-2

[53] https://usrtk.org/biohazards-blog/ecohealth-alliance-orchestrated-key-scientists-statement-on-natural-origin-of-sars-cov-2/
[54] https://www.independentsciencenews.org/news/peter-daszaks-ecohealth-alliance-has-hidden-almost-40-million-in-pentagon-funding/
[55] https://www.nature.com/articles/s41591-020-0820-9

receptor. This near perfect binding has never been seen before in a recent interspecies transmission jump.

- "Polybasic cleavage sites have not been observed in related 'lineage B' betacoronaviruses, although other human betacoronaviruses, including HKU1 (lineage A), have those sites and predicted O-linked glycans. Given the level of genetic variation in the spike, **it is likely that SARS-CoV-2-like viruses with partial or full polybasic cleavage sites will be discovered in other species.**" [emphasis added.]

    - As of the writing of this manuscript no other lineage B (sarbecovirus) has been found to have a furin site. In addition, the furin site of CoV-2 has the unusual -CGG-CGG- codon dimer, which has never been seen in an analysis of 58 other sarbecoviruses, that is, 580,000 codons. Since recombination between subgenera of beta coronaviruses is rare, or unknown, there is no source for the CGG-CGG dimer via a natural recombination event.

- "The acquisition of polybasic cleavage sites by HA has also been observed after repeated passage in cell culture or through animals."

    - It is curious why the above statement did not lead to a hypothesis somewhere in the article about a similar mechanism on CoV-2, a clear indication of a laboratory origin.

- "It is improbable that SARS-CoV-2 emerged through laboratory manipulation of a related SARS-CoV-like coronavirus."

    - This conclusory statement is unsupported my evidence.

- "Furthermore, if genetic manipulation had been performed, one of the several reverse-genetic systems available for betacoronaviruses would **probably have been used**. However, the genetic data irrefutably show that SARS-CoV-2 is not derived from any previously used virus backbone." [emphasis added.]

    - There is no explanation for why a prior backbone would necessarily be used. All synthetic biology chimera coronaviruses created in the past as published in prior papers have each used a unique backbone with no particular pattern in backbone selection. Each backbone was selected for the particular needs of those current experiments. This non-repeating prior pattern of reverse-genetic systems makes the above statement untenable. And with 16,000+ reported coronavirus specimens at the WIV it entirely reasonable a non-published virus could have been used.

- "Natural selection in an animal host before zoonotic transfer. For a precursor virus to acquire both the polybasic cleavage site and mutations in the spike protein suitable for

binding to human ACE2, **an animal host would probably have to have a high population density (to allow natural selection to proceed efficiently**) and an ACE2-encoding gene that is similar to the human ortholog." [emphasis added.]

  - The paragraph discusses the pangolin as the possible intermediate host but at the time of this manuscript the coronavirus data from pangolins has been discredited. This author agrees with statement that selection of the two unique features of CoV-2 require a high population density of the animal host. Of course, in the laboratory the animal hosts for either *in vitro* cell culture experiments or in animal experiments are a single species at high density.

- Natural selection in humans following zoonotic transfer. "It is possible that a progenitor of SARS-CoV-2 jumped into humans, acquiring the genomic features described above through adaptation during **undetected human-to-human transmission**. Once acquired, these adaptations would enable the pandemic to take off and produce a sufficiently large cluster of cases to trigger the surveillance system that detected it." [emphasis added.]

- "Studies of banked human samples could provide information on whether such cryptic spread has occurred. Further serological studies should be conducted to determine the extent of prior human exposure to SARS-CoV-2."

  - As will be shown in later sections, this prior undetected human-to-human transmission would be evident in archived specimens from before the fall of 2019. In both SARS-CoV-1 and MERS, this prior seroconversion averaged about 0.6% with almost 5% among workers exposed to the intermediate hosts. At the time of the writing of this manuscript, in limited sampling of archived specimens there has been no seroconversion detected. The author believes there are thousands of archived specimens from Wuhan taken in the fall of 2019 and these should be immediately examined for evidence of seroconversion. Since finding seroconversion among these specimens would be strong evidence for a zoonotic origin and not a laboratory accident, the absence of any information from China on this important evidence is hard to understand.

- Selection during passage. "Basic research involving passage of bat SARS-CoV-like coronaviruses in cell culture and/or animal models has been ongoing for many years in biosafety level 2 laboratories across the world, and there are documented instances of laboratory escapes of SARS-CoV. We must therefore examine the possibility of an inadvertent laboratory release of SARS-CoV-2."

- "In theory, it is possible that SARS-CoV-2 acquired RBD mutations during adaptation to passage in cell culture, as has been observed in studies of SARS-CoV."

- "New polybasic cleavage sites have been observed only after prolonged passage of low-pathogenicity avian influenza virus in vitro or in vivo. Furthermore, a hypothetical generation of SARS-CoV-2 by cell culture or animal passage would have required prior isolation of a progenitor virus with very high genetic similarity, **which has not been described.** Subsequent generation of a polybasic cleavage site would have then required repeated passage in cell culture or animals with ACE2 receptors similar to those of humans, **but such work has also not previously been described**." [emphasis added.]

    - The authors correctly describe a method for CoV-2 to have been generated in the laboratory and then dismiss it because the work has not been published previously. As active scientists themselves, the authors must know how disingenuous this sounds. Almost by definition elite scientists, like Dr. Shi of the WIV, work in secret until the publication of any given line of research. As the say, the absence of evidence cannot be used as evidence of its absence.

    - A peer-reviewed paper[56] entitled, "Might SARS-CoV-2 Have Arisen via Serial Passage through an Animal Host or Cell Culture? A potential explanation for much of the novel coronavirus' distinctive genome," provides a compelling argument that serial passage in the laboratory might indeed have been the manner in which CoV-2 acquired many of its devastating traits.

- "Although the **evidence shows that SARS-CoV-2 is not a purposefully manipulated virus**, it is currently impossible to prove or disprove the other theories of its origin described here. However, **since we observed all notable SARS-CoV-2 features, including the optimized RBD and polybasic cleavage site, in related coronaviruses in nature, we do not believe that any type of laboratory-based scenario is plausible**." [emphasis added.]

    - This author could identify no prior evidence in the paper to warrant saying it is not a purposefully manipulated virus. There is also no evidence that would point to a purposely manipulated virus.

    - The evidence in the paper shows that no prior zoonotic interspecies transmission has ever had an RBD as optimized as the CoV-2 RBD for the human ACE2. The evidence also shows that there is no natural source for the polybasic cleavage site (PCS). No other member of the subgenera to which CoV-2 belongs has a PCS. Since these are the only coronaviruses from which recombination could supply a polybasic cleavage site, the data in this paper refutes the natural origin.

[56] https://onlinelibrary.wiley.com/doi/full/10.1002/bies.202000091

- The belief statement concerning a laboratory-based scenario would be closer to the evidence if it was professed with, "despite evidence which is consistent with a laboratory-based scenario."

Based on the author's analysis of the paper, the following email was sent to the lead author:

Gmail Steven Quay, MD, PhD [redacted]

SARS-CoV-2 origin

[redacted]

Steven Quay, MD, PhD [redacted] Mon, May 25, 2020 at 7:14 PM
To: [redacted]

Dr. Andersen-

I read with interest your paper titled, The proximal origin of SARS-CoV-2, in which you conclude this is a natural, zoonotic-sourced infection. Three different approaches of analysis that I have done do not support this conclusion. Can you comment please:

1. The furin cleavage site insert has the unusual codon usage for the RR dimer of CGG-CGG. As you probably know, the frequency of this codon usage in the SARS-CoV-2 genome is 0.09. So having two next to each other is not likely as a random event. As support for the unlikeliness of these codons, using GISAID data, by March there is evidence of the third G being mutated out for either A or T at three-times the rate of the background mutation rate, 26/year from Nextstrain.org. Since codon usage in coronaviruses are not greatly influenced by the host it resides in, this means a jump to humans must have been in a host which did not have even a few months history with the virus, otherwise the terminal G would have been purified out. On the other hand, most laboratory use optimized codon primers and kits use CGG routinely; including in primers in published papers from the Wuhan Institute of Virology. So a laboratory source for a gain-of-function furin cleavage site would probably use these codons.

2. In the over 16,000 genomes in GISAID there is not one example of posterior diversity. With MERS, 93% of sequenced genomes did not pass through the index case but represented separate reservoir host to human jumps and this was apparent within 60 days of the index case. They collectively showed the most recent common ancestors among themselves was over 12 months before the index case. With SARS-CoV-2 it is acting like a 'pure culture' growth from the index case outward with no evidence of a reservoir host in the background. This would be the case for a laboratory acquired infection.

3. If you use a map of Wuhan and overlay the first four hospitals that saw cases with a map of the Metro system, you see that the hospitals straddle Line 2, which runs approximately east to west, carries 1,000,000 people a day, and is the Metro line with stops closest to both the Wuhan Institute of Virology and the original wet market that was considered an early source for the infection. There are 11 Metro lines in Wuhan, hundreds of stops on those lines, and over a dozen hospitals spread out over the city. I am working with a UCLA statistician to perform tests about the probability of this being simply an accident of statistics but the gestalt is, it does not look like a chance occurrence. But it is consistent with someone getting infected in the lab, riding Line 2 for a few days, and off you go.

It might be a truism to say that the six proven cases of laboratory derived SARS escapes occurred in big cities, Beijing, Singapore, or Taipei where the labs are located. But if you follow it with the fact that MERS and SARS, both proven as true zoonotic sources, on other hand began in rural settings in China and the Middle East, respectively. I am not sure why this obvious correlation was not at least pointed out in your paper and then addressed with a cogent argument.

I look forward to hearing your thoughts.

Regards, Steve

Soon after this email was written Dr. Andersen blocked the author from following his Twitter account. A reply to the above email was never received.

Conclusion. Three high visibility papers were published between January and May 202 which purported to settle the question of the origin of SARS-CoV-2 as a zoonotic transmission and not a laboratory accident. The analysis above concludes that these papers are not persuasive. The author has elected to not use evidence within these papers to change the prior likelihood of a

zoonotic versus laboratory origin. They are presented here as neutral evidence that supports neither theory.

Likelihood from initial state is unchanged following this evidence analysis:

Zoonotic origin (98.8%) and laboratory origin (1.2%)

Evidence. SARS-like infections among employees of the Wuhan Institute of Virology in the fall of 2019

The State Department of the United States issued the following statement on January 15, 2021[57]:

"1. Illnesses inside the Wuhan Institute of Virology (WIV):

- The U.S. government has reason to believe that several researchers inside the WIV became sick in autumn 2019, before the first identified case of the outbreak, with symptoms consistent with both COVID-19 and common seasonal illnesses. This raises questions about the credibility of WIV senior researcher Shi Zhengli's public claim that there was "zero infection" among the WIV's staff and students of SARS-CoV-2 or SARS-related viruses."

There is no additional evidence to support either parties position in the above statement. The U.S. Government statement would be considered hearsay in a court of law and probably not admissible. The veracity of Dr. Shi's statement above could be called into question due to other inconsistencies in some of her testimony, as reported elsewhere in this document.

At this time, the above evidence cannot be used to change the likelihood of either theory about the origin of SARS-CoV-2. The statement is kept within this analysis with the hope that in the future new information will come to light that could make this evidence a useful addition to the overall analysis.

Likelihood from initial state is unchanged following this evidence analysis:

Zoonotic origin (98.8%) and laboratory origin (1.2%)

[57] https://2017-2021.state.gov/fact-sheet-activity-at-the-wuhan-institute-of-virology//index.html

Evidence. A Bayesian Analysis of one aspect of the SARS-CoV-2 origin, where the first recorded outbreak occurred, increases the probability of a laboratory origin.

Introduction. The two competing hypotheses of the origin of SARS-CoV-2 as a natural, zoonotic spillover event versus a laboratory-acquired infection (LAI) or other laboratory accident each had supporting evidence from the very beginning of the pandemic.

On the one hand, about 40% of early patients with COVID-19 had an association with the Hunan Seafood Market in Wuhan. Since this mirrored SARS-CoV-1, where markets selling civet cats were determined to be the origin of that human epidemic, the natural origin hypothesis seemed logical. The Chinese CDC have now ruled out the market as a source for the outbreak.

On the other hand, the laboratory origin hypothesis also had an early beginning with the fact that the outbreak began adjacent to the only high security, BSL-4 laboratory in all of China, and one of the top coronavirus research centers in the world, was the Wuhan Institute of Virology (WIV). The hospitals of the first COVID patients were very close to the WIV.

This evidence statement is taken from an article applying a Bayesian analysis to the hypothesis that the proximal origin of SARS-CoV-2 was an uncontrolled[58] release from a laboratory using, as evidence, one aspect of the SARS-CoV-2 origin story — where the first recorded outbreak occurred.[59]

Hypothesis: The first recorded outbreak of SARS-CoV-2 in the human population occurred in a city that is also home to a virology laboratory that actively performs research on closely related viruses.

In this case, the city is Wuhan, and the virology laboratory is run by the Wuhan Institute of Virology.

Analysis. This analysis set the likelihood of a laboratory escape (the prior probability the hypothesis was true) at three values, 0.01%, 0.1%, and 1.0%. The second term was the conditional probability of the evidence, given that the hypothesis is actually false. This was set at 0.01. Finally, the third term was the conditional probability of the evidence, given the hypothesis is true. This was set, biasing to the natural origin, at 0.71.

Results. The paper provides the three-by-three cube of results for the three parameters of interest.

The ardent sceptic's probability begins at 0.01% and the revised estimate is no more than 0.05% or 5/10000. It applies to someone who was initially very skeptical about a lab origin (0.01% probability), who believes there is no more than 51% chance that an uncontrolled release of a highly contagious disease would lead to a local outbreak, and who thinks there was at least a

[58] By using the term uncontrolled release, the author was specifically excluding from consideration the possibility that the pathogen was deliberately released from the laboratory.
[59] https://jonseymour.medium.com/a-bayesian-analysis-of-one-aspect-of-the-sars-cov-2-origin-story-where-the-first-recorded-1fbdcbea0a2b

10% chance that a natural outbreak of a virus native to Yunnan would have occurred in Wuhan before any place else.

On the other extreme, is the ardent believer who started with at least a 1% belief in a laboratory outbreak, is 100% certain that an uncontrolled laboratory release would result in a local outbreak and believes that the probability that a natural outbreak of a virus native to Yunnan would occur in Wuhan before any place else is less than 0.1%. The ardent believer's revised belief is that the probability that the Wuhan outbreak was caused by an uncontrolled laboratory release changes from 1% to at least 91%.

In the center, is the so-called "central" observer who accepts that the central values for each of the parameter ranges are reasonable estimates of the true values of the probability being estimated. The central observer started with an initially skeptical belief in the hypothesis of 0.1%, believes that average citizen in Wuhan was a likely as any other citizen of China to be the initial vector of the virus into the human population and believes that there is no more or less than a 71% chance that an uncontrolled release from a laboratory of a highly contagious pathogen such as SARS-CoV-2 would result in a local outbreak as opposed to an outbreak in some other location. The central observer's revised belief in the hypothesis is 6.8%. If the central observer began with a 1% belief in a laboratory origin, this analysis would change that to 41.8%.

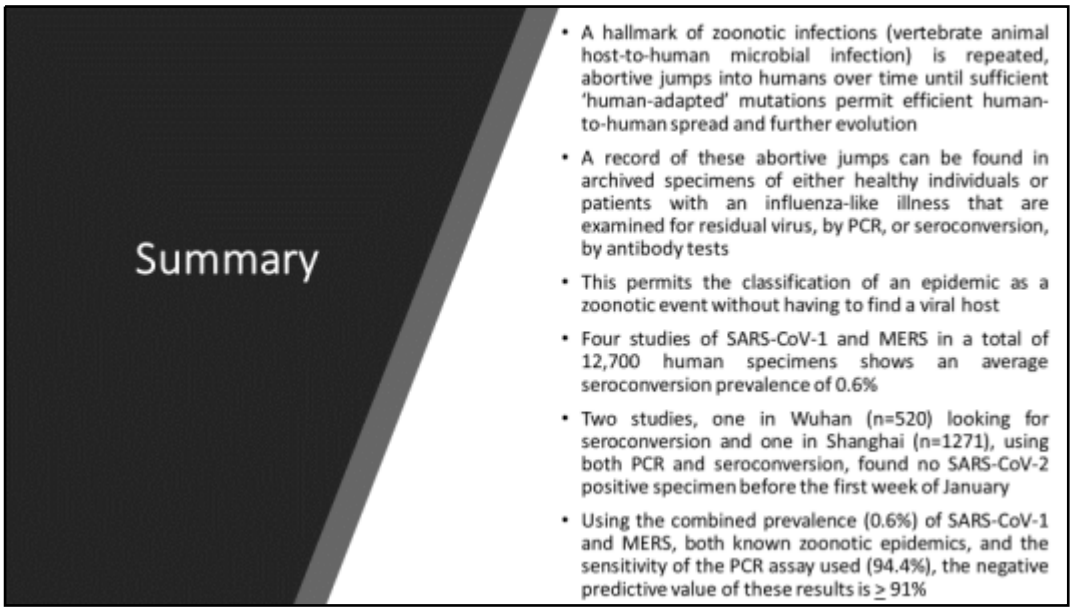
Conclusion. For purposes of this analysis and to be as conservative as possible, the assumptions will be that there is at least a 1% prior belief in a laboratory outbreak (because that was our starting probabilities), but there is no more than a 51% chance that an uncontrolled release of a highly contagious disease would lead to a local outbreak, and that there was at least a 10% chance that a natural outbreak of a virus native to Yunnan would have occurred in Wuhan before any place else. Using these assumptions, the initial likelihood of a 1% laboratory origin changes to 4.9%.

Starting likelihood from initial state: Zoonotic origin (98.8%) and laboratory origin (1.2%)

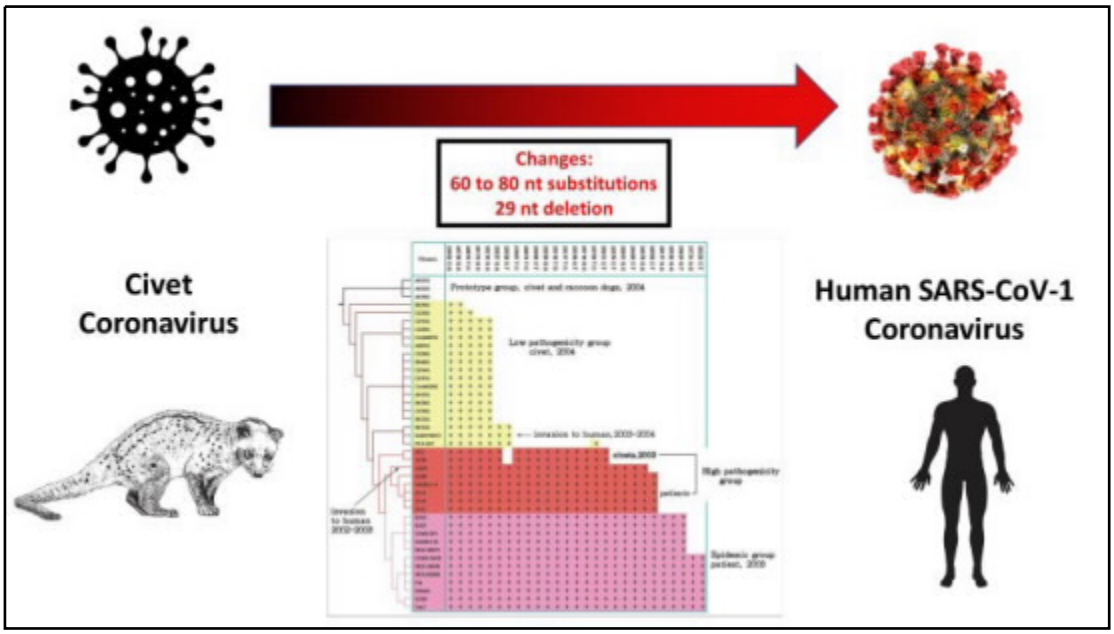
Adjusted likelihood: Zoonotic origin (95.1%) and laboratory origin (4.9%)

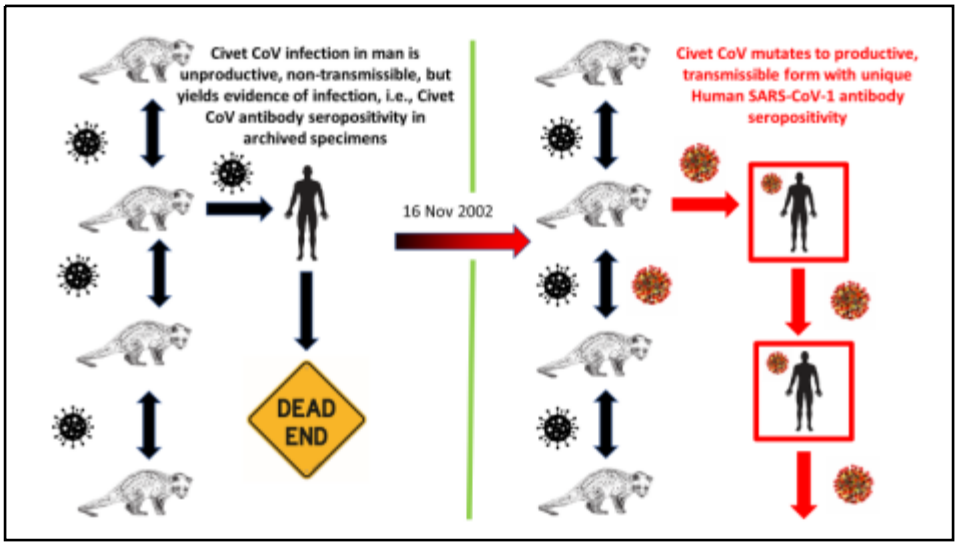
Evidence: Lack of seroconversion in Wuhan and Shanghai. Summary of evidence:

- A hallmark of zoonotic infections (vertebrate animal host-to-human microbial infection) is repeated, abortive jumps into humans over time until sufficient 'human-adapted' mutations permit efficient human-to-human spread and further evolution

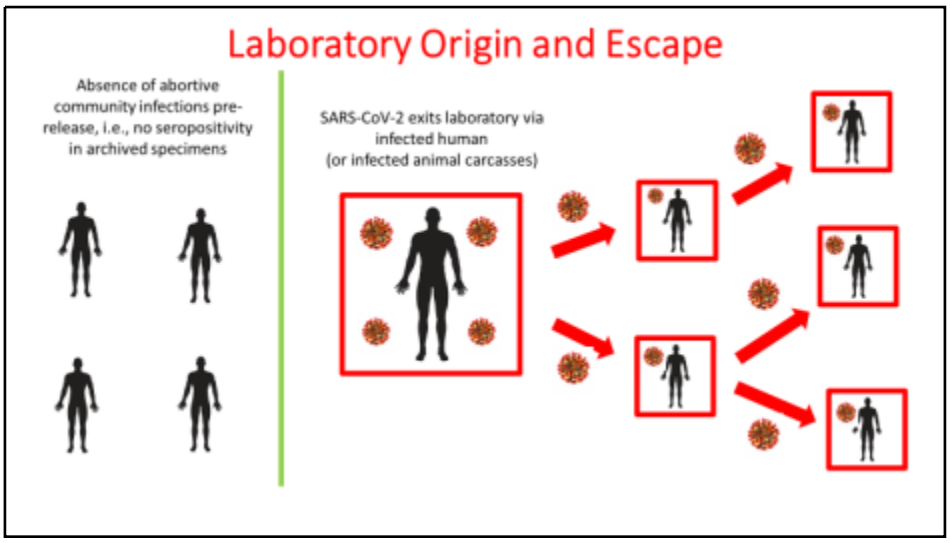


- A record of these abortive jumps can be found in archived specimens of either healthy individuals or patients with an influenza-like illness that are examined for residual virus, by PCR, or seroconversion, by antibody tests





- This permits the classification of an epidemic as a zoonotic event without having to find a viral host
- A laboratory accident is a situation in which there are no prior exposures within the human population as shown in the Figure below:



- Four studies of SARS-CoV-1 and MERS in a total of 12,700 human specimens shows an average seroconversion prevalence of 0.6%

SARS-related Virus Predating SARS Outbreak, Hong Kong

SARS-CoV-1 began in fall of 2002 in southern China

Patient Population	Serum samples collected in May 2001 from 938 healthy adults in Hong Kong	48 confirmed SARS patients diagnosed in February and March 2003 in Guangdong
Civet CoV > SARS-CoV-1 Seropositivity	13	0
SARS-CoV-1 > Civet CoV Seropositivity	4	48
Total	17 out of 938 = 1.8%	48 out of 48 = 100%

Pre-epidemic seroprevalence in the adult community

Prevalence is 0.6% for SARS-CoV-1 and MERS in 12,700 specimens

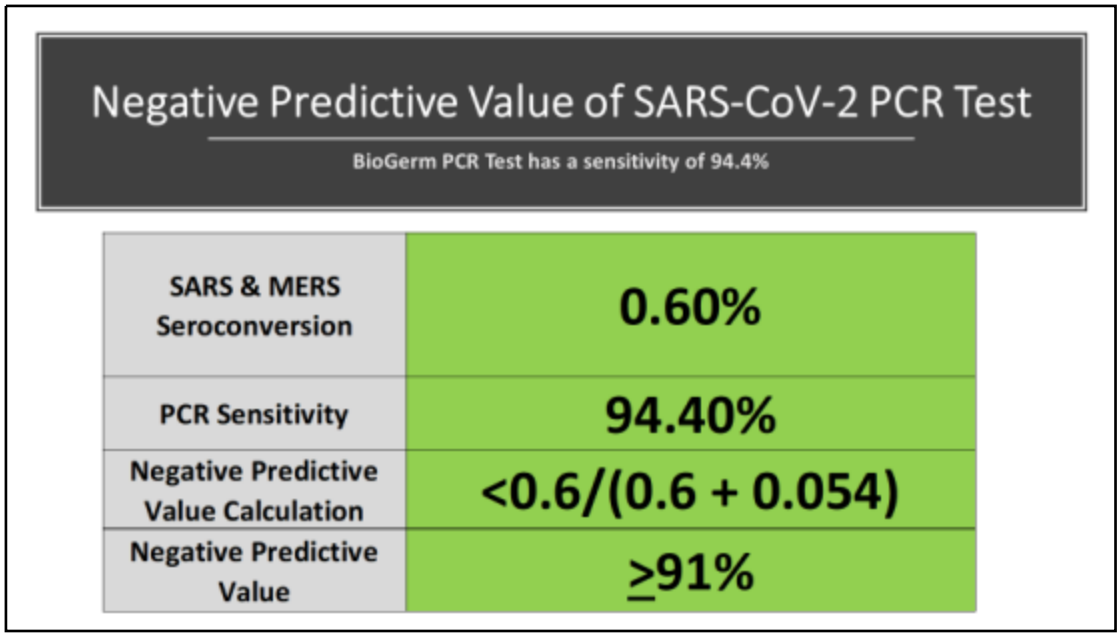
	CoV-2 Studies Combined	**0/1791**	**Probability is one in 14,881**

- Using the combined prevalence (0.6%) of SARS-CoV-1 and MERS, both known zoonotic epidemics, and the sensitivity of the PCR assay used (94.4%), the negative predictive value of these results is $\geq$ 91%



Here, the negative predictive value (NPV) represents the probability that a CoV-2 is not a zoonosis, given the negative seroconversion findings.

Subjective Discount Factor: 90% (a one in 10 chance this is wrong). This is a subjective value.

The change in origin likelihoods from this evidence and the calculations are shown in the Text-Table below.

Evidence or process	Zoonotic Origin (ZO)	Laboratory Origin
Starting likelihood	0.951	0.049
Negative predictive value of lack of seroconversion	0.91	
Reduced by 90% Subjective Discount Factor	0.91 x 0.9 = 0.82	
Impact of this evidence	Reduces the likelihood of ZO by 82/18 or 4.6-fold. For every 100 tests, a true ZO would be seen 18 times and a non-ZO would be seen 82 times	
Impact of evidence calculation	0.951/4.6 = 0.207	
Normalize this step of analysis	0.207/(0.207 + 0.049) = 0.809	0.049/(0.207 + 0.049) = 0.191

Adjusted likelihood: Zoonotic origin (80.9%) and laboratory origin (19.1%)

Evidence: Lack of posterior diversity for SARS-CoV-2 compared to MERS and SARS-CoV-1

- The earliest stages of human CoV-1 and MERS infections were characterized by viral genome base diversity as expected for multiple, independent jumps from a large and diverse intermediate host population into humans.
- Combining MERS and CoV-1 studies, out of the earliest 255 human infections in which virus genome sequences are available, 137 could not be rooted in a prior human-to-human infection and so are attributed to an independent intermediate host-to-human infection.[60]
- That is about 54% non-human-to-human transmission.
- On the other hand, Ralph Baric has written[61] that CoV-2 is different: "SARS-CoV-2 probably emerged from bats, and early strains identified in Wuhan, China, showed limited genetic diversity, which suggests that the virus **may have been introduced from a single source**." [emphasis added.]
- With CoV-2, there are 249 viral genomes in GISAID from Hubei province, where Wuhan is located, collected between Dec 24, 2019 and Mar 29, 2020.
- From Dec 24, 2019 to November 2020, there are 1001 genomes sequenced from all of China and 198,862 worldwide.
- For CoV-2, every single genome sequence is rooted in the first sequence from the PLA Hospital in Wuhan.
- Not one case of posterior diversity.
- Using the frequency of non-rooted genome diversity seen with MERS and CoV-1, about 50:50 or a coin toss, the probability that CoV-2 is a zoonotic pandemic with 0/249 genomes is the chance of tossing a coin 249 times and getting heads every time!
- Mathematically that is nonexistent; specifically, one in 10 with 84 zeros.
- Since Wuhan had approximately 500,000 cases during the time interval of this sampling, the potential sampling error of testing only 249/500,000 or 0.05% is significant. This sampling error, while large, is unable to obliterate the overwhelming odds that this did not arise from an intermediate host in Wuhan.
- Therefore, to permit continued evidence analysis, this finding will be set at the boundary of customary statistical significance, a p-value of 0.05 or a 1 in 20 likelihood that this is zoonotic.

Detailed explanation

[60] https://elifesciences.org/articles/31257#abstract ; https://www.researchgate.net/publication/225726653_Molecular_phylogeny_of_coronaviruses_including_human_SARS-CoV ; https://science.sciencemag.org/content/300/5624/1394/tab-pdf ; https://pubmed.ncbi.nlm.nih.gov/14585636/ ; https://www.microbiologyresearch.org/content/journal/jgv/10.1099/vir.0.016378-0?crawler=true ; https://www.ncbi.nlm.nih.gov/pmc/articles/PMC7118731/

[61] https://www.nejm.org/doi/10.1056/NEJMcibr2032888

A fundamental difference between a laboratory and a non-laboratory acquired zoonotic disease, the imprint of phylogenetic diversity through pre-human spread within the source population, can be examined by the posterior diversity of human cases with no *a priori* knowledge of an intermediate host.

MERS. The MERS epidemic has been documented to have arisen from the initial jump from bats to camels, a three-to-five-year expansion within the camel population in which mutational diversity arose by random mistakes, and then a jump into humans. This model of spread predicts that there would, at some point, be additional jumps from other camels into other patients, and a pattern of "posterior diversity," would be found in the human specimens. If the COVID-19 pandemic arose by a similar mechanism the same pattern would be seen. The following Text-Table contains such data.

Phylogenetic Feature	MERS	SARS-CoV-2
Posteriority Diversity	28/30 (93%)	0
No Posteriority Diversity	2/30 (7%)	7666
Time from first patient to first example of posterior diversity	About 60 days	None at >120 days
Depth of posterior diversity to first patient	>365 days	None

The study of MERS noted above was published in 2013 in Lancet[62] in an article entitled, "Transmission and evolution of the Middle East respiratory syndrome coronavirus in Saudi Arabia: a descriptive genomic study." Thirty specimens were used in the analysis. The features of a camel-to-human zoonotic epidemic are easily identified. Specimens taken within sixty days of the first patient, "Patient Zero," began to show a background diversity that could not be traced back through Patient Zero. The analysis of all thirty, in fact, documented that 93% were transmitted directly from the camel intermediate reservoir. And looking only at the "background" diversity permitted a calculation of the last common ancestor for the spread within the camel population of over 365 days.

A study of SARS-CoV-2[63] available May 5, 2020 and entitled, "Emergence of genomic diversity and recurrent mutations in SARS-CoV-2," looked at 7666 patient specimens from around the world for phylogenetic diversity. The authors state: "There is a robust temporal signal in the data, captured by a statistically significant correlation between sampling dates and 'root-to-tip' distances for the 7666 SARS-CoV-2 ($R^2 = 0.20$, $p < .001$). Such positive association between sampling time and evolution is expected to arise in the presence of measurable evolution over the timeframe over which the genetic data was collected." This conclusion also argues against a MERS-like pattern of posterior diversity. In fact, the 95% upper bound for the probability of no posterior diversity being seen in SARS-CoV-2, given the data in MERS, is 3.9×10^{-4}.

[62] https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3898949/
[63] https://www.sciencedirect.com/science/article/pii/S1567134820301829

The finding of posterior diversity in MERS was seen quickly, that is, within 60 days of the first patient and in only 30 specimens. In this study of COVID-19 the cutoff date of the 7666 specimens was April 19, 2020 or approximately 140 days after the first documented case. The lack of posterior diversity in COVID-19 at a much later date than what was seen with MERS also argues against a non-laboratory source for this pandemic.

A useful avenue of future research for those working to find an animal source for COVID-19 would be new mathematical models or statistical methods that might find a "hidden" signal of posterior diversity in the current data set which shows none. And given access to the unprecedented quantity of human data for COVID-19 which can be mined via bioinformatics, efforts to find the "missing link" in the wild through search and sample should be a second priority to mining the human specimen data set.

SARS-CoV-1. A similar pattern of clinical cases that do not show a common ancestor in the human population but instead is evidence of posterior diversity is shown in the Text-Table on the left for SARS-CoV-1[64] compared to CoV-2 on the right[65]. SARS-CoV-1 shows clusters of cases in humans that are connected only by phylogenetic branches that reach back in time (all of the branches inside the purple box. This is because of the extensive mutational background created while being in the intermediate host, the civet. With CoV-2 on the right, every clinical case descends from the first clinical case, in the 19A clade. There are no background mutations to account for. I will show elsewhere that the first Clade A patient was at the PLA Hospital about 3 km from the WIV.

[65] https://nextstrain.org/

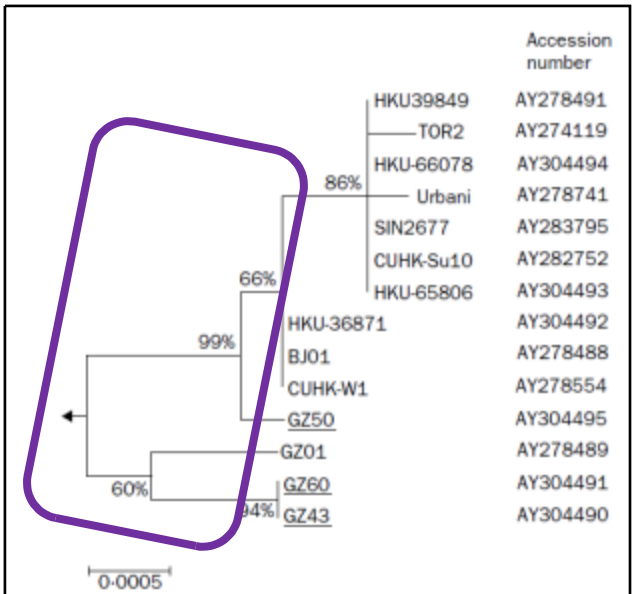

Figure 4: **Phylogenetic analysis of nucleotide acid sequence of spike gene of SARS CoV viruses**
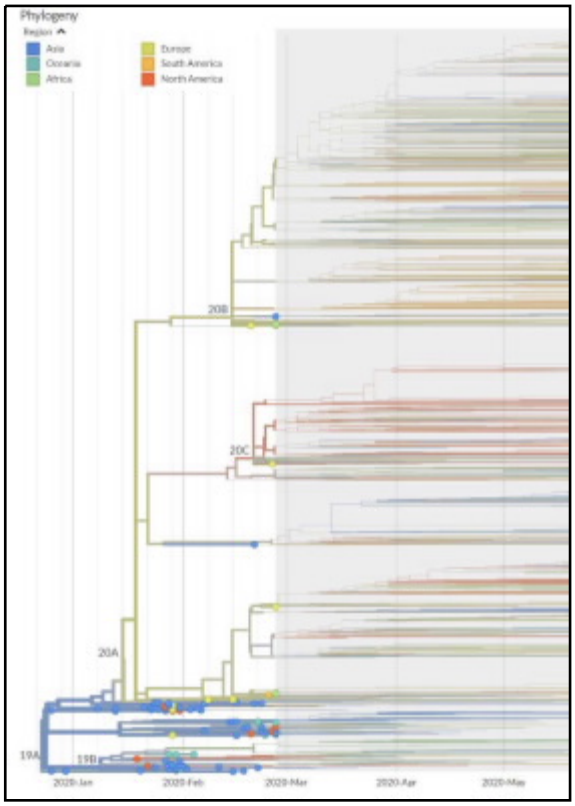
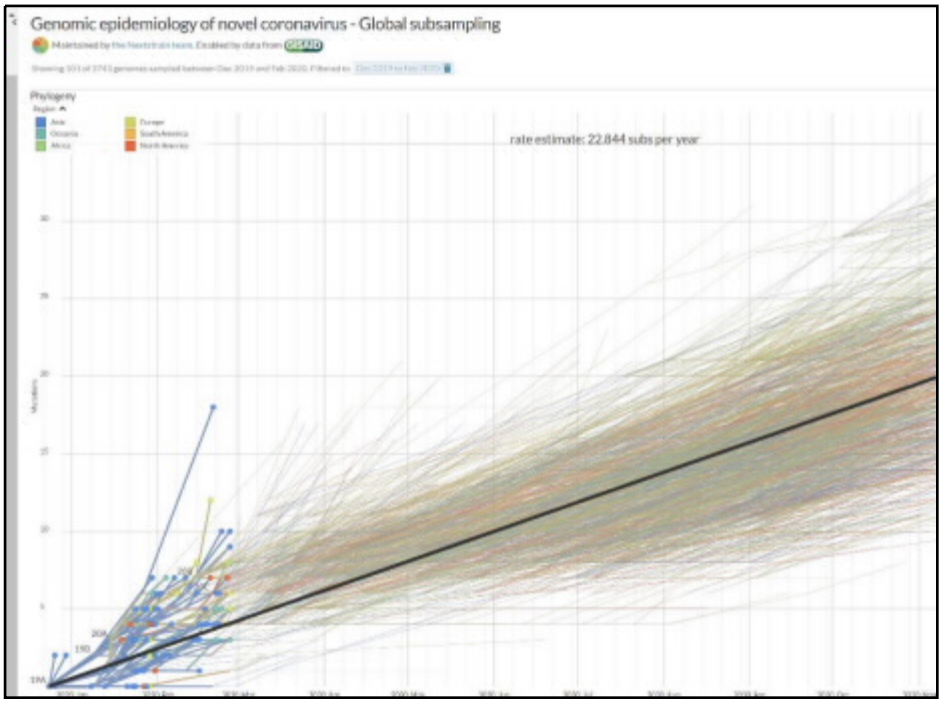
Bootstrap values are shown as a percentage. The scale bar shows genetic distance estimated using Kimura's two parameter substitution model.[14] The nucleotide sequences of representative SARS CoV S genes (S gene coding region residue, 3765 bp) were analysed. Viruses sequenced in this study are underlined, and the other sequences used in the analysis can be accessed in GenBank with accession numbers as shown.



Given the rate of mutations of 22.8 per year for CoV-2 as shown in the Nextstrain graph below and a sequencing accuracy of about two calls per genome, CoV-2 could not have spent more than a few weeks in an intermediate host before a pattern of background mutations would be identified as posterior diversity. In the laboratory a pure culture on a single genome is used and the CoV-2 pattern is most consistent with a single pure culture infection a first human.

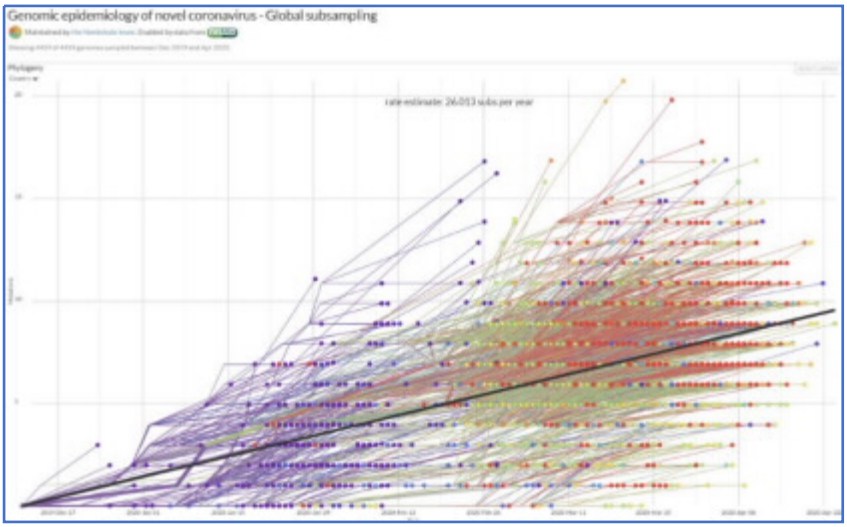


Non-zoonotic evolution. In a hypothetical in which there was a singular event in which one genetically pure virus infected one person and then the epidemic grow the development of the genetic diversity would have a clear, identifiable pattern: every new mutation would only appear on a background of the previous mutations.

The mutations in this virus are literally a personal tag. The general mutation rate leads to one mutation per patient. So, by definition, Patient Zero will have just one mutation. And then the 2-4 people that patient passes it to will have that mutation and then will add a new one, and so on. As time goes by two things happen: each patient gets a new mutation of their own and they pass on all the mutations of the past.

Since the virus has 29,900 nt and the mutation rate, as shown in this graph prepared by NextStrain is 26 mutations per year, there is very little chance a mutation will appear and then later get undone. By carefully going back in time, it is possible to literally name each person at each generation by the one (on average) new mutation they have and all of those that went before.

This graph of mutations on the Y-axis shows them gradually increasing and the color coding shows where they came from. In this infection, they only came from a previous patient and from the next previous patient and so on.



A NextStrain graphic.

How is that different from MERS, which was passed from camels to humans in a true zoonotic process?

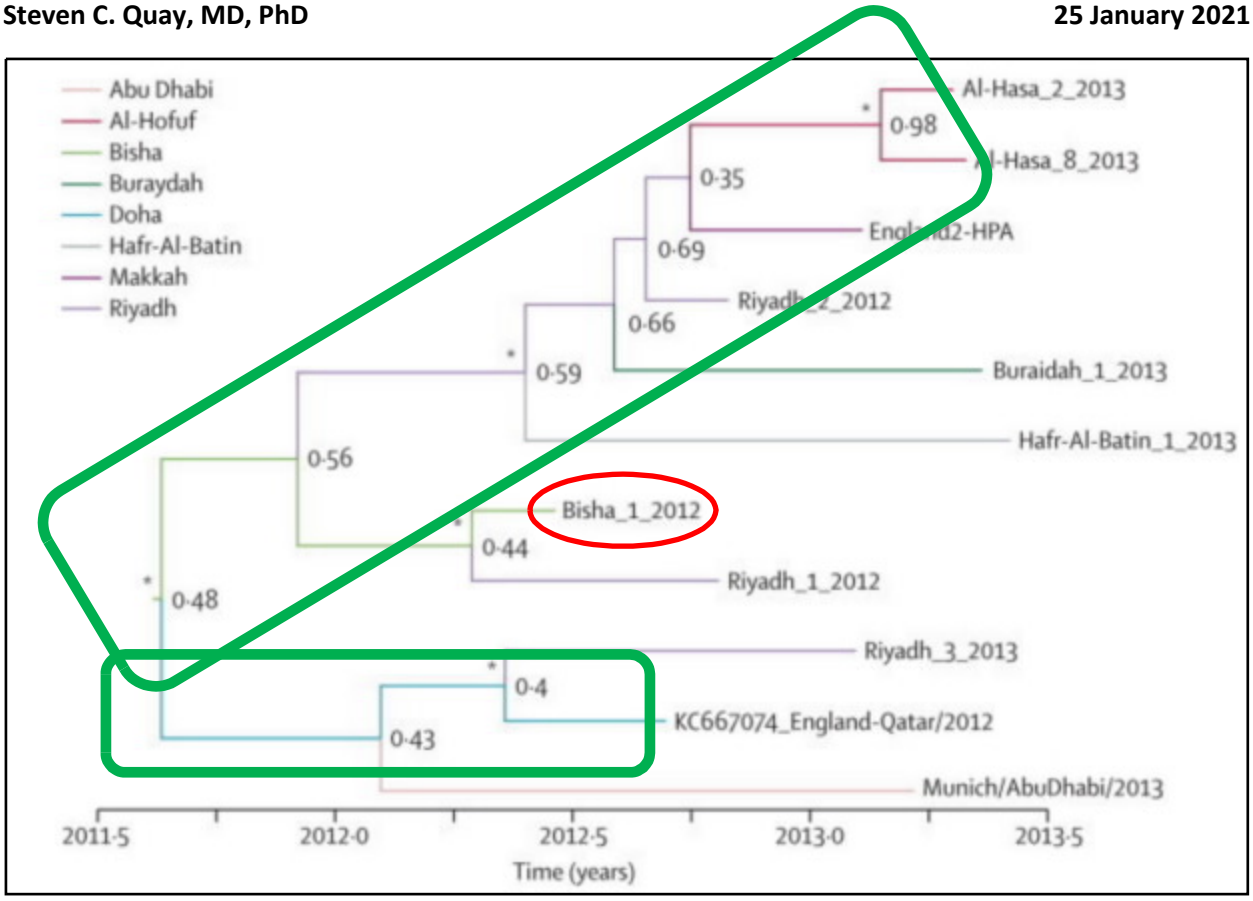
In a true zoonotic spread to humans there is usually an initiating species (in MERS it is bats), and then an intermediate species (in MERS it is camels), and then it moves to humans, either because of a new "enabling mutation" or for a non-domestic species, a chance encounter, and Source Zero and Patient Zero meet, and a cross species event occurs. But "Source Zero" doesn't stop there with one infection in one human; the virus also transmits itself vertically into the intermediate species. Source Zero also creates a vertical infection in the camels. Whether it is mild or not doesn't matter. The new human jumping gene is moving into a very diverse population of viruses, who have themselves been evolving since the first bat to camel transmission.

What is the outcome in terms of a test to show this is happening?

The diversity of the virus in humans becomes great, and the spots where the mutations occur don't match up to MERS Patient Zero like they do in COVID-19. In MERS, the virus in Patient Zero and the virus in a later infection are not direct descendants but cousins and only descended from an earlier virus that spent time in another camel population, collecting random mutations until it got the one it needed to infect humans, and then it begins again.

The chart below, from Lancet. 2013 Dec 14; 382(9909): 1993–2002, shows just how this works. The patient at Bisha is the earliest case in this chart (Patient Zero in the red circle). But notice, no other case comes from that patient. The viruses have such a diverse genetic background they appear to only be related to the Bisha virus with a posterior timeline of about one year. Their background is in the green boxes and it skips Patient Zero.

.



Even without knowing that camels are the zoonotic source for MERS, this data, from clinical sample only and without any field work in cave or camels, is all you need to know that this arose in the wild.

A paper just appeared with this analysis for a region of China and the posterior genomic diversity indicated a single starting point on December 1, 2019 for all cases. There was no posterior diversity. At this point with over 322,000 full genomes sequenced[66] and all showing an additive pattern of mutations and with none showing background diversity before the known appearance in Wuhan, the only conclusion is that there is no reservoir of genetic diversity.

On January 26, 2020 in an article in *Science* written by Jon Cohen, Kristian Andersen, an evolutionary biologist at the Scripps Research Institute who had analyzed sequences of CoV-2 to try to clarify its origin said: "The scenario of somebody being infected outside the market and then later bringing it to the market is one of the three scenarios we have considered that is still consistent with the data. It's entirely plausible given our current data and knowledge."

The negative predictive value of finding no posterior diversity in CoV-2 with 322,000 total infections sequenced, over 1000 in China, is 95%

Subjective Discount Factor: 95% (a one in 20 chance this is wrong)

[66] https://www.gisaid.org/

Below is the impact of the pack of posterior diversity on the likelihood of a zoonotic versus laboratory origin

Evidence or process	Zoonotic Origin (ZO)	Laboratory Origin
Starting likelihood	0.809	0.191
Negative predictive value of lack of posterior diversity	0.95	
Reduced by 95% Subjective Discount Factor	0.95 x 0.95 = 0.90	
Impact of this evidence	Reduces the likelihood of ZO by 90/10 or 9-fold. For every 100 tests, a true ZO would be seen 10 times and a non-ZO would be seen 90 times	
Impact of evidence calculation	0.809/9 = 0.085	
Normalize this step of analysis	0.085/(0.085 + 0.191) = 0.308	0.191/(0.085 + 0.191) = 0.692

Adjusted likelihood: Zoonotic origin (30.8%) and laboratory origin (69.2%)

Evidence: Opportunity.

The Wuhan Institute of Virology has publicly disclosed that by 2017 it had developed the techniques to collect novel coronaviruses, systematically modify the receptor binding domain to improve binding or alter zoonotic tropism and transmission, insert a furin site to permit human cell infection, make chimera and synthetic viruses, perform experiments in humanized mice, and optimize the ORF8 gene to increase human cell death (apoptosis).

Wuhan Institute of Virology scientists maps RBD and then takes a civet coronavirus that won't infect human cells, changes two amino acids in the receptor binding domain & it infects human cells.[67]

converting enzyme II (ACE2), replicate efficiently in primary human airway cells and achieve in vitro titers equivalent to epidemic strains of SARS-CoV.

- Additionally, in vivo experiments demonstrate replication of the chimeric virus in **mouse lung with notable pathogenesis.**

- Evaluation of available SARS-based immune-therapeutic and prophylactic modalities revealed poor efficacy; both monoclonal antibody and vaccine approaches failed to neutralize and protect from infection with CoVs using the novel spike protein.

- On the basis of these findings, we **synthetically re-derived an infectious full-length** SHC014 recombinant virus and demonstrate robust viral replication both in vitro and in vivo."

This study was conducted, with permission, during the gain of function moratorium put in place by NIH in 2014:

"These studies were initiated before the US Government Deliberative Process Research Funding Pause on Selected Gain-of-Function Research Involving Influenza, MERS and SARS Viruses (http://www.phe.gov/s3/dualuse/Documents/gain-of-function.pdf). This paper has been reviewed by the funding agency, the NIH. Continuation of these studies was requested, and this has been approved by the NIH."

Drs. Daszak and Shi becomes world's expert on ORF8 induced apoptosis by CoVs in human cells (HeLa) & maximizing lethality.[70]

> The full-length ORF8 protein of SARS-CoV is a luminal endoplasmic reticulum (ER) membrane-associated protein that induces the activation of ATF6, an ER stress-regulated transcription factor that activates the transcription of ER chaperones involved in protein folding [35]. We amplified the ORF8 genes of Rf1, Rf4092 and WIV1, which represent three different genotypes of bat SARSr-CoV ORF8 (S3C Fig), and constructed the expression plasmids. All of the three ORF8 proteins transiently expressed in HeLa cells can stimulate the ATF6-dependent transcription. Among them, the WIV1 ORF8, which is highly divergent from the SARS-CoV ORF8, exhibited the strongest activation. The results indicate that the variants of bat SARSr-CoV ORF8 proteins may play a role in modulating ER stress by activating the ATF6 pathway. In addition, the ORF8a protein of SARS-CoV from the later phase has been demonstrated to induce apoptosis [28]. In this study, we have found that the ORF8a protein of the newly identified SARSr-CoV Rs4084, which contained an 8-aa insertion compared with the SARS-CoV ORF8a, significantly triggered apoptosis in 293T cells as well.

This paper also demonstrates the collection of 64 novel bat coronaviruses from caves in southern China, including Yunnan where Dr. Shi has said is the location of the bat ancestor of CoV-2.

This evidence is necessary for a laboratory origin hypothesis in which genetic manipulation to create CoV-2 is a precursor to a laboratory accident. However, it does not per se, provide

[70] https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5708621/

increased weight in favor of a laboratory origin. It is however provided here to be a guide for the kinds of investigations to be conducted if access to the WIV records is ever provided.

Likelihood from prior state is unchanged following this evidence analysis:

Zoonotic origin (30.8%) and laboratory origin (69.2%)

Evidence and Motive for laboratory furin site insertion:

A key to infectivity of coronaviruses is the addition, in nature or the laboratory, of a furin cleavage site (FCS) at the S1/S2 junction of the Spike Protein.

Furin cleavage sites (FCS) have been widely understood to be important for many viral infections, including HIV, influenza, and others. It has also been widely understood before now that lineage B coronaviruses do not have FCS.

It was therefore surprising when an examination of SARS-CoV-2 Spike Protein found an insertion of a 12-nt, 4-AA sequence near the junction of the S1/S2 subunits which creates a furin site that is essential to human infectivity and transmission. As expected from previous work, no lineage B (sarbecovirus) coronavirus has this feature. This is the most difficult "molecular fingerprint" of SARS-CoV-2 to explain having been acquired in the wild and for that reason there are no even passingly feasible theories.

One database of whole genome sequences of 386 coronaviruses was devoid of furin cleavage sites.[71] Another database of 2956 genomes of sarbecovirus strains sequences shows that none have a furin site.[72] This is a highly significant finding with a probability that sarbecovirus has a furin site in the wild of one in about 985.[73]

It has been known since 1994 that viral glycoproteins can be cleaved by secreted proteases, including furin.[74] Even before that, in 1992, it was known the peptide sequence R-X-K/R-R in surface glycoproteins was required for avian influenza viruses of Serotype H7 pathogenesis.[75] The first paper using furin inhibitors to define a role for an FCS in coronavirus-cell fusion was published in 2004.[76]

Since that time, it has become common practice to insert FCS during laboratory gain-of-function experiments to increase infectivity. The following Text-Table illustrates the scope of just a few of the experiments conducted, with the hyperlink to the paper in column one.

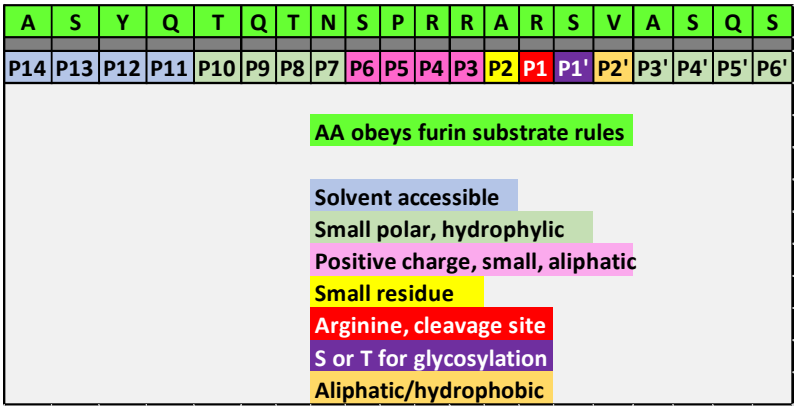
The creation in the wild of a coronavirus FCS that is used as an example of what might have happened in SARS-CoV-2 is uninformative. In this case, a strain of influenza, in which a new polybasic site appears spontaneously leads to increased infectivity and lethality,[77] was reported by Tse *et al*. 2014. The mechanism of the FCS acquisition in this paper is an RNA polymerase dependent stuttering at a small, constrained loop in which one or more A nt were inserted, removing the strain in the loop and inserting an AAA codon which represents the basic amino acid lysine. No such method exists for the insertion of arginine, the amino acid in the CoV-2 furin site that needs to be created.

The insert generates a canonical 20 AA furin site sequence. In 2011 Tian et al.[78] published an analysis of 126 furin cleavage sites from three species: mammals, bacteria and viruses. The analysis showed that when the furin sites are recorded as a 20-residue motif, a canonical structure emerges. It includes one core cationic region (eight amino acids, P6–P2′) and two flanking solvent accessible regions (eight amino acids, P7–P14, and four amino acids, P3′–P6′).

[77] https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3911587/
[78] https://www.nature.com/articles/srep00261



This figure above shows the 20-AA of the furin motif in SARS-CoV-2 (in green) with the P14 to P6' AA positions marked with the cleavage site being the amide bond between P1-R and the P1' residue. The motif is color coded with the requirements (in most cases, except for the positively charged AA requirements, most position requirements can be relaxed).

With the insertion, all 20 residues obey the rules as established by Tian. Since there are 20^4 different 4-AA peptides or 160,000 choices, it is remarkable that the 4 AA insert created a sequence that contained a small or cationic AA (8 AA/20 qualify), a cationic AA (3/20), another cationic AA (3/20), and a small AA (5/20) in that order. In fact, there are only 360 or the total or about 0.2% of all four amino acid inserts that would be expected to follow the exact rules for furin substrates. Of course, given the increase in infectivity SARS-CoV-2 has over other coronaviruses that do not have a well-designed furin cleavage site, selection pressure would drive this rare mutational event once it happened randomly. It would also be a likely choice for a laboratory designed furin cleavage site created *de novo*.

Based on the evidence that there are no furin cleavage sites in 2956 sarbecovirus (beta coronavirus) genome sequences[79], the likelihood that CoV-2 acquired the furin site from a wild sarbecovirus is one in 985 or 0.001. Because this is highly significant, we will use the conservative rule established in the beginning and use a likelihood of 0.05 for this evidence.

Subjective Discount Factor. 95% confidence (only a one in 20 chance this is wrong). Below is the calculation of the Bayesian adjustment.

Evidence or process	Zoonotic Origin (ZO)	Laboratory Origin
Starting likelihood	0.308	0.692
Negative predictive value of a lack of furin sites in sarbecovirus genomes	0.95	
Reduced by 95% Subjective Discount Factor	0.95 x 0.95 = 0.90	
Impact of this evidence	Reduces the likelihood of ZO by 90/10 or 9-fold. For every 100 tests, a true ZO would be seen 10 times and a non-ZO would be seen 90 times	
Impact of evidence calculation	0.308/9 = 0.034	
Normalize this step of analysis	0.034/(0.034 + 0.692) = 0.047	0.692/(0.692 + 0.034) = 0.953

Adjusted likelihood. Zoonotic origin (4.7%), laboratory origin (95.3%).

[79] https://academic.oup.com/database/advance-article/doi/10.1093/database/baaa070/5909701

Evidence: Codon usage can distinguish insertion events in the wild from those created in the laboratory.

Not only is the insertion of an FCS peptide unique among lineage B coronaviruses, the nt sequence used for the process is more broadly unique among coronaviruses in general, regardless of lineage:

-CCT-**CGG-CGG**-GCA-

I will now use synonymous codon bias methods to try to inform the question of the origin of SARS-CoV-2.

Because of the redundancy of the genetic code, more than one 3-nt sequence specifies any given amino acid. For example, there are six codons that specify arginine, R. The frequencies with which such synonymous codons are used are unequal and have coevolved with the cell's translation machinery to avoid excessive use of suboptimal codons that often correspond to rare or otherwise disadvantaged tRNAs. This results in a phenomenon termed "synonymous codon bias," which varies greatly between evolutionarily distant species and possibly even between different tissues in the same species.

Decades of research has identified that all life forms, viruses, bacteria, and humans alike, use the codons in a signature pattern of frequency which can be used to identify a particular sequence of RNA or DNA as human or non-human; viral or non-viral.

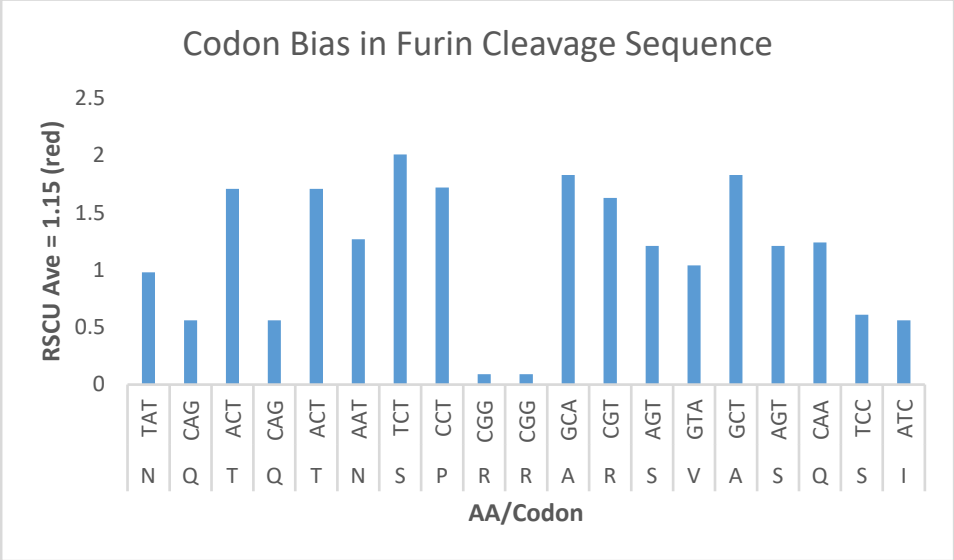
In this way, viruses in nature and scientists in the laboratory, with different goals and motivations, make distinguishing codon usage decisions which can sometimes provide a fingerprint of their source.

The Text-Table below contains the arginine codon usage for two populations, pooled data for SARS-CoV 2003 and related viruses and 13 Sars-CoV-2 human specimens from widely dispersed locations.

Codon	SARS-CoV 2003 and ten other evolutionary related viruses in the Nidovirales	SARS-CoV-2 from 13 Geo-locations
CGG	0.09	0.09
CGA	0.44	0.37
CGC	0.72	0.37
AGG	0.9	1.07
CGU	1.77	1.63
AGA	2.08	2.48

Since these values are of a type of multiplicative scale, they were fit using a log-normal distribution, which appears appropriate (although the sample size is small). Using the log mean and standard deviation and this distribution, the probability of finding a CGG codon is about 0.024. Assuming they are independent the probability of finding a CCG-CCG codon pair is effectively 0.024^2 or 0.00058. This is a likelihood of about one in 1700.

The following Figure shows the RSCU for the amino acids that comprise the new furin cleavage site in SARS-CoV-2. As one can see, the RSCU values are similar to each other with the exception of the RR dimer insert, which have a very low RSCU of 0.09.



The RSCU value for the CGG codon for R of 0.09 was taken from a 2004 paper of the RSCU for SARS-CoV 2003 and ten other evolutionary related viruses in the *Nidovirales* and is confirmed by 13 SARS-CoV-2 specimens obtained from diverse geographic locations. If one assumes that the RSCU observations are independent and that the probability distribution of these measurements is Gaussian (normal; a reasonable assumption), then one can calculate the probability of obtaining a result as small as 0.09. Removing the two 0.09 values, then the mean and standard deviation of the remaining values are 1.275 and 0.4992, respectively. Then the probability of a single 0.09 value is 0.0088. However, there are two 0.09 values. If we assume that these are independent findings, then the probability of both values being seen is 0.0088^2 or 7.7×10^{-5}. Using the RSCU of 0.2 from the Table above does not change the immense improbability of the usage of a CGGCGG codon pair in the wild.

Single Arginine CGG codon usage analysis suggests this will not be found in the wild.

The codon usage for SARS-CoV-2, like most coronaviruses studied, has a bias toward AT and away from GC nucleotides. The frequency of third position G use in CoV-2, for example, is 13%, 21%, 17%, and 16% for the spike protein, envelope, membrane, and nucleocapsid protein, respectively.

In that context, the scarcity of the CGG genome in SARS-CoV-2 and related coronaviruses, the relative synonymous codon usage, determined by the method of Behura and Severson,[80] was calculated and tabulated below. The color coding is blue for underutilized codons (RSCU < 1.0) and red for overutilized codons (RSCU > 1.0); light blue for RSCU values of 0.60 to 0.99 and

[80] https://www.ncbi.nlm.nih.gov/pubmed/22889422

light red for RSCU of 1.01 to 1.60. The highest RSCU usage of CGG is 1.21 in the membrane protein in the MERS virus but zero in SARS-CoV-2.

RSCU	SARS-CoV-2	Beta CoV Pangolin	SARS CoV	Bat SARS CoV	MERS CoV
Spike	0.29	0	0.19	0.08	0.25
Envelope	0	0	0	0	0
Membrane	0	0.35	0.74	0.24	1.21
Nucleocapsid	0.41	0.16	0.03	0.04	0.8

Looking at these five coronaviruses:

The largest structural protein of the coronaviruses is the spike protein, with 1273 amino acids. In SARS-CoV-2 there are 42 R residues, with only one RR dimer, the one in the insert that created SARS-CoV-2.

As a reminder none of these related coronaviruses have the 12-nucleotide insertion that forms the putative furin site in CoV-2. Interestingly, the pangolin coronavirus has no CGG residues in the spike protein. The significance of this is it makes the acquisition of this insert from pangolin by recombination impossible.

The smallest structural protein, the envelope protein, has 75 amino acids, including three R residues, but has no CGG codons in any of the related coronaviruses examined.

The SARS-CoV-2 membrane protein has 441 amino acids, 14 R residues and no CGG codons. Among related coronaviruses, this is the most unique finding of the four proteins for SARS-CoV-2 since the other four coronaviruses all utilize CGG to some extent in this protein. In the case of the MERS virus, this protein is the only occurrence in which this codon is overutilized.

The nucleocapsid protein has 418 amino acids and is responsible for packing the RNA genome. As expected for the role of R in protein-RNA interactions, it has 29 R residues and four RR dimers. None of the dimers use the CGGCGG sequence.

The nt usage of the 12-nt insert which forms the FCS cleavage site has a probability this sequence was selected for in the wild of one in 129,870.

A blast search was performed for the 12-nt inserted sequence and adjacent extensions and only the SARS-CoV-2 sequences were identified.

Shortening the search to just the two CGG-CGG codons was only slightly more fruitful. The Text-Table below shows the frequency of the middle half of the insert, CGGCGG, across the genomes of all seven known human coronaviruses, as well as a specimen bovine coronavirus and the bat and pangolin coronaviruses with greatest homology to SARS-CoV-2. Only a single example, outside of the Spike Protein gene, has been found.

* - Includes both in phase codons as well as out of phase, frameshift codons.					

To understand what this means for the search for the zoonotic source for SARS-CoV-2, a statistical approach was taken. Using the data from the nine viruses other than SARS-COV-2 there was a single incidence of the CGGCGG found in the bat coronavirus. Assuming 10,000 codons per genome, the frequency of CGGCGG in coronaviruses can be estimated at 2 per 45,000 codons or 4×10^{-5}. Therefore, the frequency of finding the center half of the SARS-CoV-2 insert is very small. This is consistent with the strong bias in all coronaviruses to place an A/U nt in the third codon position.

The last column above, the presence of -CCG-CCG- in these coronaviruses was included because it is the hybridization sequence partner for the negative strand sequence, which arises during genome replication. This eliminates the possibility of a strand jumping event to generate a CGGCGG codon dimer.

A similar analysis for the spike protein gene can be done. Since there are no instances of CGGCGG in the spike protein genome, and the gene is 3819 nucleotides long, there are 636 pairs of codons Thus, over the 9 other viruses, there are 5724 pairs of codons and no cases of the CGGCGG pair. To calculate the upper bound on the probability of such a pair from these data, one can use the Poisson "Rule of Three", which yields a value of 3/5724 or 0.00052 with 95% confidence. Now examining the SARS-COV-2 genome, there was one instance of the pair in question out of 636 pairs. The probability of this happening if the true rate of this occurrence for a beta coronavirus is 0.00052 is 0.044. Obviously for smaller assumed rates of this occurrence, this would result in probabilities less than 0.044.

Since the 12-nt insert has been found nowhere in the coronavirus genomic universe, examining over 300,000 sequences and using the Poisson "Rule of Three" again, the upper bound on the frequency that it exists in nature is less than one in 100,000 with 95% confidence.

This observation in conjunction with the lack of finding the 12-nt sequence in any candidate zoonotic species makes unlikely a natural source for the virus. One line of investigation to establish a wild source for this infection would be to find a coronavirus strain with the 12-nt sequence somewhere in nature. The fact that 10 of the 12 nts are either G or C coupled, the documented bias against GC suggests this search would be futile.

Based on these analyses that demonstrate that the finding of a -CGG-CGG- codon pair in the furin site of CoV-2 is a highly improbable event, and using the conservative value of a one in 20 chance (the value for a p-value of 0.05), one can recalculate the likelihood of the choice between a zoonotic origin and a laboratory origin.

Subjective Discount Factor. 95% confidence (only a one in 20 chance this is wrong). Below is the calculation of the Bayesian adjustment.

Evidence or process	Zoonotic Origin (ZO)	Laboratory Origin
Starting likelihood	0.047	0.953
Negative predictive value of the absence of the -CGG-CGG- pair in any coronavirus in nature	0.95	
Reduced by 95% Subjective Discount Factor	0.95 x 0.95 = 0.90	
Impact of this evidence	Reduces the likelihood of ZO by 90/10 or 9-fold. For every 100 tests, a true ZO would be seen 10 times and a non-ZO would be seen 90 times	
Impact of evidence calculation	0.047/9 = 0.005	
Normalize this step of analysis	0.005/(0.005 + 0.953) = 0.005	0.953/(0.953 + 0.005) = 0.995

Adjusted likelihood. Zoonotic origin (0.5%), laboratory origin (99.5%).

Evidence. Laboratory codon optimization uses CGG for laboratory insertions of arginine residues 50% of the time.

Codon optimization by recombinant methods (that is, to bring a gene's synonymous codon use into correspondence with the host cell's codon bias) has been widely used to improve cross-species expression of protein.

Though the opposite objective of reducing expression by intentional introduction of suboptimal synonymous codons has not been extensively investigated, isolated reports indicate that replacement of natural codons by rare codons can reduce the level of gene expression in different organisms. For example, one approach to vaccine development is to create an attenuated virus which comprises a modified viral genome containing nucleotide substitutions engineered in multiple locations in the genome, wherein the substitutions introduce synonymous de-optimized codons.

In US Patent 9,476,032[81] titled, "Attenuated viruses useful for vaccines," they state: "In one high-priority redesigned virus, most or all Arg codons are changed to CGC or **CGG** (the top two frequent human codons). This does not negatively affect translation." The patent contains numerous codon usages optimized for vaccine production, including the SARS-CoV virus, and in fact they use the CGG-CGG codon pair 45 times.

Beginning with a paper in 2004,[82] one motivation for codon-optimized SARS genomes is stated here: "The gene encoding the S protein of SARS-CoV contains many codons used infrequently in mammalian genes for efficiently expressed proteins. We therefore generated a codon-optimized form of the S-protein gene and compared its expression with the S-protein gene of the native viral sequence. S protein was readily detected in HEK293T cells transfected with a plasmid encoding the codon-optimized S protein."

Since that time, human optimized codons have been frequently used for coronavirus research, mostly in gain-of-function experiments. In that context the "molecular fingerprint" of CGG for R is one of those common laboratory reagent gene manipulators.

One relevant paper,[84] in which arginine residues were being inserted into bovine herpesvirus-1, used primers to create RR dimers with nine separate -CGG-CGG- codon pairs. as testament to their broad use in the Wuhan Institute of Virology laboratory.

Scientists from the Wuhan Institute of Virology provided the scientific community with a technical bulletin on how to make genetic inserts in coronaviruses and proposed using the very tool that would insert this CGGCGG codon.

A Technical Appendix[85] entitled, "Detailed methods and primer sequences used in a study of genetically diverse filoviruses in Rousettus and Eonycteris spp. bats, China, 2009 and 2015, by Yang, Xinglou & Zhang, Yunzhi & Jiang, Ren-Di & Guo, Hua & Zhang, Wei & Li, Bei & Wang, Ning & Wang, Li & Rumberia, Cecilia & Zhou, Ji-Hua & Li, Shi-Yue & **Daszak, Peter** & Wang, Lin-Fa & **Shi, Zheng-Li.** (2017), from the Wuhan Institute of Virology identifies primer sequences for doing genetic experiments in coronaviruses and identifies CGG containing primers when a R amino acid is being inserted.

[83] Since the codon usage here was not reported I contacted Professor Nunberg to inquire which arginine codons were used. He replied: "Unfortunately, those files have all been archived and access to the nt sequences would involve considerable digging. If it is useful to you, I typically choose codons that are more frequent in highly expressed human proteins."
[84] From the Wuhan Institute of Virology; https://www.ncbi.nlm.nih.gov/pmc/articles/PMC7125963/
[85] https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5382765/

Given that there are two codons of six possibilities that are used in codon optimization, CGG and CGC, the finding of a CGG pair would have a likelihood of happening by chance of (2/6) times (2/6) or one in nine.

Subjective Discount Factor: 80% (this has a probability of being wrong one in five times). This is arbitrary. The calculation to make this adjustment in likelihood is shown here:

Evidence or process	Zoonotic Origin (ZO)	Laboratory Origin (LO)
Starting likelihood	0.005	0.995
This is the outcome expected 8 of 9 times if this is codon optimization		0.88
Reduced by 80% confidence		0.88 x 0.8 = 0.704
Impact of this evidence		Increases the likelihood of LO by 70.4 divided by 29.6 or 2.378.
Impact of evidence calculation		0.995 x 2.378 = 2.37
Normalize this step of analysis	0.005/(2.37 + 0.005) = 0.002	2.37/(0.005 + 2.37) = 0.998

Adjusted likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

Evidence: SARS-CoV-2 Spike Protein is Highly Optimized for ACE2 Binding and Human Cell Infectivity, a Finding that is Inconsistent with Natural Selection but is Consistent with Laboratory Creation

Summary:

- Andersen et al.[86] hypothesized that if the CoV-2 interaction with the human ACE2 was apparently "not ideal," it was evidence that CoV-2 arose by natural selection.

- The alternative hypothesis would be that a finding that CoV-2 was optimized for ACE2 binding and human infection from the initial infection would be evidence of laboratory creation.

- Andersen relied on a paper for the "not ideal" interaction that relied on a computer algorithm rather than laboratory data, was qualitative in nature, sampled only five amino acids or 0.45% of the interaction region, and was over-interpreted.

- The analysis of the Baric et al. paper cited by Andersen as evidence the interaction was not ideal was reexamined, and it was concluded that Andersen had over-interpreted the paper. The paper was a computer simulation study of only 5 of 201 amino acids in the CoV-2-ACE2 interaction region. Only one of the five amino acids discussed was said to be inferior to the equivalent amino acid in SARS-CoV-1; the remainder were either positive or neutral with respect to binding.

- More recently, Baric has clarified his thoughts concerning the CoV-2 ACE2 receptor binding interaction. In a December 31, 2020 *New England Journal of Medicine* paper[57] he wrote: "Early zoonotic variants in the novel coronavirus SARS-CoV that emerged in 2003 affected the receptor-binding domain (RBD) of the spike protein and thereby enhanced virus docking and entry through the human angiotensin-converting–enzyme 2 (hACE2) receptor. **In contrast, the spike-protein RBD of early SARS-CoV-2 strains was shown to interact efficiently with hACE2 receptors early on**." [emphasis added.]

- A comprehensive, laboratory-based, and quantitative paper by Starr et al. of all 201 amino acids in the receptor binding region, not just five amino acids, was examined. Fully 99.6% of all of the possible 3819[87] amino acid substitutions were tested for their effect on CoV-2 binding to ACE2. Only 21 substitutions of the 3819 improved ACE2 binding. Therefore, CoV-2 has been optimized for human ACE2 binding in 99.45% of the possible amino acids in its Spike Protein interaction region.

[86] https://www.nature.com/articles/s41591-020-0820-9

[87] There are 201 amino acids in the residue 331 to 531 interaction region and so 201 times the 19 possible alternative amino acids not found in CoV-2 equals 3819.

- To support this finding, Starr also made an examination of 31,570 CoV-2 sequences from human infections, looking for the 21 substitutions that had been shown to improve CoV-2 binding in the above in vitro laboratory experiments. Among the 31, 570 CoV-2 cases, they failed to find even a single case in which there was an amino acid substitution that improved binding at the time of writing this analysis.[88]

- Based on Andersen's hypothesis and its alternative, SARS-CoV-2 is fully optimized for interaction with the human ACE2 receptor and was at the time of the first patient. There is no evidence of an evolving SP binding region, as was seen with SARS-CoV-1. This is consistent with a laboratory optimized coronavirus which entered the human population fully evolved.

Analysis

Quote from Andersen: "While the analyses above suggest that SARS-CoV-2 may bind human ACE2 with high affinity, computational analyses predict that the interaction is not ideal (reference 7) and that the RBD sequence is different from those shown in SARS-CoV to be optimal for receptor binding (references 7,11).

Thus, the high-affinity binding of the SARS-CoV-2 spike protein to human ACE2 is most likely the result of natural selection on a human or human-like ACE2 that permits another optimal binding solution to arise. This is strong evidence that SARS-CoV-2 is not the product of purposeful manipulation."

The apparent **hypothesis** for the above conclusion is:

"If the SARS-CoV-2 (CoV-2) Spike Protein interaction with the ACE2 receptor is not maximized, then it is evidence that the interaction is the product of natural selection and not purposeful (laboratory) manipulation."

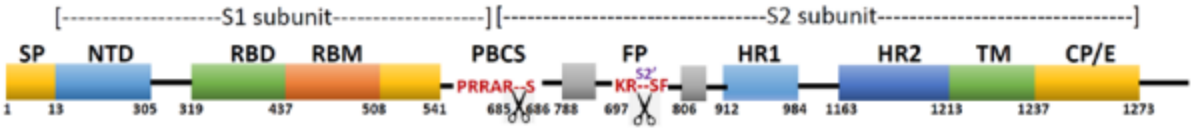
This would lead to an **alternative hypothesis**:

"If the CoV-2 Spike Protein interaction with the ACE2 receptor is maximized, then it is evidence that the interaction *was* the product of purposeful (laboratory) manipulation."

Background.

The Spike Protein (SP) structure and its functional domains are shown in this Figure. The S1 subunit is the initial host interaction portion while the S2 is the post-binding portion responsible for initiating host cell entry, with HR1, HR2, and TM being responsible for breaching the host cell membrane. Allowing viral RNA to enter the cell.

[88] The recent finding of the N501Y variant, first in the UK, and now spreading globally, is evidence of the power of this analysis. N501Y is one of only five potential substitutions in the Starr analysis that had a major effect in improving ACE2 binding.



The interaction of the SP portions which interact with the ACE2 of the host cell, which begins the internalization, infectious process, are contained in the Receptor Binding Domain (RBD) and to a lesser extent the Receptor Binding Motif (RBM), specifically residues 331 to 531. Herein, residues 331 to 531 are called the "interaction region."

Evidence given by Andersen:

Reference 7 in the Andersen paper above is a Ralph Baric paper[89] from early in the pandemic (submitted January 22, 2020) and examines five key residues in the receptor binding domain of the Spike Protein (SP) and whether they are "ideal" for interacting with the ACE2 of human cells. The entire paper is based on computer calculations or prior laboratory work but importantly does not do any new "wet" lab work with CoV-2.

Baric et al. had previously identified five amino acid residues that are important for SP-ACE2 interaction. Using the amino acid numbers of CoV-2, these amino acids are: 455, 486, 493, 494, and 501. Baric opines that the most critical residues are 493 and 501 and the next most important residues are 455, 486, and 494. The authors then discuss each amino acid in turn:

Residue 493: "Gln493 in 2019-nCoV RBD is compatible with hot spot 31, suggesting that 2019-nCoV is capable of recognizing human ACE2 and infecting human cells." In this analysis, 4 of the 20 amino acids are probed.

Residue 501: "This analysis suggests that 2019-nCoV recognizes human ACE2 less efficiently than human SARS-CoV (year 2002) but more efficiently than human SARS-CoV (year 2003). Hence, at least when considering the ACE2-RBD interactions, 2019-nCoV has gained some capability to transmit from human to human."

Direct binding evidence has shown that this statement is misleading, and CoV-2 binds the ACE2 receptor about ten-times better than SARS-CoV (year 2002).[90] In this analysis 3 of the 20 amino acids are probed.

Residues 455, 486, and 494: First, Baric et al. state: "Leu455 of 2019-nCoV RBD provides favorable interactions with hot spot 31, hence enhancing viral binding to human ACE2."

Next, they state: "Phe486 of 2019-nCoV RBD provides even more support for hot spot 31, hence also enhancing viral binding to human ACE2." Importantly, they also talk about their own laboratory work on an "optimized" receptor binding domain and state: "Leu472 of human and

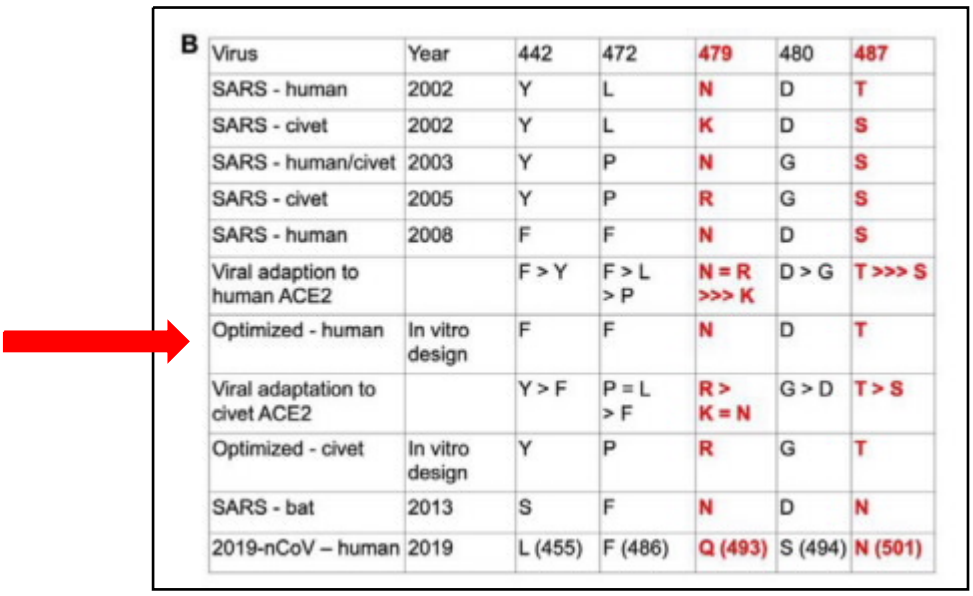
[89] https://jvi.asm.org/content/94/7/e00127-20
[90] https://www.cell.com/action/showPdf?pii=S0092-8674%2820%2931003-5 ; https://www.nature.com/articles/s41586-020-2179-y ; https://www.sciencedirect.com/science/article/pii/S0092867420302622 ; https://science.sciencemag.org/content/367/6483/1260

civet SARS-CoV RBDs provides favorable support for hot spot 31 on human ACE2 through hydrophobic interactions with ACE2 residue Met82 and several other hydrophobic residues **(this residue has been mutated to Phe472 in the optimized RBD)**." [emphasis added.]

Finally, they state: Ser494 in 2019-nCoV RBD still provides positive support for hot spot 353, but the support is not as favorable as that provided by Asp480. Overall, Leu455, Phe486, and Ser494 of 2019-nCoV RBD support the idea that 2019-nCoV recognizes human ACE2 and infects human cells."

In this analysis they probe 3 of 20 amino acid residues for position 480, 4 of 20 for position 486, and 4 of 20 for position 442.

As shown in the Figure below from the Baric paper, the in vitro designed, optimized human SP (red arrow) had the amino acid residues F, F, N, D, and T at these five key residues. Since CoV-2 was identical in only one of these five it was not "optimal" and, according to Andersen, it therefore was not laboratory derived.



B

Virus	Year	442	472	479	480	487
SARS - human	2002	Y	L	N	D	T
SARS - civet	2002	Y	L	K	D	S
SARS - human/civet	2003	Y	P	N	G	S
SARS - civet	2005	Y	P	R	G	S
SARS - human	2008	F	F	N	D	S
Viral adaption to human ACE2		F > Y	F > L > P	N = R >>> K	D > G	T >>> S
Optimized - human	In vitro design	F	F	N	D	T
Viral adaptation to civet ACE2		Y > F	P = L > F	R > K = N	G > D	T > S
Optimized - civet	In vitro design	Y	P	R	G	T
SARS - bat	2013	S	F	N	D	N
2019-nCoV – human	2019	L (455)	F (486)	Q (493)	S (494)	N (501)

Conclusion from the above paper: by examining five amino acid residues of the 200 residues encompassing the interaction region, and calculating the expected interaction of a total of 18 of the 4000 possible residues or 0.45% of all possibilities, they conclude CoV-2 can infect human cells, but is not optimized to do so. This data was twisted by Andersen to show 'strong evidence' of natural selection.

An alternative and comprehensive analysis in another paper:[91]

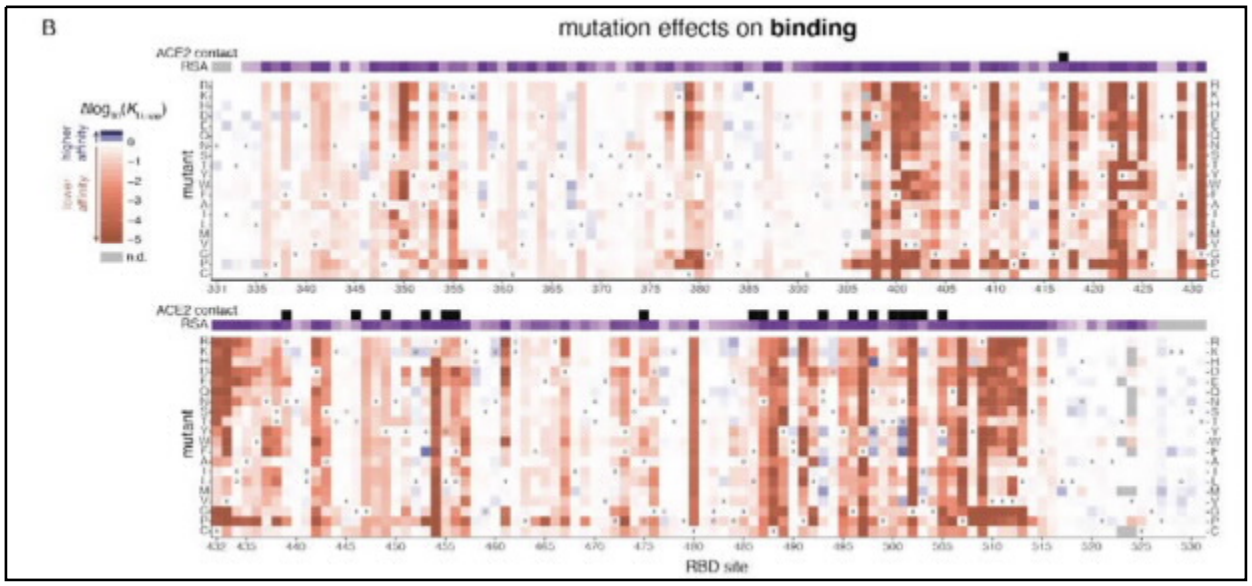
The receptor binding domain (RBD) of the CoV-2 SP is included in residues 331 to 531, a 201 amino acid sequence, of the SP. To examine the effect of each and every amino acid in each and every position, all 19 different amino acids were changed into all 201 positions of the RBD to the extent possible. Out of a total potential of 3819 different single amino acid variants, the scientists

[91] https://www.cell.com/action/showPdf?pii=S0092-8674%2820%2931003-5

were able to create 3804 of the potential variants or 99.6% of the possible variants. It is probable that the variants with the 0.4% amino acid substitutions could not be made for one reason or another. These 3804 were then tested for binding to the human ACE2. Finally, the RBD from SARS-CoV-1 also was tested.

The Figure below is the result of the experiment. Starting with amino acid 331 and ending with amino acid 531, the amino acids that were changed are in vertical columns and are color coded. Shades of brown are amino acid substitutions that reduce ACE2 binding affinity and blue are amino acid substitutions that improve binding, in all cases compared to the 'native' CoV-2 SP sequence. White is the color of a neutral substitution which neither enhances nor diminishes binding. Only the dark blue substitutions provide a strong improvement in ACE2 binding. There is a black square along the top row that denotes amino acids in the SP that interact with the ACE2 protein. Unlike in the Baric analysis above, in which only five amino acids were considered, this group of 19 amino acids provide a more complete interaction picture.

The first overarching observation is that most amino acid substitutions among the 201 amino acids are negative; while a large number are neutral. The fact that the vast majority of amino acid substitutions do not provide an improved ACE2 interaction is clear evidence that the CoV-2 SP interaction region is not newly evolved to the human ACE2 but arrived in the first patient having been "trained" to invade and kill human cells.

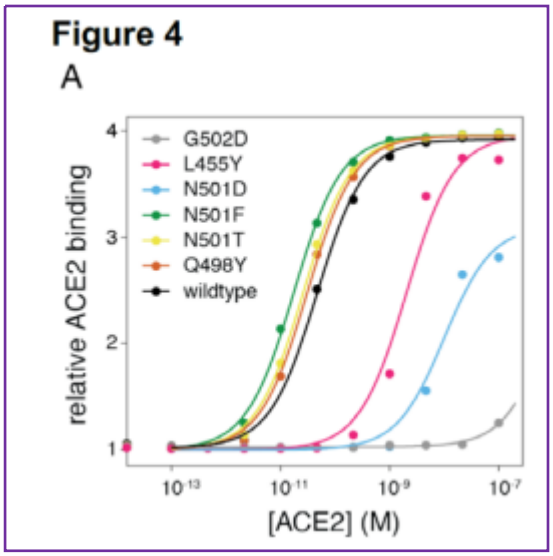


There are three levels of improved binding as designated by dark blue, medium blue, and pale blue. Out of the 3804 variants tested, there are 4 dark blue substitutions or 0.11% and 17 medium blue or 0.45%. According to the paper, the binding effect of the light blue could not be measured as different from the native sequence.

The conclusion of this comprehensive work is the demonstration that for 99.45% of the amino acids in the 201 amino acid interaction region, the CoV-2 choice is optimized, where any substitution is either detrimental or, at best, neutral with respect to the first step of CoV-2 entry to human cells, the binding step to the ACE2 receptor.

How much could CoV-2 binding be improved or made worse by substitutions during the human-to-human transmission of the pandemic?

The Figure 4 below, taken from the paper, shows that the three best amino acid substitutions have only a slight effect on the binding curve (Black is wildtype; curves to the left are better binding; curves to the right are worse binding). This is further evidence that CoV-2 is an optimized form of the original virus.



The authors also concluded that Anderson et al. was wrong: "An initially surprising feature of SARS-CoV-2 was that its RBD tightly binds ACE2 despite differing in sequence from SARS-CoV-1 at many residues that had been defined as important for ACE2 binding by that virus (Andersen et al., 2020; Wan et al., 2020)."

In fact, multiple studies have shown that CoV-2 binds ACE2 better than SARS-CoV-1, contradicting Andersen.

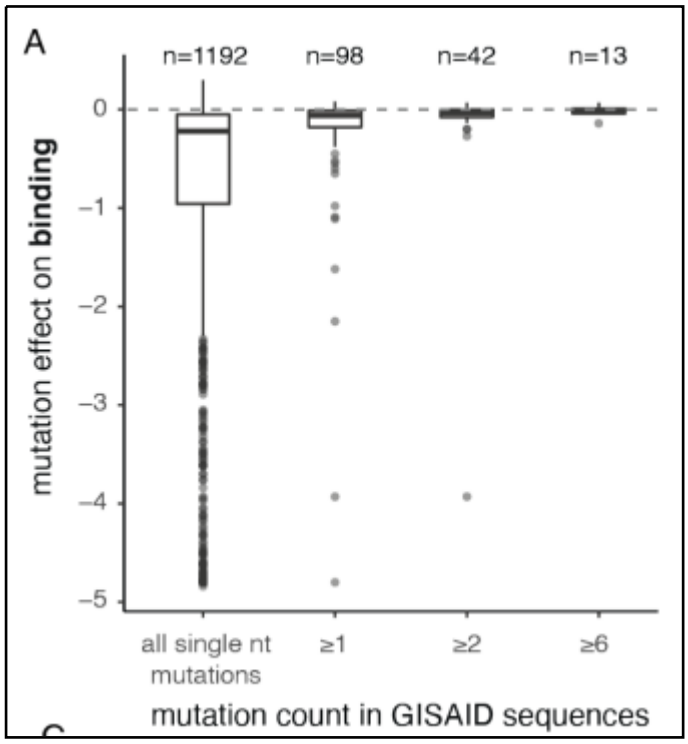
Is there evidence that CoV-2 in human circulation has mutations that enhance ACE2 binding?

Another measure of whether CoV-2 is optimized for human infection is to see if Spike Protein mutations have arisen during the pandemic that improve binding of the virus to the ACE2 receptor or if the SP amino acids are ideal from the very first human patient.

The Starr paper addressed this issue as well. A total of 31,570 human sequences were analyzed to see if any of the 21 amino acid substitutions from the binding experiments (or any other for that matter) were being selected for. That is, if there is any evidence of evolutionary pressure to improve SARS-CoV-2 infectivity.

Below is Figure 8 of the Starr paper. Of the 31,570 sequences, all mutations in the receptor interaction region were analyzed for their effect on ACE2 binding. The data below are for all examples of a single nt mutation (1192), two mutations (98), 3-5 mutations (42), and six or more (13) and the effect the mutation would have on ACE2 binding. The logarithmic scale has the

wildtype CoV-2 as 0 and each negative integer is a 10-fold reduction in affinity. Shockingly, there is not a single mutation that is above the 0 line, which would be an improved affinity for the ACE2 receptor. All of the mutations lower the receptor affinity.



Here are the results, in the words of Starr:

"Our discovery of multiple strong affinity-enhancing mutations to the SARS-CoV-2 RBD raises the question of whether positive selection will favor such mutations, since the relationship between receptor affinity and fitness can be complex for viruses that are well-adapted to their hosts (Callaway et al., 2018; Hensley et al., 2009; Lang et al., 2020). Strong affinity-enhancing mutations are accessible via single-nucleotide mutation from SARS-CoV-2 (Figure S8C), but **none are observed among circulating viral sequences in GISAID** (Figure 8A), and **there is no significant trend for actual observed mutations to enhance ACE2 affinity more than randomly drawn samples of all single nucleotide mutations** (see permutation tests in Figure S8D). **Taken together, we see no clear evidence of selection for stronger ACE2 binding, consistent with SARS-CoV-2 already possessing adequate ACE2 affinity at the beginning of the pandemic."** [emphasis added.]

It is striking that the authors, in observing the complete absence of any evidence for stronger ACE2 binding in over thirty thousand cases, would describe this as evidence of "adequate ACE2 affinity" and not as an exceptional finding of "optimized ACE2 affinity." Of course, calling the SP affinity exceptional from the beginning of the pandemic would beg the question of a laboratory derived virus.

Returning to the initial hypotheses, since the 3804 possible amino acids at the receptor interaction region of CoV-2 are 99.45% optimized for ACE2 binding, and there is not a single

example in 31,570 human CoV-2 genomes of a substitution that enhances ACE2 binding, the CoV-2 interaction with ACE-2 was maximized from the get-go.

Therefore, the hypothesis, "If the SARS-CoV-2 (CoV-2) Spike Protein interaction with the ACE2 receptor is not maximized, then it is evidence that the interaction is the product of natural selection and not purposeful (laboratory) manipulation," is **rejected**.

The alternative hypothesis, "If the CoV-2 Spike Protein interaction with the ACE2 receptor is maximized, then it is evidence that the interaction was the product of purposeful (laboratory) manipulation," is thus **accepted**.

At the time of this writing, a new RBD mutant N501Y has been observed. It is one of the five potential mutations that could be expected to increase RBD-ACE2 affinity.

This is the first example of evidence that will not be statistically quantified but treated as a 51%.49% preponderance of the evidence adjustment. The evidence is more consistent with having been optimized by various methods used in the laboratory than with the slow natural process as seen with SARS-CoV-1, and so the conservative rule that this is consistent with a laboratory origin (51%) versus zoonotic origin (49%) will be used. There will be no confidence adjustment.

The adjusted likelihoods are shown in the following table.

Evidence or process	Zoonotic Origin (ZO)	Laboratory Origin (LO)
Starting likelihood	0.002	0.998
This is the outcome favors LO over ZO at 51% versus 49%		0.51
Impact of this evidence		Increases the likelihood of LO by 51/49 = 1.041
Impact of evidence calculation		1.041 x 0.998 = 1.039
Normalize this step of analysis	0.002/(0.002 + 1.039) = 0.002	1.039/(0.002 + 1.039) = 0.998

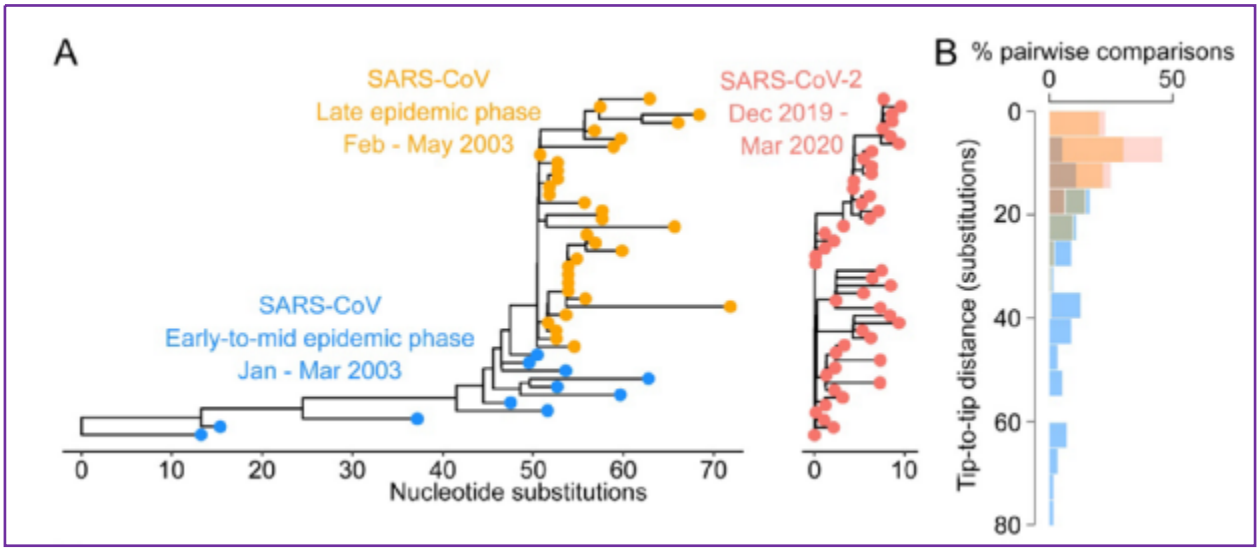
Adjusted likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

Evidence. Whole genome comparison of human adaption of CoV-2 compared to SARS-CoV-1 is consistent with a "pre-adaption" of CoV-2 to the human host

A paper[92] entitled, "SARS-CoV-2 is well adapted for humans. What does this mean for re-emergence?" by Shing Hei Zhan, Benjamin E. Deverman, and Yujia Alina Chan states in the abstract:

"In a side-by-side comparison of evolutionary dynamics between the 2019/2020 SARS-CoV-2 and the 2003 SARS-CoV, we were surprised to find that SARS-CoV-2 resembles SARS-CoV in the late phase of the 2003 epidemic, after SARS-CoV had developed several advantageous adaptations for human transmission. Our observations suggest that **by the time SARS-CoV-2 was first detected in late 2019, it was already pre-adapted to human transmission to an extent similar to late epidemic SARS-CoV**. **However, no precursors or branches of evolution stemming from a less human-adapted SARS-CoV-2-like virus have been detected.** The sudden appearance of a highly infectious SARS-CoV-2 presents a major cause for concern that should motivate stronger international efforts to identify the source and prevent re-emergence in the near future. [Emphasis added.]

The following Figure from the paper best illustrates the relative SNV adaption for SARS-CoV-1 versus CoV-2.



The paper also makes a tangential comment about posterior diversity: "It would be curious if no precursors or branches of SARS-CoV-2 evolution are discovered in humans or animals."

This is another example of evidence that will not be statistically quantified. The evidence is more consistent with having been adapted by various known methods used in a laboratory than with the slow natural process as seen with SARS-CoV-1, and so the conservative rule that this is consistent with a laboratory origin (51%) versus zoonotic origin (49%) will be used. There will be no confidence adjustment.

[92] https://www.biorxiv.org/content/10.1101/2020.05.01.073262v1

The adjusted likelihoods are shown in the following table.

Evidence or process	Zoonotic Origin (ZO)	Laboratory Origin (LO)
Starting likelihood	0.002	0.998
This is the outcome favors LO over ZO at 51% versus 49%		0.51
Impact of this evidence		Increases the likelihood of LO by 51/49 = 1.041
Impact of evidence calculation		1.041 x 0.998 = 1.039
Normalize this step of analysis	0.002/(0.002 + 1.039) = 0.002	1.039/(0.002 + 1.039) = 0.998

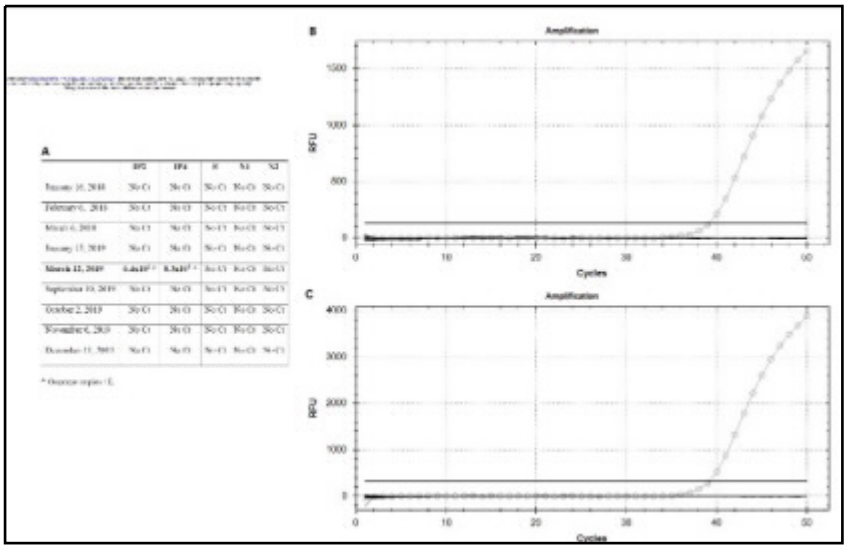
Adjusted likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

Evidence: Evidence of CoV-2 during early 2019 in wastewater from Barcelona, Spain is a false positive artifact

A paper entitled "Sentinel surveillance of SARS-CoV-2 in wastewater anticipates the occurrence of COVID-19 cases"[93] claims CoV-2 was present in Barcelona, Spain in March 2019. Specifically, they state:

"This possibility prompted us to analyze some archival WWTP samples from January 2018 to December 2019 (Figure 2). All samples came out to be negative for the presence of SARS-CoV-2 genomes with the exception of March 12, 2019, in which both IP2 and IP4 target assays were positive. This striking finding indicates circulation of the virus in Barcelona long before the report of any COVID-19 case worldwide."

This is a false positive



As shown above from the paper, they found 43/45 runs with zero and two runs had only 600-800 CoV-2 copies/L

But the limit of detection (LoD) of their assay is 1,000,000 CoV-2/L.

According to the Promega PCR assay FDA clearance package, the Ct at the LoD is 33-34 for the N1 and N2, respectively (Table 17, page 51).[94] Here the LoD is listed as 1 RNA/µL.

In the paper the Ct is 40 or 6-7 above the LoD.

This evidence is neutral as to origin and will not be used to adjust the likelihoods. It does reduce the credibility of some of the new origin theories coming out of China.

Evidence: WHO and Dr. Shi have spoken of the singular nature of the beginning of COVID-19

On January 23, 2020 Dr. Shi wrote in the draft of her paper: "The almost identical sequences of this virus in different patients imply a probably recent introduction in humans…"[95] By February 3, 2020, when the final version of this paper was published, this sentence had been **deleted**.[96]

On April 23, 2020 the WHO stated: "All the published genetic sequences of SARS-CoV-2 isolated from human cases are very similar. This suggests that the start of the outbreak resulted from a single point introduction in the human population around the time that the virus was first reported in humans in Wuhan, China in December 2019."[97]

The evidence, like the lack of posterior diversity and seroconversion reported earlier, is more consistent with a single introduction in a laboratory accident. This evidence will not be used to adjust probabilities but is included because it could be a form of party admissions of unfavorable facts.

Evidence. As documented by Drs. Daszak, Humes, and Shi, mammalian biodiversity and bat species differences between Yunnan and Hubei Provence are significant and do not support a zoonotic origin

Summary. SARS-CoV-2 is most closely related to bat coronaviruses from Yunnan, a rural province in South West China. Wuhan, where the pandemic began, is a large urban city of 11 million inhabitants in north central China. These two areas are approximately 1900 km apart.

This is the US equivalent of the difference between New York City (population 8.4 million) and the Everglades in Florida, 2000 km away. The incongruent image of a bat or intermediate host in the Everglades somehow finding its way to New York City is a clear demonstration of the difficulty in this hypothetical transmission process. Nonetheless, a strict literature-based analysis will be conducted.

If COVID-19 is a zoonotic disease it must have travelled from bats to humans or from bats to an intermediate species to humans. Therefore, an examination of mammalian biodiversity differences and commonalities between Yunnan and Wuhan might provide useful information about the intermediate host or the particular bat species.

Peter Daszak, Zhengli-li Shi and colleagues published an August 2020 paper entitled, "Origin and cross-species transmission of bat coronaviruses in China,"[98] in which they make a number of observations that are relevant to this analysis. It should be remembered that both lead authors have made multiple, strong, public statements over many months where they assert that SARS-CoV-2 is a natural virus of zoonotic origin.

Yunnan and Hubei Provinces have very dissimilar mammalian diversity

Quoting from the Methods section of the Daszak, Shi paper:

"Defining zoogeographic regions in China:

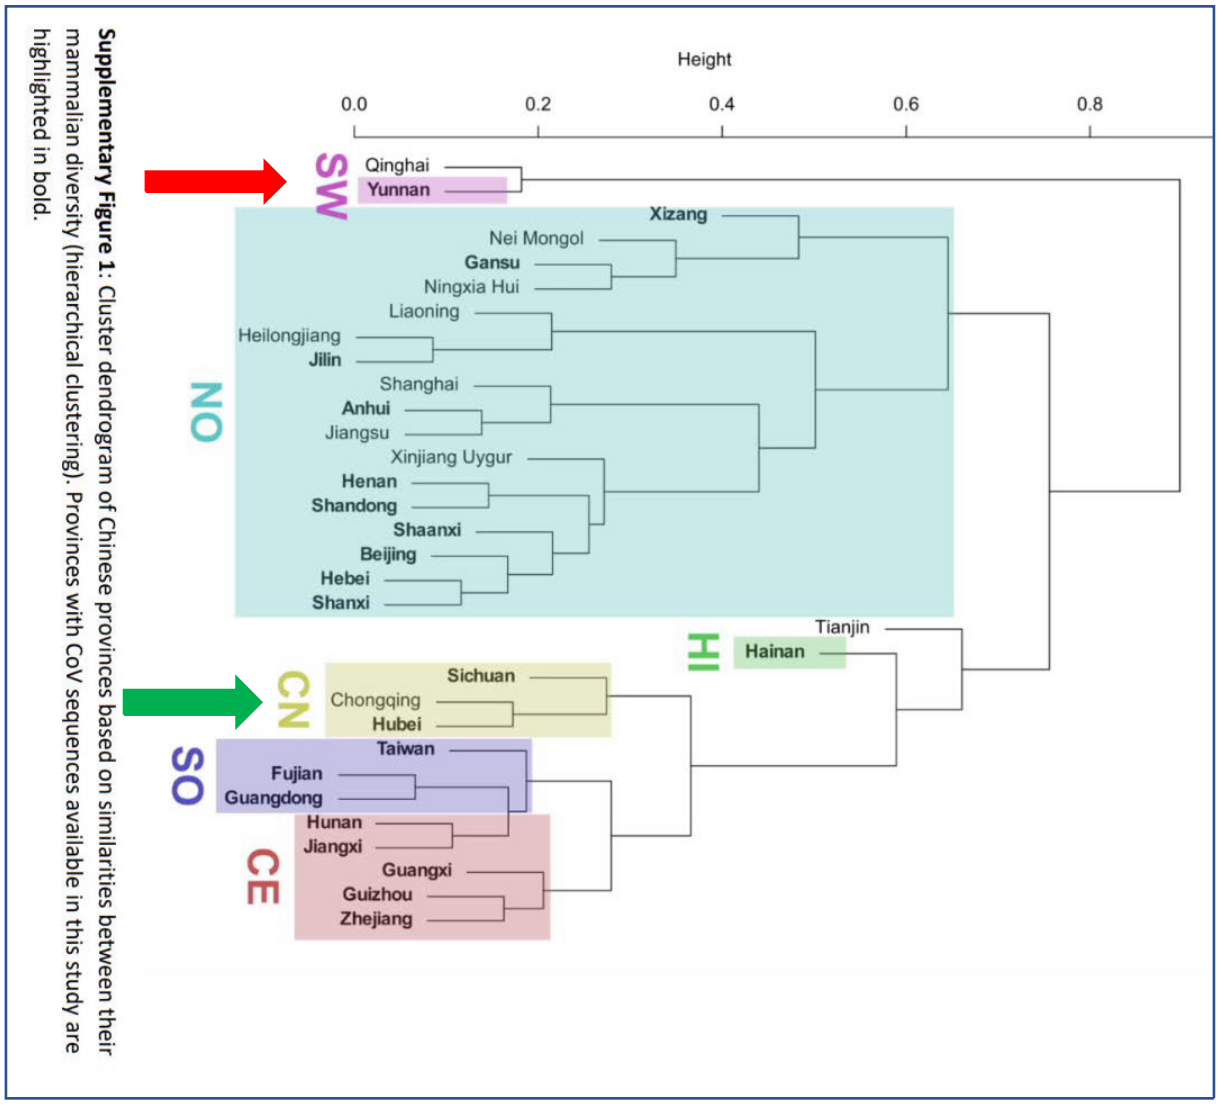
Hierarchical clustering was used to define zoogeographic regions within China by clustering provinces with similar mammalian diversity. Hierarchical cluster analysis classifies several objects into small groups based on similarities between them. To do this, we created a presence/absence matrix of all extant terrestrial mammals present in China using data from the IUCN spatial database and generated a cluster dendrogram using the function *hclust* with average method of the R package stats. Hong Kong and Macau were included within the neighboring Guangdong province. We then visually identified geographically contiguous clusters of provinces for which CoV sequences are available (Fig. 1 and Supplementary Fig. 1).

We identified six zoogeographic regions within China based on the similarity of the mammal community in these provinces: **SW (Yunnan province)**, NO (Xizang, Gansu, Jilin, Anhui, Henan, Shandong, Shaanxi, Hebei, and Shanxi provinces and Beijing municipality), **CN (Sichuan and Hubei provinces)**, CE (Guangxi, Guizhou, Hunan, Jiangxi, and Zhejiang provinces), SO (Guangdong and Fujian provinces, Hong Kong, Macau, and Taiwan), and HI.

[98] https://www.nature.com/articles/s41467-020-17687-3#Sec19

Hunan and Jiangxi, clustering with the SO provinces in our dendrogram, were included within the central region to create a geographically contiguous Central cluster (Supplementary Fig. 1). These six zoogeographic regions are very similar to the biogeographic regions traditionally recognized in China. The three β-CoV sequences from HI were included in the SO region to avoid creating a cluster with a very small number of sequences."

Below is a cluster dendrogram of Chinese provinces based on similarities between their mammalian diversity (hierarchical clustering). Provinces with CoV sequences available in this study are highlighted in bold.



Supplementary Figure 1: Cluster dendrogram of Chinese provinces based on similarities between their mammalian diversity (hierarchical clustering). Provinces with CoV sequences available in this study are highlighted in bold.

The y-axis height is a measure of the biodiversity with 1.0 being complete similarity and 0.0 being no similarity. As expected for the geography and location of the two provinces, Yunnan (red arrow above) and Hubei (green arrow above) have a height score of about 0.1, with seven branches and six nodes separating them. This is close to the biggest different in mammalian biodiversity of any two locations in all of China.

In conclusion, Daszak and Shi et al. demonstrate that the mammalian biodiversity between Yunnan and Hubei is very significant, reducing the options for a common intermediate host to be the natural conduit between bats and humans.

Shi, Humes, and Daszak statement: "SARS-CoV-2 is likely derived from a clade of viruses originating in horseshoe bats (*Rhinolophus* spp.). The geographic location of this origin appears to be Yunnan province."

This evidence will not be statistically quantified. The evidence reduces the biodiversity overlap needed to create a common intermediate species between the two provinces, and so the conservative rule that this is consistent with a laboratory origin (51%) versus zoonotic origin (49%) will be used. There will be no subjective discount factor adjustment.

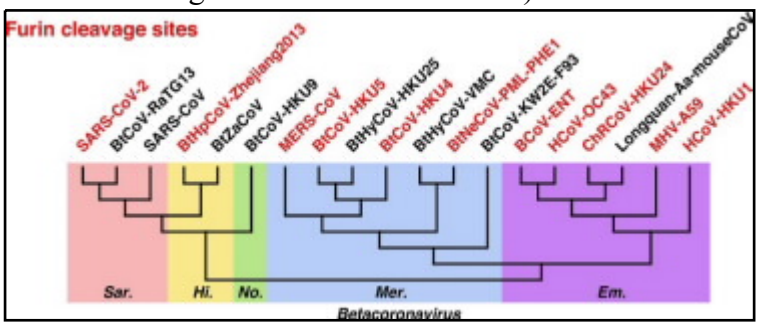
Evidence or process	Zoonotic Origin (ZO)	Laboratory Origin (LO)
Starting likelihood	0.002	0.998
This is the outcome favors LO over ZO at 51% versus 49%		0.51
Impact of this evidence		Increases the likelihood of LO by 51/49 = 1.041
Impact of evidence calculation		1.041 x 0.998 = 1.039
Normalize this step of analysis	0.002/(0.002 + 1.039) = 0.002	1.039/(0.002 + 1.039) = 0.998

Because of the rule on the use of significant figures, the likelihood does not change.

Adjusted likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

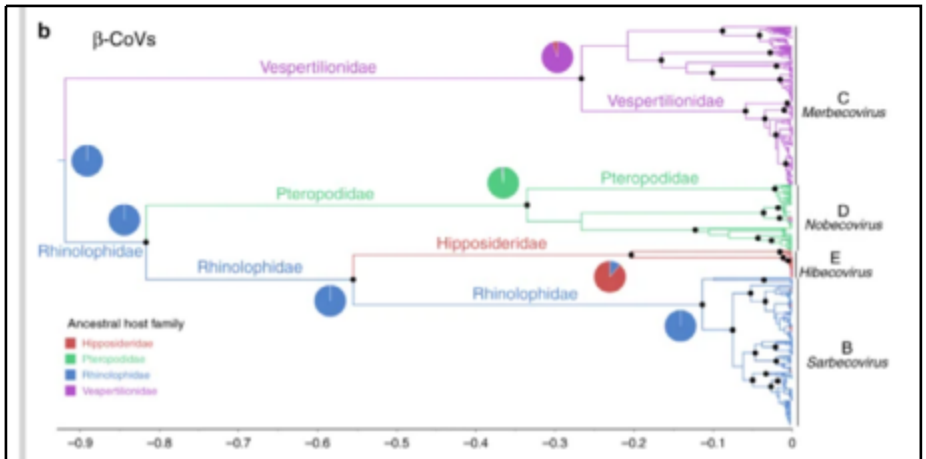
Evidence: The ancestor of SARS-CoV-2 can hypothetically only obtain a furin site by recombination outside of the sarbecovirus subgenera but there is strong evidence that coronavirus recombination is largely limited to the clade level, with limited evidence of sub-genera or genera recombination

- SARS-CoV-2 is a beta coronavirus, subgenera sarbecovirus and is the only sarbecovirus with a furin site.[99]
- Furin sites can be found in either alpha or gamma coronaviruses or the other beta coronavirus subgenera. The following Figure from reference 66 shows examples of such coronaviruses (furin containing viruses are shown in red):



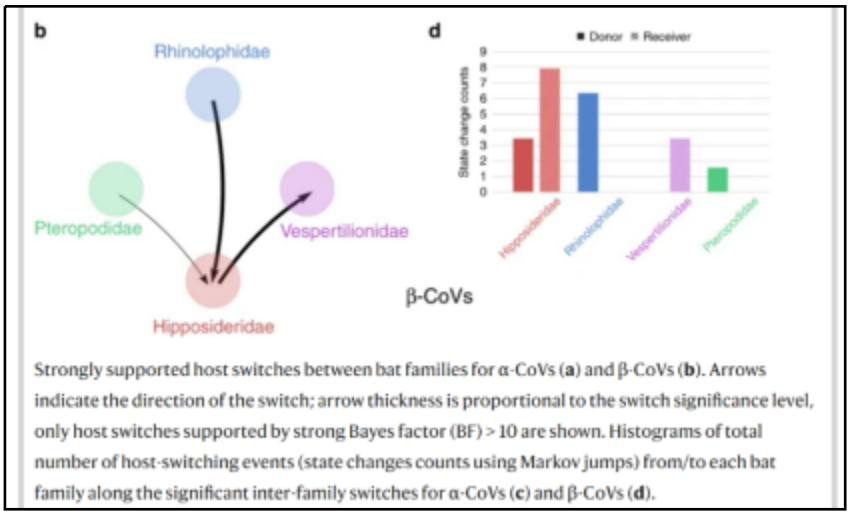
- To acquire a furin site in nature would require a co-infection between the CoV-2 sarbecovirus ancestor and a furin-containing non-sarbecovirus as shown above.
- However, there is no evidence of recombination in coronaviruses at either the genus level or the subgenus level; only at the clade level.[100][101]
- There is also evidence from Daszak and Shi that within the subgenera of the beta coronaviruses, there is bat host specificity. So, each subgenera of coronaviruses has a preferred bat host species. This reduces the opportunities for a co-host event to permit recombination.[102] The phylogeny below shows the problem of host incompatibility for beta coronaviruses:

[99] https://www.sciencedirect.com/science/article/pii/S1873506120304165#f0015
[100] file:///C:/Users/Steven%20Quay/Desktop/journal.pgen.1009272.pdf
[101] https://academic.oup.com/mbe/advance-article/doi/10.1093/molbev/msaa281/5955840
[102] https://www.nature.com/articles/s41467-020-17687-3#Sec2



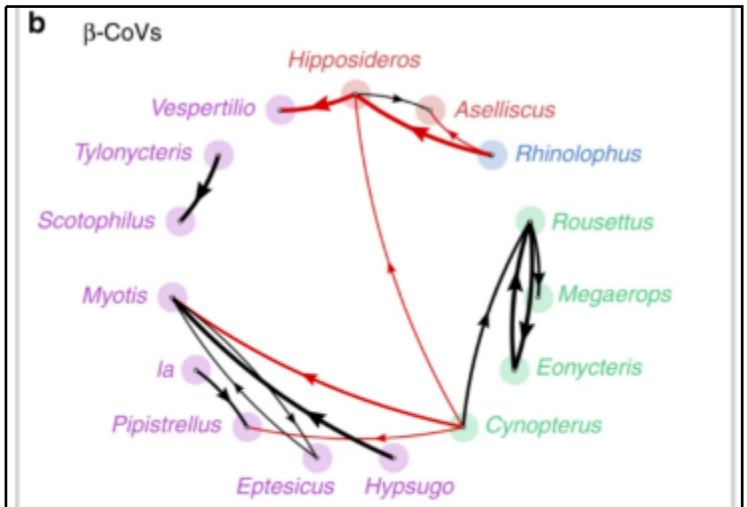
α-CoV (**a**) and β-CoV (**b**) maximum clade credibility annotated trees using complete datasets of *RdRp* sequences and bat host family as discrete character state. Pie charts located at the root and close to the deepest nodes show the state posterior probabilities for each bat family. Branch color correspond to the inferred ancestral family with the highest probability. Branch lengths are scaled according to relative time units (clock rate = 1.0). Well-supported nodes (posterior probability > 0.95) are indicated with a black dot. The ICTV approved CoV subgenera were highlighted: *Rhinacovirus* (L1), *Decacovirus* (L2), *Myotacovirus* (L3), *Pedacovirus* (L5), *Nyctacovirus* (L6), *Minunacovirus* (L7), and an unidentified lineage (L4) for α-CoVs; and *Merbecovirus* (Lineage C), *Nobecovirus* (lineage D), *Hibecovirus* (lineage E), and *Sarbecovirus* (Lineage B) for β-CoVs.

- Daszak and Shi also identified preferred directions of host switching. Since RaTG13, the closest coronavirus to SARS-CoV-2, is most closely related to viruses with bat hosts from the family, Rhinolophidae, it would be reasonable to expect furin-containing viruses from other bat hosts to migrate into Rhinolophidae, recombine by methods which have not been identified, and then the furin-containing sarbecovirus could evolve into the ancestor of SARS-CoV-2. Unexpectedly, Daszak et al. found host migration for the Rhinolophidae bats only outward and not inward, as required by the above, admittedly, convoluted process. The data Figure is shown here:



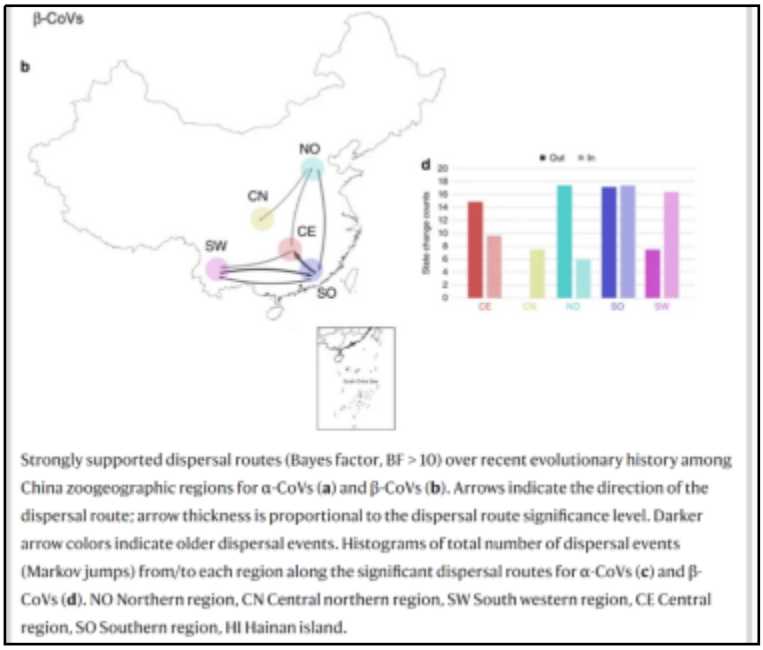
Strongly supported host switches between bat families for α-CoVs (**a**) and β-CoVs (**b**). Arrows indicate the direction of the switch; arrow thickness is proportional to the switch significance level, only host switches supported by strong Bayes factor (BF) > 10 are shown. Histograms of total number of host-switching events (state changes counts using Markov jumps) from/to each bat family along the significant inter-family switches for α-CoVs (**c**) and β-CoVs (**d**).

- Daszak and Shi also observed outward host switches from *Rhinolophus* at the genera level as well, also against a hypothesis for furin-site acquisition:



Strongly supported host switches between bat genera for α-CoVs (**a**) and β-CoVs (**b**) and their significance level (Bayes factor, BF). Only host switches supported by strong BF values >10 are shown. Line thickness is proportional to the switch significance level. Red lines correspond to host switches among bat genera belonging to different families, and black lines correspond to host switches among bat genera from the same family. Arrows indicate the direction of the switch. Genus names are colored according to the family they belong to using the same colors as in Figs. 2 and 3.

- Finally, this paper by Daszak and Shi states: "We used our Bayesian discrete phylogeographic model with zoogeographic regions as character states to reconstruct the spatiotemporal dynamics of CoV dispersal in China." If SARS-CoV-2 began in Yunnan and first crossed over into humans in Wuhan, this analysis should support a northernly spatiotemporal dispersal of beta coronaviruses. Unfortunately, Daszak and Shi cannot catch a break; their own data do not support the expected route of dispersion:



Strongly supported dispersal routes (Bayes factor, BF > 10) over recent evolutionary history among China zoogeographic regions for α-CoVs (**a**) and β-CoVs (**b**). Arrows indicate the direction of the dispersal route; arrow thickness is proportional to the dispersal route significance level. Darker arrow colors indicate older dispersal events. Histograms of total number of dispersal events (Markov jumps) from/to each region along the significant dispersal routes for α-CoVs (**c**) and β-CoVs (**d**). NO Northern region, CN Central northern region, SW South western region, CE Central region, SO Southern region, HI Hainan island.

As shown in the above Figure the only dispersal routes into Wuhan, which is in the CN region, are from the northern region. And the northern region has no inward dispersals from the SW, southwest region, where Yunnan and the origin of the ancestor of SARS-CoV-2, is located.

- Independent evidence documents that Hubei province does not have the bat species needed for SARS-CoV-2 reservoir host[103]

While statistical models of this data could be interesting and informative for general research about future spillovers, this is evidence will not be statistically quantified for this analysis. The evidence reduces the opportunities for subgenera co-infection and furin-site recombination into the CoV-2 ancestor and so the conservative rule that this is less consistent with a zoonotic origin (49%) versus laboratory origin (51%) will be used. There will be no subjective discount factor adjustment.

The results from the calculations are shown below.

Evidence or process	Zoonotic Origin (ZO)	Laboratory Origin (LO)
Starting likelihood	0.002	0.998
This is the outcome favors LO over ZO at 51% versus 49%		0.51
Impact of this evidence		Increases the likelihood of LO by 51/49 = 1.041
Impact of evidence calculation		1.041 x 0.998 = 1.039
Normalize this step of analysis	0.002/(0.002 + 1.039) = 0.002	1.039/(0.002 + 1.039) = 0.998

Adjusted likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

[103] file:///C:/Users/Steven%20Quay/Desktop/Zhangetal2009.pdf

Evidence: Of 410 vertebrate species tested for affinity to CoV-2 Spike Protein binding domain, primate ACE2 receptor, including human and VERO monkey cells, are the best at binding and bat species ACE2 are the worse, making direct bat-to-human host jumping extremely unlikely

- An examination of the ACE2 receptor binding domain amino acid sequences and their suitability for interacting with SARS-CoV-2 was performed in 410 vertebrates, including 252 mammals.[104]
- A five-category binding score was developed based on the conservation properties of 25 amino acids important for the binding between ACE2 and the SARS-CoV-2 spike protein.
- Only mammals fell into the medium to very high categories and only primates scored 25/25 for binding.
- This implies that SARS-CoV-2 is optimized for human ACE2-bearing cells from the first introduction into the human population, an observation that contradicts a zoonotic origin.
- It also suggests that other primates may be the proximate species from which SARS-CoV-2 entered the human population.
- Both VERO monkey kidney cells and ACE2 humanized mice would quality as an intermediate species by this criterion.
- Surprisingly, "all chiropterans (bats) scored low (n = 8) or very low (n = 29), including the Chinese rufous horseshoe bat, from which a coronavirus (SARSr-CoV ZC45) related to SARS-CoV-2 was identified."
- This is evidence that bats are probably not a reservoir host for SARS-CoV-2.
- A separate study observed: "Severe acute respiratory syndrome coronavirus 2 did not replicate efficiently in 13 bat cell lines."[105]
- The following two Tables are taken from the paper and are organized according to ACE2 SARS-CoV-2 affinity, from highest to lowest:

While statistical models of this data could be interesting and informative, this is evidence will not be statistically quantified for this analysis. The evidence is another way of looking at the pre-adapted state of the CoV-2 for humans and suggests that primate animals, monkey cell cultures like the VERO cell, and humanized mice could be likely laboratory models that were used by the

WIV in GoF research. This will contribute a 51%/49% contribution in favor of laboratory compared to zoonotic origin. There will be no subjective discount factor adjustment.

The results from the calculations are shown below.

Evidence or process	Zoonotic Origin (ZO)	Laboratory Origin (LO)
Starting likelihood	0.002	0.998
This is the outcome favors LO over ZO at 51% versus 49%		0.51
Impact of this evidence		Increases the likelihood of LO by 51/49 = 1.041
Impact of evidence calculation		1.041 x 0.998 = 1.039
Normalize this step of analysis	0.002/(0.002 + 1.039) = 0.002	1.039/(0.002 + 1.039) = 0.998

Adjusted likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

Evidence: Did a Review of Samples Collected from a Mineshaft Cause the COVID-19 Pandemic?[106]

Abstract. The origin of the COVID-19 pandemic caused by SARS-CoV-2 has been hotly debated. Proponents of the natural spillover theory allege that the virus jumped species, possibly via an intermediary host, to cross over to humans via the wildlife trade or by other means. Proponents of a rival theory claim that the virus escaped from a laboratory in Wuhan. This research presents circumstantial evidence of a transmission route via a late 2019 review of samples collected from a mineshaft in Mojiang, Yunnan Province, China. It examines the activity at the Wuhan Institute of Virology in late 2019, when samples from a mineshaft associated with a suspected SARS outbreak were being reviewed. It proposes that spillover occurred during this review of samples including of a virus (BtCoV/4991) only 1% different to SARS-CoV-2 in its RNA-dependent RNA polymerase (RdRp).

It is a meticulous sourced analysis. It purposely avoids the question of whether SARS-CoV-2 was being grown or manipulated in the laboratory, but only addresses the evidence that events in the fall of 2019 are consistent with a laboratory accident.

This will not be used to adjust the likelihoods.

Current likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

[106] https://zenodo.org/record/4029545#.X-x_f9gzbOg. Author anonymous. A meticulously documented analysis that concludes an accident occurred at the Wuhan Institute of Virology during the fall of 2019.Includes many primary documents from Mandarin. No direct evidence of 'what' was the nature of the accident or if it was SARS-CoV-2.

Evidence: The Hunan market was not the source of SARS-CoV-2

From the WHO Terms of Reference for the investigation of the origin of SARS-CoV-2:[107]

"The Huanan wholesale market is a large market (653 stalls and more than 1180 employees) mainly supplying seafood products but also fresh fruits and vegetables, meat, and live animals. In late December 2019, 10 stall operators were trading live wild animals including chipmunks, foxes, racoons, wild boar, giant salamanders, hedgehogs, sika deer, and many others. Farmed, wild and domestic animals were also traded at the market including snakes, frogs, quails, bamboo rats, rabbits, crocodiles, and badgers. The market was closed on 1 January 2020, and several investigations followed, including environmental sampling, as well as sampling of frozen animal carcasses at the market. **Of the 336 samples collected from animals, none were PCR positive for SARS-CoV-2**, whereas 69 out of 842 environmental samples were positive by PCR for SARS-CoV-2. Sixty- one of those (88%) were from the western wing of the market. Of these, 22 samples were from 8 different drains and sewage, and 3 viruses were isolated, sequenced and shared on GISAID. These were virtually identical to the patient samples collected at the same time (>99.9 % homology)."

For contrast, with SARS-CoV-1 91 civets & 15 raccoon dogs in wet markets were tested with 106/106, 100% positive.[108]

This will not be used to adjust the likelihoods.

Current likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

[107] https://drive.google.com/file/d/1rx0W2efbE0R1Aq-lALWTqD22VsWbTlO-/view
[108] https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1212604/

Evidence: Analysis of the hospital of admission for COVID-19 patients during December 2019 places "ground zero" for the outbreak somewhere along Line 2 of the Wuhan Metro System.

Line 2 carries one million people per day and services the Wuhan Institute of Virology, the Hunan Seafood Market, the high-speed rail system, and the Wuhan International Airport

A preprint manuscript[109] reported that the earliest genomic cluster of SARS-CoV-2 patients is a group of four individuals associated with the General Hospital of Central Theater Command of People's Liberation Army (PLA) of China in Wuhan. This cluster contains the "Founder Patients" of both Clade A and Clade B, from which every SARS-CoV-2 coronavirus that has infected every patient with COVID-19 anywhere in the world has arisen.

The PLA Hospital is about one mile from the Wuhan Institute of Virology (WIV) and the closest hospital to WIV. Both the PLA Hospital and WIV are serviced by Line 2 of the Wuhan Metro System. The Hunan Seafood Market is also located adjacent to Line 2. All patients between December 1st, 2019 and early January 2020 were first seen at hospitals that also are serviced by Line 2 of the Metro system.

With 40 hospitals located near seven of the nine Metro Lines, the likelihood that all early patients were seen at hospitals only near Line 2 by chance is about 1 in 68,500 (p-value = 0.0000146). The inference then would be that the early spread of SARS-CoV-2 was through human-to human transmission on Line 2.

Line 2 carries one million passengers per day and assuming most are round trip business workers going to and from work in the morning and evening, represents 500,000 riders or about 5% of the Wuhan population. A very recent publication determined that, in fact, 500,000 residents of Wuhan contracted COVID-19, a ten-fold upper estimate.[110] The coincidence of my prediction that 500,000 riders on Line 2 were likely exposed to SARS-CoV-2 in late 2019 and the recent admission from Chinese CDC that Wuhan had 500,000 COVID-19 cases is duly noted!

Line 2 connects to all eight other lines of the Wuhan Metro System (1, 3, 4, 6, 7, 8, 11, and Yanglu) facilitating rapid spread in Wuhan and Hubei Province, and also services both the high-speed rail station (Hankou Railway Station), facilitating rapid spread throughout China, and the Wuhan International Airport (Tianhe International Airport), facilitating rapid spread throughout Asia, Europe, and to the United States. In fact, direct human-to-human spread from the Reference Sequence patient to patients around the world is suggested by an unexpectedly reduced genome base substitution rate seen in patient specimens in cities with direct flights from Wuhan.

[109] https://zenodo.org/record/4119263#.X-rszNgzbOg
[110] https://mp.weixin.qq.com/s/LXTfDmsQLf3qZnu_S_MxcA ; https://thehill.com/policy/international/china/531935-study-shows-wuhan-coronavirus-cases-may-have-been-10-times-higher

In a separate paper by Quay and Dr. Martin Lee, Adjunct Professor of Statistics, UCLA, from May 2020, now accepted for publication in *Epidemics,*[111] the authors provide evidence that COVID-19 was appearing in California as early as the first week of 2020. This is likely due to direct flights connecting Line 2 to the Wuhan airport and then to San Francisco.

In conclusion, Line 2 of the Wuhan Metro System services the PLA Hospital with the first genomic cluster of patients with COVID-19, the hospitals where patients first went in December 2019 and early January 2020 and is the likely conduit for human-to-human spread throughout Wuhan, China, and the world.

The following slide overview provides a visual analysis of this evidence:

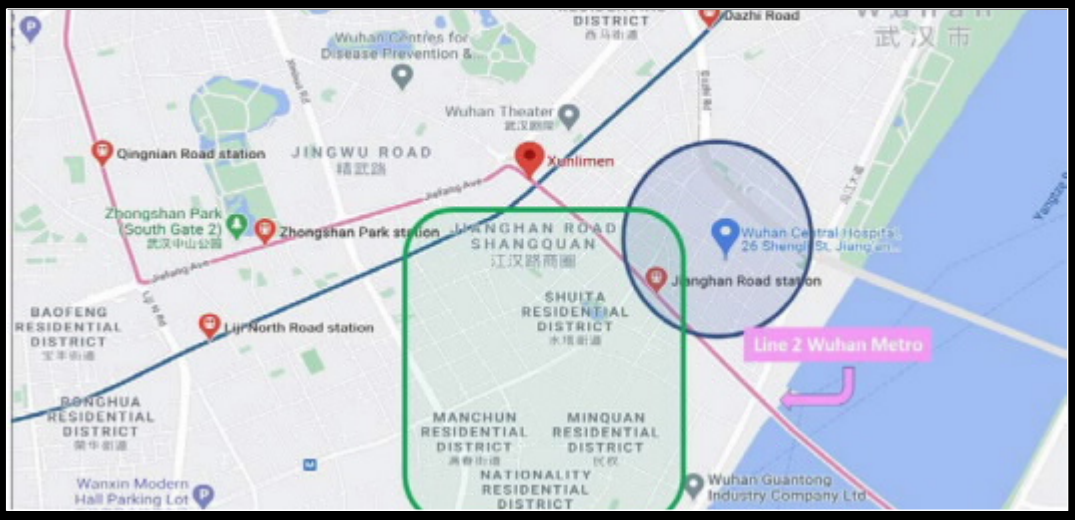
The PLA patient cluster

- PLA-4 is genetically the closest human infection to the three closest bat viruses
- The four PLA patients have the close sequence pattern usually seen only in family transmissions

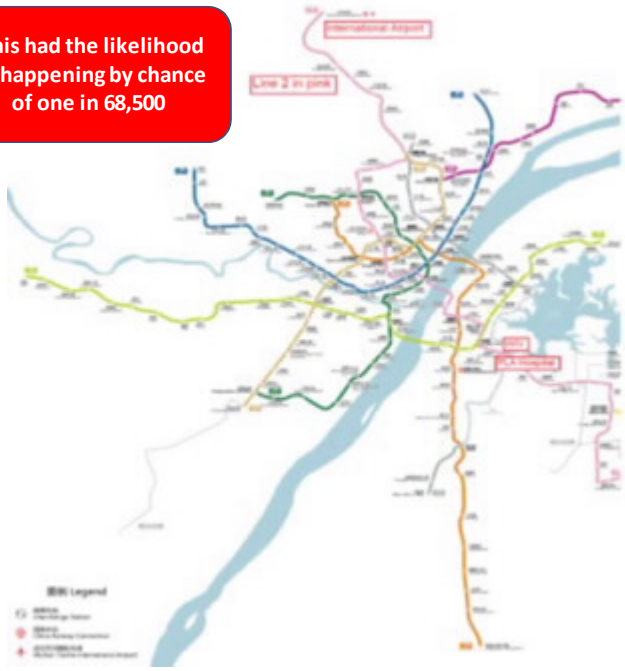
The Wuhan Metro System



Methodology: Metro station line for intersection of hospital catchment zone and residential living district zone was identified

All COVID patients from Dec 1 to early Jan were admitted to hospitals on Metro Line 2

This had the likelihood of happening by chance of one in 68,500



Feature	Relationship to Pandemic
Line 2 carried 1 MM passengers a day before COVID	Assuming 2 trips/d for commuters, about 5% of the Wuhan population uses this Line, making it an efficient transmission route for all of Wuhan as well as Hubei Provence. A single patient can leave a droplet/aerosol cloud for hours to infect others.
Line 2 shares stations with every other Metro Line	Permits human-to-human spread to every part of Wuhan at the stations shared with Line 2
Line 2, Hankou Railway Station	Connects Wuhan to all of China by high speed rail
Line 2, Tianhe International Airport	International destinations: New York City, San Francisco, London, Tokyo, Rome, Istanbul, Dubai, Paris, Sydney, Bali, Bangkok, Moscow, Osaka, Seoul, and Singapore.

The Line 2 COVID Conduit

The Line 2 COVID Conduit

- Line 2 Hankou High Speed Railway Station to all of China
- Line 2 Tianhe International Airport Station to the world

The Hunan Seafood Market, Wuhan Institute of Virology, and the Wuhan CDC, all locations suggested to be the possible source of SARS-CoV-2 in Wuhan, are also all serviced by Line 2 of the Metro system, suggesting this public transit line should become the focus for further investigations into the origin of this pandemic.

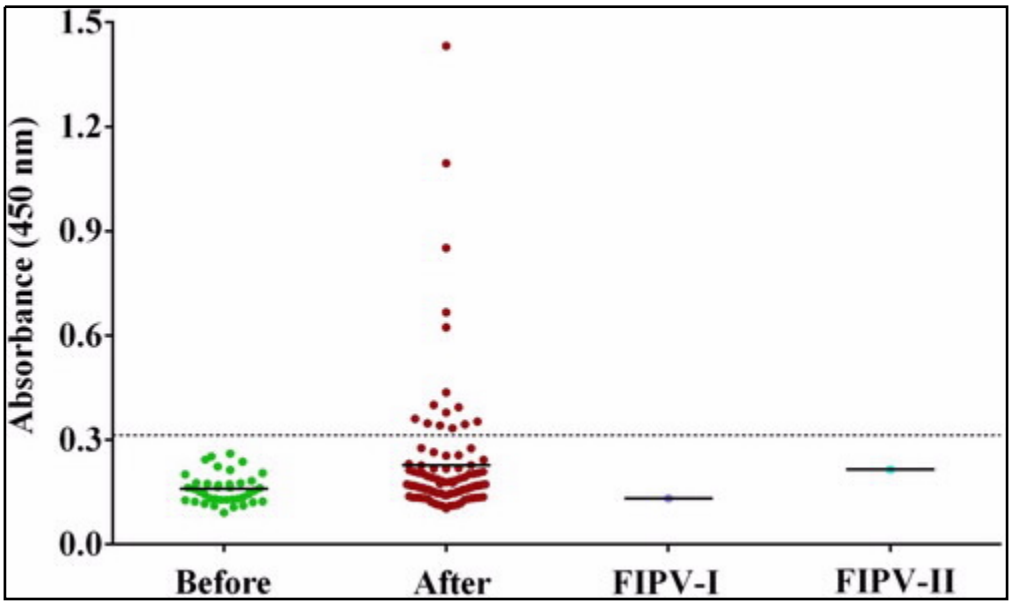
Given that the Hunan Seafood Market has been removed as a source for the origin of CoV-2, this evidence will contribute a 51%/49% contribution in favor of laboratory compared to zoonotic origin. There will be no Subjective Discount Factor adjustment.

The results from the calculations are shown below.

Evidence or process	Zoonotic Origin (ZO)	Laboratory Origin (LO)
Starting likelihood	0.002	0.998
This is the outcome favors LO over ZO at 51% versus 49%		0.51
Impact of this evidence		Increases the likelihood of LO by 51/49 = 1.041
Impact of evidence calculation		1.041 x 0.998 = 1.039
Normalize this step of analysis	0.002/(0.002 + 1.039) = 0.002	1.039/(0.002 + 1.039) = 0.998

Adjusted likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

Evidence: SARS-CoV-2 infection, based on antibody seroconversion, was not found in 39 archived specimens taken from cats (1/3 feral) between March and May 2019[112]



Based on these results, the prevalence of SARS-CoV-2 in domestic and feral cats prior to January 2020 is less than 8% with a 90% confidence interval.

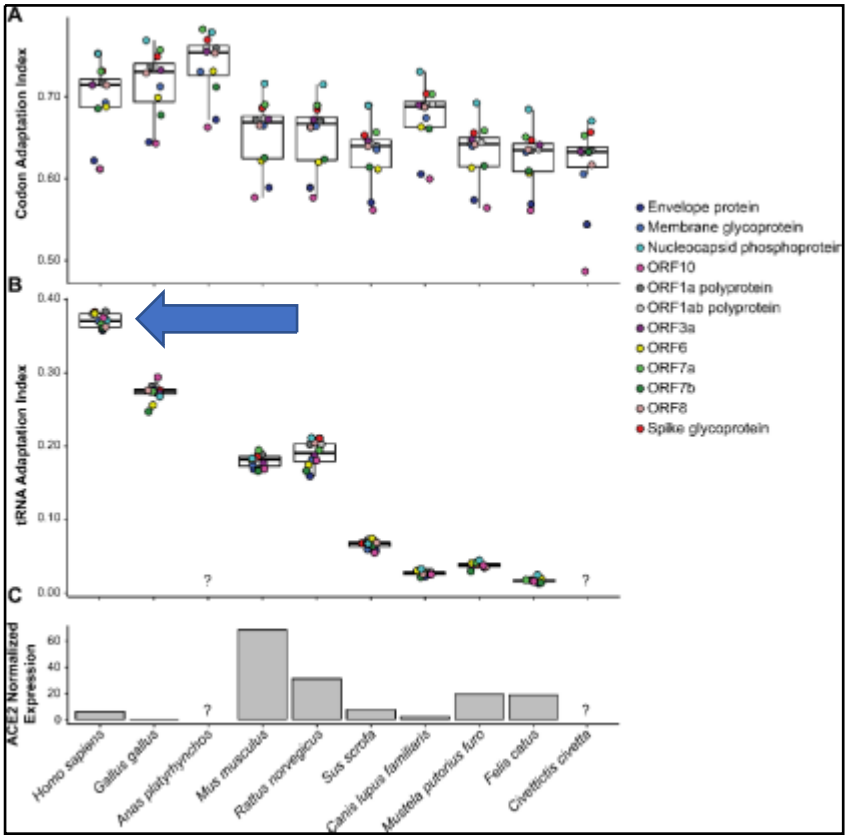
This will not be used to adjust the likelihoods.

Current likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

[112] https://www.tandfonline.com/doi/full/10.1080/22221751.2020.1817796

Evidence: The extraordinary pre-adaption of SARS-CoV-2 for human cells is demonstrated by a paper looking at a tRNA adaption index.[113]

"The proteome of SARS-CoV-2 is mainly composed of the replicase polyprotein (ORF1ab) and of structural proteins: the spike glycoprotein, the membrane and envelope proteins, and the nucleoprotein [41]. Based on the genomic codon usage of each of the possible host species, we compute the codon adaptation index (CAI) and the tRNA adaptation index (tAI) to estimate the translational efficiency of SARS-CoV-2 proteins in each host (Fig 3A and 3B and S2 Table). Humans are among the top three species whose CAIs are mostly over 0.70, together with ducks and chickens. In terms of the tAI, humans show the highest translational adaptation among all others, followed by chickens, and, to some extent, mice and rats. On the other hand, cats, ferrets, pigs, and dogs are less translationally adapted than humans both by CAI and tAI."



As shown in panel B above, the tRNA Adaption Index is highest, by far, for humans (blue arrow) followed by the red junglefowl. This is additional evidence of the extraordinary adaption of SARS-CoV-2 to humans from the very beginning. This also is the first evidence of a reasonable intermediate host but based only on these *in silico* data.

This will not be used to adjust the likelihoods.

Current likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

[113] https://journals.plos.org/ploscompbiol/article?id=10.1371/journal.pcbi.1008450#pcbi.1008450.s004

Evidence: Evidence of Lax procedures and disregard of laboratory safety protocols and regulations in China, including the Wuhan Institute of Virology

A collection[114] from the Chinese Q&A website, https://www.zhihu.com/, of first-hand documentation of laboratory safety breaches and incidents within a large number of laboratories with diverse research subjects and purposes in the People's Republic of China (PRC) is provided. The laboratories involved include Chemistry labs, Biolabs, Computer labs as well as Physics and Engineering labs.

From this first-hand documentation, we obtained evidence of relaxed safety regulations and frequent breaches of such regulations, with reasons ranging from poor training/education on lab safety and chronic ignorance of safety rules, to intentional breaches of protocols for purposes other than the research projects of the lab(s) of which the breach was documented in.

Such breaches often resulted in safety accidents ranging from physical injury, chemical burns, chemical leaks, and damage to property, to lab-acquired infection and escape of in-lab pathogens. With consequences ranging from personal-level to institution-wide impacts.

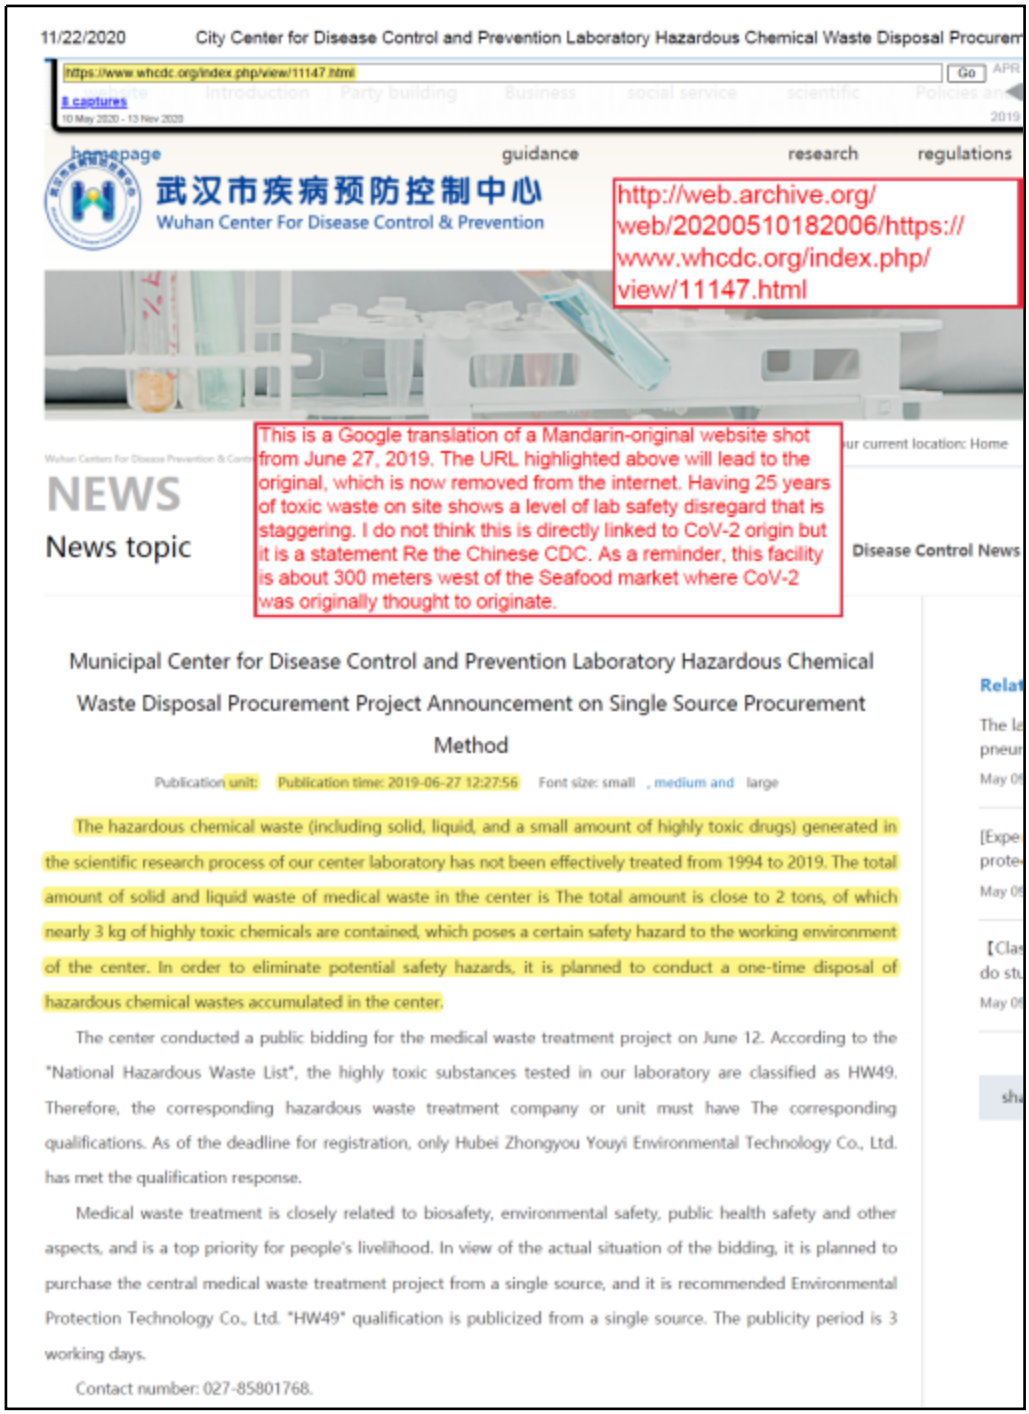
Here is the reference to the State Department cables concerning safety concerns at the WIV.[115]

The following document shows that in June 2019, the Chinese CDC was soliciting for the removal of 25-years-worth of solid and liquid medical waste. The total weight is close to two tons including three kg of highly toxic waste.

This is a Google translation of a Mandarin-original website shot from June 27, 2019. The URL highlighted above will lead to the original, which now has been removed from the internet. Having 25 years of toxic waste on site shows a staggering level of disregard for lab safety.

I do not think this is directly linked to CoV-2 origin, but it is a statement about the Chinese CDC. As a reminder, this facility is about 300 meters west of the Seafood market where CoV-2 was first thought to have originated.

[114] https://zenodo.org/record/4307879#.X-yUo9gzbOh
[115] https://foia.state.gov/Search/Results.aspx?caseNumber=F-2020-05255

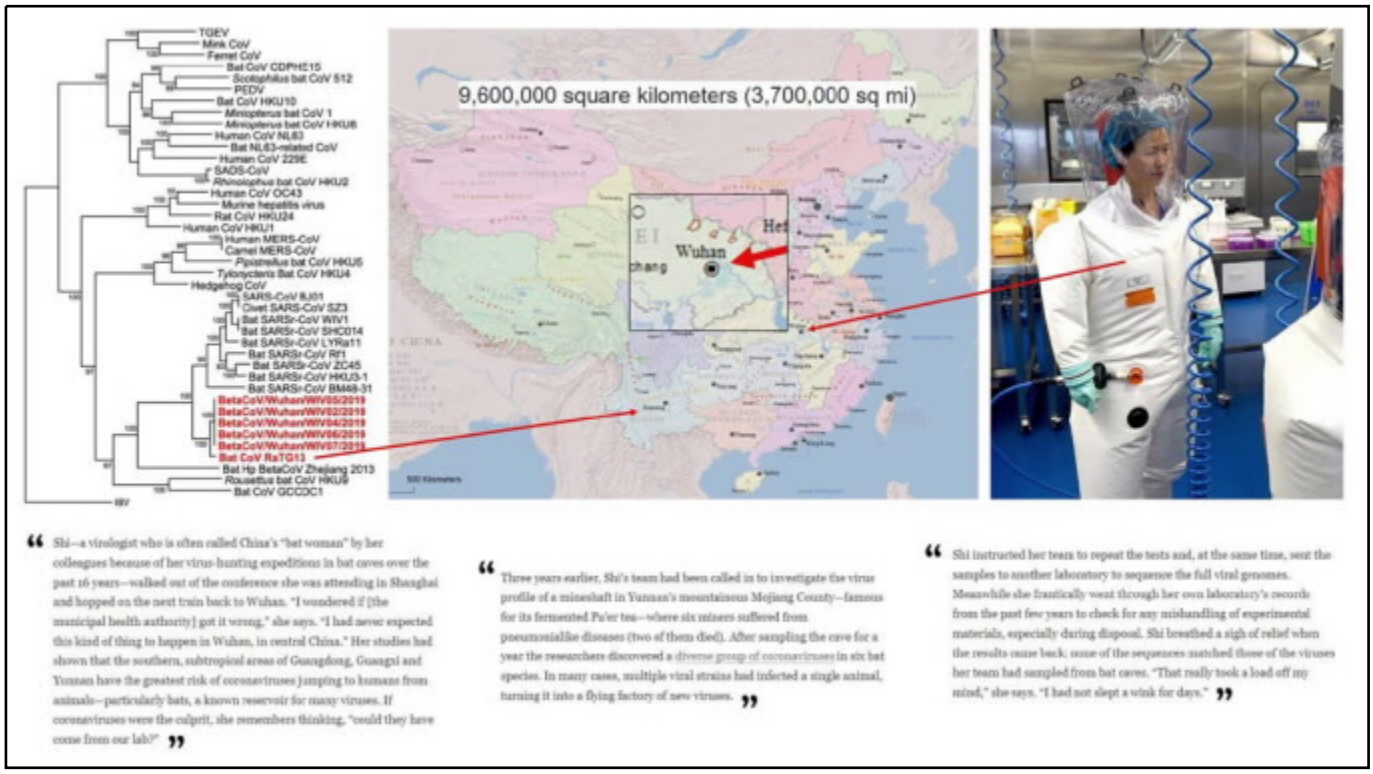


This will not be used to adjust the likelihoods.

Current likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

Evidence: The careful words of Dr. Shi do NOT say she did not have SARS-CoV-2 at the WIV.

This Figure contains quotes from an article about Dr. Shi and her reaction to the beginning of the COVID-19 pandemic.



Notice in the last frame Dr. Shi says two strange sentences:

Sentence 1: "…she frantically went through her own laboratory's records from the past few years to check for any mishandling of experimental materials, **especially during disposal**."

Why did she mention disposal? If you don't know what you are looking for this, "especially during disposal," is a bit of an odd qualifier. Other evidence from Wuhan suggests that, in fact, disposal may have been a likely source of the accidental lab release.

Sentence 2: "She breathed a sigh of relief when the results came back: none of the sequences matched those of the viruses her team had sampled from bat caves."

If Dr. Shi had created SARS-CoV-2 as a chimera, perhaps starting with one of those cave viruses, of course you would no longer have a sequence match. This is a probably truthful statement that leaves open the question of lab creation.

This will not be used to adjust the likelihoods.

Current likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

Evidence: The Good, the Bad, and the Ugly: a review of SARS Lab Escapes[116]

In 2003–04, in the wake of the SARS epidemics, there were multiple cases of laboratory acquired infection (LAI) with SARS within just a few months: first in a P3 in Singapore, then in a military P4 in Taipei and last a protracted case in a P3 in Beijing. The 'WHO SARS Risk Assessment and Preparedness Framework' has a good summary of these lab accidents:

Since July 2003, there have been four occasions when SARS has reappeared. Three of these incidents [note: Singapore, Taipei and Beijing] were attributed to breaches in laboratory biosafety and resulted in one or more cases of SARS. The most recent laboratory incident [note: in Beijing] resulted in 9 cases, 7 of which were associated with one chain of transmission and with hospital spread. Two additional cases at the same laboratory with a history of illness compatible with SARS in February 2004 were detected as part of a survey of contacts at the facility.[i.1]

This article reviews some of these cases and discusses briefly some of the insights that were gained from these at the time.

Another article along the same lines is, "10 incidents discovered at the nation's biolabs"[117] This included Dr. Baric's laboratory in which "(b)etween April 2013 and September 2014, eight individual mouse escapes were reported at the University of North Carolina-Chapel Hill. Several of the mice were infected with either SARS or the H1N1 flu virus."

Dozens of holes in BSL-4 'spacesuits'

As a key protection against the world's most deadly pathogens, including the Ebola virus, scientists in the BSL-4 labs at the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) at Fort Detrick in Maryland wear pressurized, full-body spacesuit-like gear and breathe purified air. Yet those suits ruptured or developed holes in at least 37 incidents during a 20-month period in 2013 and 2014, according to lab incident reports obtained by USA TODAY under the federal Freedom of Information Act.

This will contribute a 51%/49% contribution in favor of laboratory compared to zoonotic origin. There will be no confidence adjustment. The results from the calculations are shown below.

Evidence or process	Zoonotic Origin (ZO)	Laboratory Origin (LO)
Starting likelihood	0.011	0.989
The history of SARS laboratory accidents is consistent with the laboratory origin hypothesis		0.51
Impact of this evidence		Increases the likelihood of LO by 51/49 = 1.041
Impact of evidence calculation		1.041 x 0.989 = 1.030
Normalize this step of analysis	0.011/(0.011 + 1.030) = 0.011	1.030/(0.011 + 1.030) = 0.989

Adjusted likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

[116] https://gillesdemaneuf.medium.com/the-good-the-bad-and-the-ugly-a-review-of-sars-lab-escapes-898d203d175d
[117] https://www.usatoday.com/story/news/2015/05/29/some-recent-us-lab-incidents/25258237/

Evidence: Drs. Shi and Daszak use Wuhan residents as negative controls for zoonotic coronavirus seroconversion[118]

"As a control, we collected 240 serum samples from random blood donors in **Wuhan >1000 km away from Jinning & where inhabitants have a much lower likelihood of contact with bats due to its urban setting**" [emphasis added]. As expected, 0/240 samples from the patients from Wuhan had a positive serological evidence of prior coronavirus infection.

"The 2.7% seropositivity for the high-risk group of residents living in close proximity to bat colonies suggests that spillover is a **relatively rare event**, however this depends on how long antibodies persist in people, since other individuals may have been exposed and antibodies waned."

In this paper from 2018, Drs. Shi and Daszak conclude that bat-to-human transfer is relatively rare for high-risk people living in close proximity to bat colonies and much less likely in Wuhan, a conclusion that does not support a hypothesis of bat-to-human transmission.

This will not be used to adjust the likelihoods.

Current likelihood: Zoonotic origin (0.2%), laboratory origin (99.8%).

[118] https://www.ncbi.nlm.nih.gov/pmc/articles/PMC6178078/

Evidence. The Bat Coronavirus RaTG13 has the Unique Genome Sequences Necessary to be the Precursor of SARS-CoV-2 Using the 'No See 'Em' Synthetic Biology Technology. ***The probability that RaTG13 acquired these 'No See 'Em' synthetic biology assembly sequences in nature is one in a billion.***

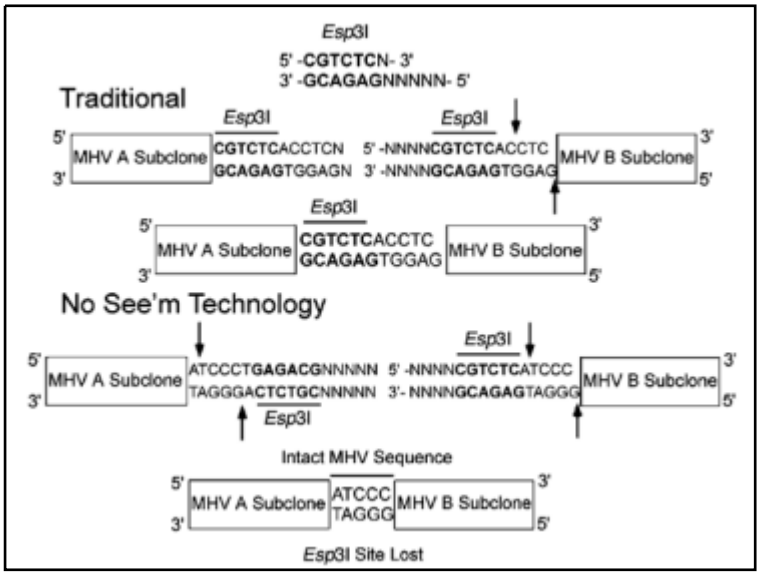
Summary.

- Synthetic biology techniques, like the engineered "No See 'Em'[119] restriction enzyme-enabled insertion method,[120] have been developed that, by design, extinguish the fingerprints of the insertion when only looking at the final genome.

- The use of these techniques is revealed however, if the precursor-product genome pair of such an insertion is available for inspection.

- **Hypothesis: the unique features of the SARS-CoV-2 Spike Protein, the receptor binding domain ACE2 contact amino acid residue region and the polybasic (furin) cleavage site, are the product of a genome insertion sequence into RaTG13 using engineered Esp3I restriction enzyme sites, the so-called, 'No See 'Em,' technology.**

- An example of the 'No See'm' Technology is shown below, taken from Baric and Sim.[1] By placing the restriction sites symmetrically on both strands of the cDNA, the resulting insertion no longer contains the identifying restriction site nts.



- According to Baric and Sims[1] "the type IIS restriction enzyme, Esp3I, recognizes an asymmetric sequence and makes a staggered cut 1 and 5 nucleotides downstream of the recognition sequence, leaving 256, mostly asymmetrical, 4-nucleotide overhangs

[119] Variably spelled 'No See 'Em,' 'No See 'um,' and 'No See'm.'
[120] https://www.researchgate.net/publication/8119695_Development_of_mouse_hepatitis_virus_and_SARS-CoV_infectious_cDNA_constructs

(GCTCTCN#NNNN). As identical Esp3I sites are generated every ~1,000,000 base pairs or so in a random DNA sequence, most restricted fragments usually do not self-assemble."

- Examination of RaTG13 identified two Esp3I cleavage sites in the Spike Protein gene, at nts 1366 and 2941 (positions 22,910 and 24,485 in the entire genome).

- As expected from the above rarity of such sites in an approximately 3800 nt gene, SARS-CoV-2 has no Esp3I sites in its SP gene. Neither do twelve other coronaviruses, including SARS-CoV-1, MERS, and other related human or bat coronaviruses.

- From all of the species other than bat RaTG13 gene source, the frequency of Esp3I sites **at any location** is 2 in 54,131 nucleotides or 0.000036947. If we assume the possibility of the occurrence of such a site at a given nucleotide is independent of any other nucleotide, then it is possible to use a binomial distribution calculation to determine the probability of 2 Esp3I sites in 3809 nucleotides for the bat RaTG13 gene. This calculation yields a probability of at least 2 sites anywhere in the Spike Protein gene of 0.009 or about one in a hundred. The probability of exactly 2 sites is 0.0086.[121]

- The 5' restriction site in RaTG13 begins at aa residue 455L, identified by Andersen et al, Nature, 2020. as the start of the "receptor-binding domain ACE2 contact residues." The downstream amino acids from this site are critical for why RaTG13 has such poor affinity for human ACE2 and the substitutions in CoV-2 are precisely why CoV-2 has such high affinity for human ACE2, why CoV-2 seems so 'preadapted' to human infections, etc. So this is the most important part of CoV-2 in explaining its ACE2 binding and infectivity. Further downstream is arguably the second most important site, the polybasic (furin) cleavage site.[122] Polybasic cleavage sites have not been observed in related 'lineage B' betacoronaviruses,' according to Andersen et al, Nature, 2020. and so there has been much speculation about how this site was acquired.

- The 3' restriction site in RaTG13 is at residue 980L. There is no protein-based rationale for this position.

- Comparing the nt sequences between RaTG13 and CoV-2, at the 5' restriction site, they are two codons in which only 2 of 6 nt bases are shared but, despite this low nt sequence homology, they are in fact synonymous base substitutions.

- Comparing the nt sequence between RaTG13 and CoV-2 at the 3' restriction site, this site has 5 of 6 identical nts with a single synonymous change in CoV-2 which destroys the restriction site. This is the only such five nt site in the RaTG13 spike protein gene and so

[121] Statistical analysis provided by Dr. Martin Lee, PhD, Adjunct Professor of Statistics, UCLA Fielding School of Public Health, UCLA, Los Angeles, CA.
[122] https://www.biorxiv.org/content/10.1101/2020.08.26.268854v1

is the easiest site in which a one nt substitution can create or destroy an Esp3I restriction site.

- The probability of having the restriction sites at **exactly these locations** can also be calculated.[2] Since there are 3809 nucleotides in the RaTG13 genome then, 3807 would not have a restriction site with probability (1-0.000036947), which was determined from the frequency of these restriction sites in other species. The other two sites would have this restriction site with probability 0.000036947. So the overall probability of this configuration has a probability of: $(1\text{-}0.00036947)^{3807} \times (0.000036947)^2 = 3.343 \times 10^{-10}$. This is a frequency of these site at their exact location being here from a natural process of approximately one in a billion.

- Dr. Zhengli-Li Shi, of the Wuhan Institute of Virology, collected the bat virus RaTG13 in 2013 and sequenced it between 2014 and 2018. In 2015, Dr. Shi and colleagues have also used the 'No See 'Em' technology' with a similar restriction enzyme, BgII, in the SARS-CoV reverse genetics system to generate chimeric coronaviruses. In that paper, they inserted a spike protein gene from a bat coronavirus into a mouse-adapted coronavirus, with a 'gain-of-function' phenotypic change.[123]

- **In conclusion:**

- **The bat coronavirus RaTG13 has two rare, Esp3I restriction sites strategically located to permit insertion of a genetic sequence that codes for the unique features of the SARS-CoV-2 Spike Protein, its receptor binding contact amino acids and its polybasic (furin) cleavage site, using the 'No See 'Em' synthetic biology techniques.**

- **This specific synthetic biology laboratory technique has been successfully performed previously by Wuhan Institute of Virology scientists to increase coronavirus infectivity.**

- **The probability these two sites are present and in their exact location in RaTG13 by an act of nature is one in a billion.**

[123] https://www.nature.com/articles/nm.3985

Text-Table. A record of the EspI restriction enzyme sites in the Spike Protein (SP) genes of fifteen coronaviruses, including RaTG13 and SARS-CoV-2. RaTG13 is unique in having two such sites, with SARS-CoV-2 and eleven other coronaviruses having no such site in the SP gene. The restriction sites were identified with the RestrictionMapper site algorithm: http://www.restrictionmapper.org/ .

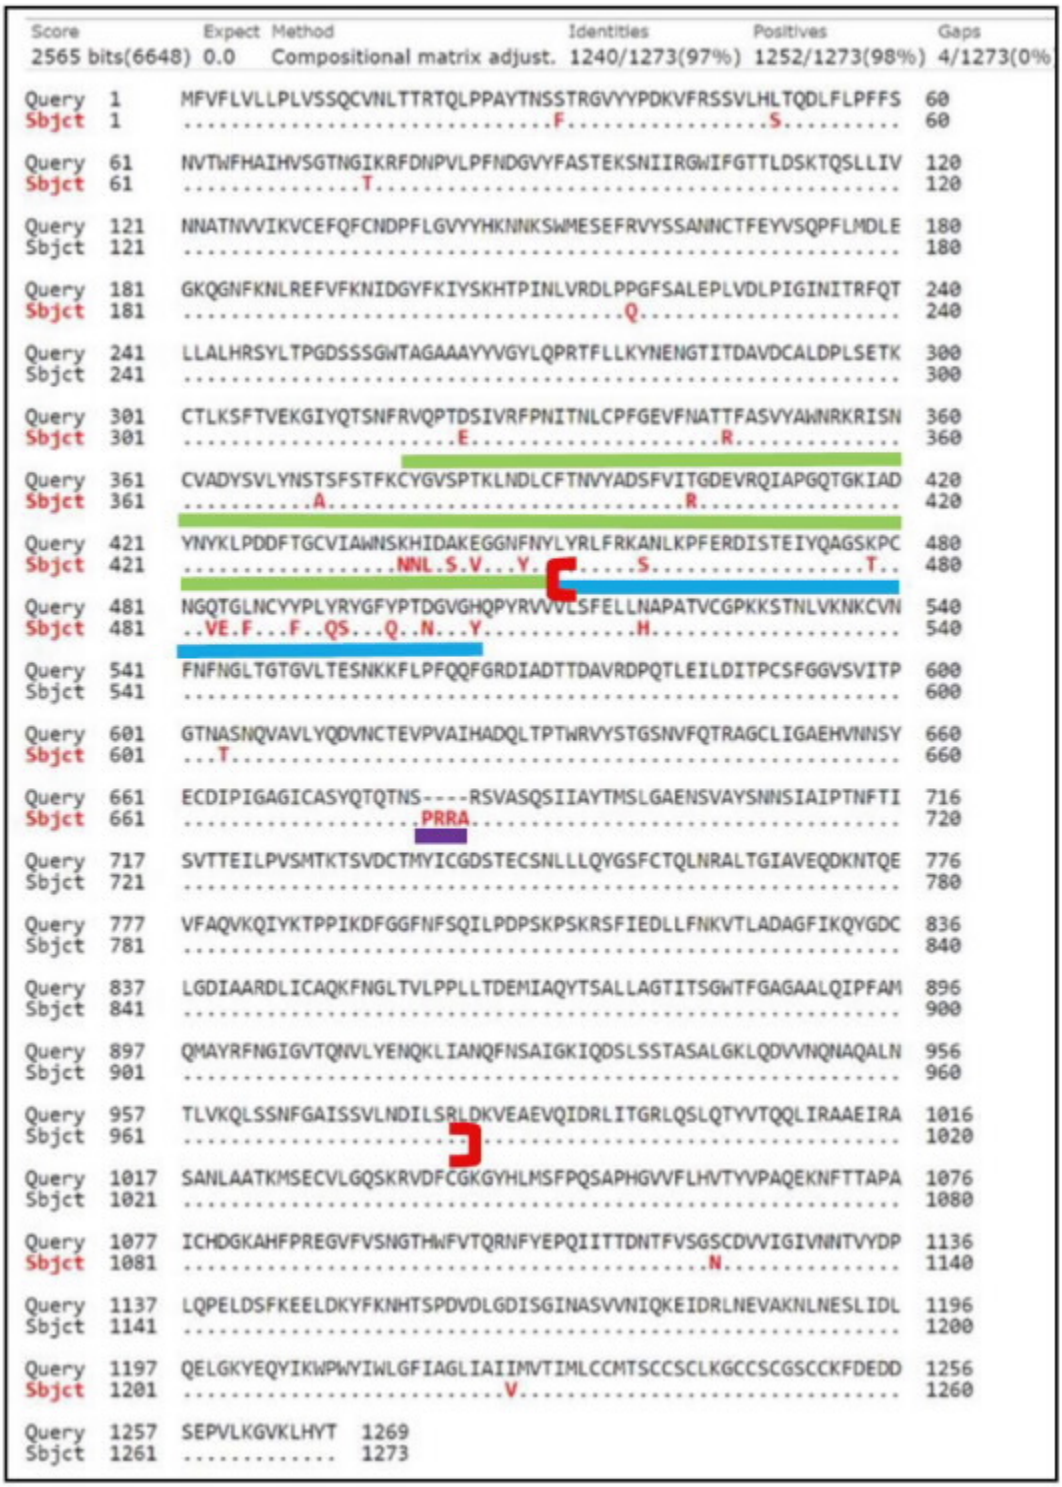
Figure. Comparison of Spike Protein amino acid sequence between RaTG13 (Query) and SARS-CoV-2 (Sbjct). Amino acid substitutions in CoV-2 are shown in red, single letter abbreviation. Green band; receptor binding domain. Blue band; receptor binding domain ACE2 contact residues (Andersen et al, Nature, 2020.). Purple band; polybasic (furin) cleavage site. Red brackets; Esp3I cleavage sites in RaTG13.



Because it has not been established that RaTG13 was the precursor of CoV-2 this evidence statement will not be used at this time to adjust the likelihoods of the origin. If additional information is obtained at a later date this may be revisited.

Likelihood from prior state is unchanged following this evidence analysis:

Zoonotic origin (0.2%) and laboratory origin (99.8%)

Evidence. Location, location, location: Based on the distance between known SARS-CoV-1 laboratory-acquired infections and the hospital of admission of the infected personnel, the WIV is within the expected hospital catchment for a CoV-2 LAI

Hypothesis. Laboratory-acquired infections (LAI) have the property that the hospital of admission of the personnel from the laboratory with the acquired infection are close together, specifically they are within 24.64 km from the laboratory.

Prior data from SARS-CoV-1. There were four LAIs of SARS-CoV-1 that can be used to determine the distance between the laboratory where the infection occurred and the hospital of first admission. The data are here:

SARS-CoV-1 Laboratory Acquired Infection (LAI)	Hospital of admission	Distance (Google Maps)	
In September 2003, a 27-year-old student from the National University of Singapore (NUS) was infected with the SARS virus due to improper experimental procedures	Singapore General Hospital (SGH)	6.3 km	
Baiji Mountain, Sanxia, Taiwan	Taiwan Hoping Hospital, Taipei, Taiwan	27.8 km	
№100 Yingxin Street, Xicheng District, Bejing	Union Hospital, Beiijing, China	7.3 km	
№100 Yingxin Street, Xicheng District, Bejing	Friendship Hospital, Beijing, China	17.6 km	
		mean = 14.75	
		SD = 10.1	
		95% Confidence Interval	14.75 ±9.887

Based on these four cases, the 95% upper confidence limit for the distance from LAI patients to the hospitals of admission is 24.6 km of the laboratory where the infection was acquired.

SARS-CoV-2. Although it is not clear which hospital the first patient was admitted to the following Text-Table contains all likely candidates.

SARS-CoV-2 Potential LAI Source	Hospital of admission	Distance (Google Maps)	Probability of being closer than the average results for SARS-CoV-1	Probability of being farther than the average results for SARS-CoV-1
Wuhan Institute of Virology, Wuhan, China	PLA Hospital, NO. 627 Wuluo Road, Wuchang District, Wuhan, China	4.8 km	0.094	0.906
Wuhan Institute of Virology, Wuhan, China	Wuhan Central Hospital, Wuhan, China	9.1 km	0.338	0.662
Wuhan Institute of Virology, Wuhan, China	Zhongnan Hospital, Wuhan, China	2.8 km	0.019	0.981
Wuhan Institute of Virology, Wuhan, China	Tongji Hospital, Wuhan, China	5.1 km	0.109	0.891
Wuhan Institute of Virology, Wuhan, China	Hubei Maternity and Child Health Care Hospital, Wuhan, China	4.4 km	0.075	0.925
Hypothesis: Given the distance from the SARS-CoV-1 laboratory where an LAI occurred to the hospital of admission for the lab workers who became infected, what is the probability that CoV-2 is also an LAI, given the distance from the hospitals where the first patients were seen to the WIV, the hypothesized source.			Probability calculations based on the use of a log-normal distribution for distances	Probability calculations based on the use of a log-normal distribution for distances

Based on the data for actual LAI for SARS-CoV-1 the distance between the WIV and the hospitals of admission for CoV-2 is consistent with the WIV being the origin for the LAI. There is no evidence the putative LAI for CoV-2 is any different than the known LAIs for CoV-1.

This evidence is not independent of other evidence that is based on location and so it cannot be used independently in the Bayesian analysis. It is included here for completeness.

Likelihood from prior state is unchanged following this evidence analysis:

Zoonotic origin (0.2%) and laboratory origin (99.8%)

Evidence. Dr. Shi successfully identifies a laboratory-acquired infection outbreak from Hanta virus in laboratory rodents.

Hantavirus
Laboratory rats
Recombination

ABSTRACT

An outbreak of hemorrhagic fever with renal syndrome occurred among students in a college (College A) in Kunming, Yunnan province, China in 2003. Subsequent investigations revealed the presence of hantavirus antibodies and antigens in laboratory rats at College A and two other institutions. Hantavirus antibodies were detected in 15 additional individuals other than the index case in these three locations. Epidemiologic data indicated that the human infections were a result of zoonotic transmission of the virus from laboratory rats. A virus was isolated from rats in College A and the full-length genome sequence revealed that this was a new Hantaan virus isolate, designated strain KY. Sequence analysis of the three genome segments indicated that this new isolate is a reassortant derived from human and rat Hantaan viruses. Further sequence analysis of the medium (M) genome segment revealed that it originated from a recombination event between two rat Hantaan virus lineages.

© 2010 Elsevier B.V. All rights reserved.

The significance of this evidence is that it demonstrates the methods used by Dr. Shi and the WIV to solve a laboratory-acquired infection outbreak. The methods described herein should be applied to the WIV in order to determine if CoV-2 was also a laboratory-acquired infection.

This will not be used to directly advance the Bayesian analysis.

Likelihood from prior state is unchanged following this evidence analysis:

Zoonotic origin (0.2%) and laboratory origin (99.8%)

Evidence. Bats hibernate when the temperature is below 10.5 C;[124] in Hubei province that begins in September and ends in May.

Average Hubei Temperature by Month

Month	Recommended Rate	Max Temp.	Min Temp.
Jan.	~	-17°C	-26°C
Feb.	√	-13°C	-23°C
Mar.	√√	-3°C	-14°C
Apr.	√√	7°C	-4°C
May.	√√	16°C	4°C
Jun.	√	23°C	11°C
Jul.	√	23°C	13°C
Aug.	√	21°C	11°C
Sep.	√√	15°C	4°C
Oct.	√√	6°C	-5°C
Nov.	√√	-5°C	-16°C
Dec.	√	-15°C	-23°C

Based on this evidence, they would have been hibernating at the time of the first human outbreak in the fall of 2019. Since this evidence is cumulative to the prior evidence from Dr. Shi that the bat host species for CoV-2 does not live in Hubei Province it will not be used to change the Bayesian analysis.

Likelihood from prior state is unchanged following this evidence analysis:

Zoonotic origin (0.2%) and laboratory origin (99.8%)

Fact Sheet: Activity at the Wuhan Institute of Virology

FACT SHEET

OFFICE OF THE SPOKESPERSON

JANUARY 15, 2021

Share

For more than a year, the Chinese Communist Party (CCP) has systematically prevented a transparent and thorough investigation of the COVID-19 pandemic's origin, choosing instead to devote enormous resources to deceit and disinformation. Nearly two million

people have died. Their families deserve to know the truth. Only through transparency can we learn what caused this pandemic and how to prevent the next one.

The U.S. government does not know exactly where, when, or how the COVID-19 virus—known as SARS-CoV-2—was transmitted initially to humans. We have not determined whether the outbreak began through contact with infected animals or was the result of an accident at a laboratory in Wuhan, China.

The virus could have emerged naturally from human contact with infected animals, spreading in a pattern consistent with a natural epidemic. Alternatively, a laboratory accident could resemble a natural outbreak if the initial exposure included only a few individuals and was compounded by asymptomatic infection. Scientists in China have researched animal-derived coronaviruses under conditions that increased the risk for accidental and potentially unwitting exposure.

The CCP's deadly obsession with secrecy and control comes at the expense of public health in China and around the world. The previously undisclosed information in this fact sheet, combined with open-source reporting, highlights three elements about COVID-19's origin that deserve greater scrutiny:

1. Illnesses inside the Wuhan Institute of Virology (WIV):

- The U.S. government has reason to believe that several researchers inside the WIV became sick in autumn 2019, before the first identified case of the outbreak, with symptoms consistent with both COVID-19 and common seasonal illnesses. This raises questions about the credibility of WIV senior researcher Shi Zhengli's public claim that there was "zero infection" among the WIV's staff and students of SARS-CoV-2 or SARS-related viruses.
- Accidental infections in labs have caused several previous virus outbreaks in China and elsewhere, including a 2004 SARS outbreak in Beijing that infected nine people, killing one.

- The CCP has prevented independent journalists, investigators, and global health authorities from interviewing researchers at the WIV, including those who were ill in the fall of 2019. Any credible inquiry into the origin of the virus must include interviews with these researchers and a full accounting of their previously unreported illness.

2. Research at the WIV:

- Starting in at least 2016 – and with no indication of a stop prior to the COVID-19 outbreak – WIV researchers conducted experiments involving RaTG13, the bat coronavirus identified by the WIV in January 2020 as its closest sample to SARS-CoV-2 (96.2% similar). The WIV became a focal point for international coronavirus research after the 2003 SARS outbreak and has since studied animals including mice, bats, and pangolins.
- The WIV has a published record of conducting "gain-of-function" research to engineer chimeric viruses. But the WIV has not been transparent or consistent about its record of studying viruses most similar to the COVID-19 virus, including "RaTG13," which it sampled from a cave in Yunnan Province in 2013 after several miners died of SARS-like illness.
- WHO investigators must have access to the records of the WIV's work on bat and other coronaviruses before the COVID-19 outbreak. As part of a thorough inquiry, they must have a full accounting of why the WIV altered and then removed online records of its work with RaTG13 and other viruses.

3. Secret military activity at the WIV:

- Secrecy and non-disclosure are standard practice for Beijing. For many years the United States has publicly raised concerns about China's past biological weapons work, which Beijing has neither documented nor demonstrably eliminated, despite its clear obligations under the Biological Weapons Convention.
- Despite the WIV presenting itself as a civilian institution, the United States has determined that the WIV has collaborated on publications and secret projects with

China's military. The WIV has engaged in classified research, including laboratory animal experiments, on behalf of the Chinese military since at least 2017.

- The United States and other donors who funded or collaborated on civilian research at the WIV have a right and obligation to determine whether any of our research funding was diverted to secret Chinese military projects at the WIV.

Today's revelations just scratch the surface of what is still hidden about COVID-19's origin in China. Any credible investigation into the origin of COVID-19 demands complete, transparent access to the research labs in Wuhan, including their facilities, samples, personnel, and records.

As the world continues to battle this pandemic – and as WHO investigators begin their work, after more than a year of delays – the virus's origin remains uncertain. The United States will continue to do everything it can to support a credible and thorough investigation, including by continuing to demand transparency on the part of Chinese authorities.

Abstract

The Middle East Respiratory Syndrome coronavirus (MERS-CoV) recently spread from an animal reservoir to infect humans, causing sporadic severe, and frequently fatal respiratory disease. Appropriate public health and control measures will require discovery of the zoonotic MERS coronavirus reservoirs. The relevant animal hosts are liable to be those that offer optimal MERS virus-cell entry. Cell entry begins with virus spike (S) protein binding to DPP4 receptors. We constructed chimeric DPP4 receptors that have the virus-binding domains of indigenous Middle Eastern animals, and assessed the activities of these receptors in supporting S protein binding and virus entry. Human, camel, and horse receptors were potent and nearly equally effective MERS virus receptors, while goat and bat receptors were considerably less effective. These patterns reflected S protein affinities for the receptors. However, even the low-affinity receptors could hyper-sensitize cells to infection when S-cleaving protease(s) were present, indicating that affinity thresholds for virus entry must be considered in the context of host-cell proteolytic environments. These findings suggest that virus receptors and S protein-cleaving proteases combine in a variety of animals to offer efficient virus entry, and that several Middle Eastern animals are potential reservoirs for transmitting MERS-CoV to humans.

Keywords: virus-receptor interaction / virus entry / zoonotic infection

JVI Accepts published online ahead of print

Importance

Middle East Respiratory Syndrome (MERS) is a frequently fatal disease that is caused by a zoonotic coronavirus (CoV). The animals transmitting MERS-CoV to humans are not yet known. Infection by MERS-CoV requires receptors and proteases on host cells. We compared the receptors of humans and Middle Eastern animals, and found that human, camel and horse receptors sensitized cells to MERS-CoV infection more robustly than goat and bat receptors. Infection susceptibility correlated with affinities of the receptors for viral spike proteins. We also found that the presence of a cell-surface lung protease will greatly increase susceptibility to MERS-CoV, particularly in conjunction with low-affinity receptors. This cataloguing of human and animal host cell factors allows one to make inferences on the distribution of MERS-CoV in nature.

Introduction

The Middle East Respiratory Syndrome coronavirus (MERS-CoV) emerged into the human population in April 2012 (1). This enveloped RNA virus is acquired by respiratory spread, either from infected humans or non-human animals. In individuals with underlying co-morbidities such as diabetes, respiratory or renal disease, infection by this virus can cause widespread pneumonia (2, 3), with case fatality rates of ~ 40%. (4, 5). While possible treatment options for this devastating infection may be forthcoming (6, 7), longer-term approaches to limiting human MERS-CoV infections will come after identifying and quarantining the animal source(s) of this virus.

Bats are implicated as virus reservoirs, as several known bat CoV genomes closely match with MERS-CoV (8-10), and bats harbor the progenitors to human SARS-CoV (11). Camels are also suspected virus reservoirs, because MERS-CoV neutralizing antibodies are prevalent in camel herds from neighboring countries as well as Egypt and the Canary Islands (12, 13). Further, MERS-CoV RNA was detected in a camel herd in Qatar, and two individuals who became infected with the virus were in contact with these animals (14).

Notably, there may be several animal reservoirs, as phylogenetic analyses suggest that there have been multiple, geographically distinct MERS-CoV transmissions from animals to humans (15). Indeed, given that current human-to-human transmissibility indices are low (16), and that animals might asymptomatically and abundantly shed virus, the animal-to-human transmission route may well account for the majority of MERS-CoV infected patients.

While widespread sampling of Saudi Arabian animals will help to identify sources of the virus, a complementary strategy is to carefully assess the infection sensitivities of cells from different animal species. Several laboratories have identified MERS-CoV susceptible cell types, which include human, bat, rabbit and pig (17). Thus these animals express MERS-CoV susceptibility factors, including the MERS-CoV receptor, dipeptidyl peptidase 4 (DPP4; also known as CD26) (17) and quite likely the proteases that cleave the MERS-CoV S proteins and allow them to refold into membrane fusion-active forms (18, 19). The widespread and relatively conserved nature of these susceptibility factors likely accounts for the remarkable polytropic character of MERS-CoV.

What is not known, however, are the relative extents with which each animal DPP4 sensitizes cells to MERS-CoV infection. Organizing animal DPP4s according to their affinity for MERS-CoV, and to their effectiveness at supporting virus entry, will add to our understanding of animal reservoirs and virus transmission pathways. Furthermore, comparative analyses of animal DPP4s and associated host proteases will address important questions concerning MERS-CoV adaptation toward a more narrow range of species, including humans. Our results reveal a hierarchy in animal DPP4 abilities to sensitize cells to MERS-CoV infection, and also demonstrate that the presence of a relevant host protease can potentially alter this hierarchy.

Materials and Methods

Cells. 293β5, 293T, and 293EBNA and Vero E6 cells were maintained in DMEM-10 [Dulbecco modified Eagle medium (DMEM) supplemented with 10% heat-inactivated fetal bovine serum (FBS, Atlanta Biologicals), 100 IU/ml penicillin, 1 mg/ml streptomycin, 0.1 mM non-essential amino acids, 1 mM sodium pyruvate, 10 mM HEPES, and 2 mM L-glutamine (Hyclone)]. 293″5 and 293T cells were obtained from Drs. Christopher Wiethoff and Edward Campbell at LUMC. Mouse astrocytoma DBT cells were maintained in MEM-7.5 [Minimal essential medium (MEM) supplemented with 7.5% FBS, 10% tryptose phosphate broth (Difco), 100 IU/ml penicillin, 1 mg/ml streptomycin, and 2mM L-glutamine. All cell lines were propagated as adherent monolayer cultures.

Plasmids and construction of chimeric receptors. Untagged mouse (Ms) DPP4 plasmid pCMV-Kan/Neo-msDPP4 (GenBank BC022183) and C-terminal Myc/FLAG tagged human (Hu) DPP4 plasmid pCMV6-Entry-huDPP4 (NCBI Reference Sequence NM_001935) were purchased from OriGene. pCMV-Kan/Neo-msDPP4 was PCR-amplified with the following primers: AsiSI-forward 5' –TTGGCGATCGCCATGAAGACACCGTGGAAG-3'; NotI-reverse 5' –ATAGTTTAGCGGCCGCAGTGTAAGGAGAAGCACTGCT-3'. Subsequently, MsDPP4 was then cloned into pCMV6-Entry vector between 5'AsiSI and 3'NotI sites. The MsDPP4 vector was then PCR-amplified with the following primers: forward 5'–AGTACCACGGGCTGG-3'; reverse 5'- CTCTTCATAAACCCAGTC-3'. Synthetic DNAs encoding DPP4 blades 4 and 5 of human (Hu), horse (Hs, NCBI Reference Sequence: NC_009161.2), Dubai camel (Cm), goat (Gt, GenBank: AJPT00000000), and pipistrelle bat (Bt, GenBank: KC249974.1) were purchased from GenScript. The camel sequence was obtained by RT-PCR and sequencing from a *Camelus dromedarius* cell line (Dubca; ATCC, CRL 2276). Gibson assembly techniques (20) with the In-Fusion HD Cloning System (Clontech) were then used to insert the various animal DPP4 blades 4 and 5 (b4-5) into the MsDPP4 vector. The chimeric DPP4 receptors were designated as human [Hu(b4-5)], horse [Hs(b4-5)], camel [Cm(b4-5)], goat [Gt(b4-5)] and bat [Bt(b4-5)]. pCAGGS-TMPRSS2-FLAG and pCAGGS-TMPRSS2(S441A)-FLAG were previously constructed (21). Codon optimized MERS S containing a C9 tag was

purchased from Genscript and subsequently cloned into pcDNA3.1+ between EcoRI and NotI restriction sites.

Transfections. Transfections were performed with polyethylenimine (PEI, Polysciences) at a ratio of 1ug DNA: 3ug PEI. DNA:PEI complexes were incubated in OptiMEM (Life Technologies) for 15 minutes before added to plated cells in 6-well or 12-well test plates. One day post transfection, cells were washed with 0.9% saline, treated with trypsin (Hyclone), and then replated into 96-well test plates for later inoculation with pseudoviruses or authentic MERS-CoV.

Pseudovirus production and transduction assays. To generate VSVluc-MERS S pseudovirus, 293T cells were transfected with pcDNA3.1-MERS-S-C9 via PEI transfection. One day post transfection, cells were then inoculated with G*ΔG-VSV-luc, as per recommendations in (22). One day later, media were collected, clarified for 10 minutes at 1,000 x g, labeled as VSVluc-MERS S, and stored at -80C. For transduction assays, 293β5 or DBT cells were first transfected via PEI with the various chimeric DPP4 receptor constructs. After 24 h, cells were then transduced with VSVluc-MERS S. 16 hours after pseudovirus transduction, cells were washed with serum-free DMEM (SFM) and then lysed with 1x passive lysis buffer (Promega). Luminescence was measured after addition of luciferase substrate (Promega) using a Veritas microplate luminometer (Turner BioSystems).

MERS CoV infections. DBT cells were transfected with chimeric DPP4 cDNAs and inoculated 24 h later with MERS-CoV at 1 pfu per cell. After 1h at 37°C, inocula were removed and cells incubated for 48h. Supernatants were collected and infectivities were determined by plaque assays on Vero 81 cells.

MERS S1-Fc production. The MERS S1 coding sequence (human codon-optimized) was PCR amplified with the following primers: NotI-forward 5'-CTAGCGGCCGCAGCCATGATCCATAGCG TCTTCCTCC-3'; ClaI-reverse 5'-ATCGATATACTTACCTGTGGGGGT CAGAGTGGAGGGGGT-3'. The resulting S1-encoding fragment was then recombined via Gibson assembly techniques with a vector fragment that

JVI Accepts published online ahead of print

was PCR amplified from pCEP4-sMHVR-Ig (23) using the following primers: ClaI-forward 5'-ACCCCCTCCACTCTGACCC CCACAGGTAAGTATATCGAT-3'; NotI-reverse 5' GGAGGAAGACGCTATGGATCATGGCTGCGGCCGCTAG-3'.

The resulting plasmid, designated as pCEP4-MERS-S1-Fc, was transfected using PEI into 293 EBNA cells, which contain the EBV EBNA-1 protein necessary for stable maintenance of transfected pCEP4 plasmid DNAs. After 36 h, cells were washed with pre-warmed SFM and incubated in SFM for ~16 h. Conditioned media were collected, cells were returned to DMEM-10 for ~8 h, then placed back with SFM for a subsequent round of S1-Fc secretion and collection. Pooled collections of S1-Fc – containing SFM were concentrated ~ 100 fold using Centricon-30 centrifugation devices (Millipore). Quantifications of MERS S1-Fc protein yields were determined by comparisons with serial dilutions of human IgG standards on western immunoblots, with band intensities quantified by CCD Alphaview instrumentation and software (Protein Simple).

MERS S1-Fc Blocking Assay. DBT cells were transfected with the various chimeric DPP4 receptor constructs in 12-well cell culture plates at seeding density of $3.8x10^5$ cells/well. One day post transfection, cells were trypsinized and re-plated in 96 well plates. MERS S1-Fc was added at indicated concentrations and incubated at 37°C for 1 hour, followed by addition of VSVluc-MERS S pseudoviruses. At 16 h post transduction, cells were lysed with 1X passive lysis buffer (Promega) and luminescence were measured as described above.

Flow Cytometry. DBT cells were transfected with the various chimeric DPP4 receptor constructs, at 1 ..g DNA per 10^6 cells. One day later, cells were detached from plates using Accutase (Millipore), suspended and washed in PBS-2% FBS. Cells were incubated with rabbit anti-FLAG antibody (1:500) (Sigma F7425) or MERS S1-Fc (~50nM) for 1 h on ice, followed by either Alexafluor488 goat anti-rabbit IgG (1:1000) (Lifetech) or Dylight549 goat anti-human IgG (1:1000) (Pierce), for 1h on ice. Cells were analyzed using an LSR Fortessa (BD Biosciences). Data were analyzed using FlowJo software.

JVI Accepts published online ahead of print

TMPRSS2 titration and transduction. DBT cells were PEI transfected in 12-well test plates with Ms DPP4, Hu(b4-5) or Bt(b4-5) with increasing TMPRSS2 or TMPRSS2(S441A). One day post transfection, cells were reseeded into 96-well plates. 6h later, the cells were transduced with VSVluc-MERS S and luminescence was measured 16 h post-transduction as described above.

Cell lysis and western blot analysis. Transfected cells were dissolved on ice for 15 min with TX100 buffer (1%Triton X-100/25mM TrisHCl [pH 7.4]/125 mM NaCl/0.1% protease inhibitors/ 1mM $MgCl_2$, 1mM $CaCl_2$), and nuclei removed by centrifugation. Post-nuclear supernatants were mixed 1:5 with SDS buffer (0.375 M TrisHCl [pH 6.8], 10% SDS, 6% 2-mercaptoethanol, 30% glycerol, 0.375 M TrisHCl [pH 6.8]) , and heated to 95C for 5 min. 30,000 cell equivalents were subjected to SDS-PAGE and proteins transferred to PVDF membranes (Millipore). DPP4 and TMPRSS2 proteins were detected with rabbit anti-FLAG (1:1000; Sigma F7425) and peroxidase-conjugated goat anti-rabbit IgG (1:5000; Pierce). Actin was detected with anti-″-actin peroxidase (1:20,000; Sigma). Membranes treated with ECL substrate (Pierce) were detected with FluorChem E and analyzed with Alphaview software (Protein Simple).

Statistical analyses. Statistical tests of significance were performed using the Holm-Sidak multiple Student's t-test procedure.

JVI Accepts published online ahead of print

Results

Chimeric human – mouse DPP4 receptors. CD26/DPP4 is a type II integral membrane protein, organized as a homodimer, with each monomer comprising a membrane-proximal ±/″ hydrolase domain and a membrane-distal ″-propeller domain (24) (Fig. 1A). The receptor-binding domains (RBDs) of the MERS-CoV S proteins (25) bind to human blades 4 and 5 of the 8-blade ″-propeller (26, 27). Human blades 4 and 5 also bind extracellular adenosine deaminase (ADA) (28), tethering this enzyme onto DPP4+ T cells to provide local control of adenosine levels (29). Murine DPP4, however, does not bind ADA (28), and murine DPP4 is indeed divergent from human in the blade 4-5 region. This divergence suggests that murine DPP4 cannot bind MERS-CoV S proteins and provides an explanation for the observation that MERS-CoV does not infect murine cells (17) or mice (30, 31).

However, murine and human DPP4s are conserved at the flanking blade 3 and 6 regions. Therefore, we reasoned that murine blades 4 and 5 could be replaced with orthologous animal blades, without perturbing the seams between the murine and animal blades. We expected that, unlike the parental murine DPP4, some chimeric DPP4s would function as MERS-CoV receptors, with the receptor functions reflecting the complete, native, animal DPP4s. This expectation was based on the fact that the close contacts between MERS-CoV S and human DPP4 are within the blade 4-5 region (17, 27).

We obtained cDNA clones encoding C-terminal myc and FLAG-tagged mouse (Ms) and human (Hu) DPP4s, and synthetic DNAs encoding Ms and Hu blades 4 and 5. Gibson assembly techniques (20) were then used to replace the Ms blades with the synthetic human DNA, and to reciprocally replace Hu with Ms blades. This provided the construct designated Hu(b4-5), with humanized amino acids 194 – 350 in the Ms DPP4 background (Fig. 1A). The parental and chimeric DPP4s were evaluated by assessing their abilities to sensitize mouse DBT cells to MERS-CoV. Mouse DBT cells were chosen for these experiments because, unlike many human cell lines, they were completely refractory to MERS-CoV infection, and thus might be rendered susceptible by receptor expression. In a

JVI Accepts published online ahead of print

first test, we challenged DPP4-transfected DBT cells with VSV pseudoparticles (22) that encode firefly luciferase (luc) and also display MERS S on their surfaces (VSVluc-MERS S). These pseudoviruses serve as surrogates of authentic MERS-CoV, with Fluc activities after transduction being readouts of potential cell susceptibility to infection. By these assays, both Hu DPP4 and the chimeric Hu(b4-5) equally sensitized cells to transduction, while the Ms DPP4 did not (Fig. 1B). Notably, the reciprocal chimeric Hu DPP4 with Ms blades 4-5 also did not sensitize cells to transduction (data not shown). In a second test, we challenged the DBT-cell transfectants with authentic MERS-CoV, and measured virus output titers by plaque assays. The HuDPP4 and Hu (b4-5) DPP4-positive cells supported MERS-CoV infection equally well (Fig. 1C). Thus, in these assays, the readouts from VSVluc-MERS S pseudovirus transductions paralleled the readouts from authentic MERS-CoV infections. Additionally, the human DPP4 was indistinguishable from a mouse DPP4 that contained only human blades 4 and 5.

To further compare Hu DPP4 with the Hu(b4-5) DPP4, we measured affinities of these receptors for MERS S proteins. Coronavirus S1-Fc proteins are surrogates for authentic viral S (32) and MERS S1-Fc are known to block both MERS S-mediated transduction and MERS-CoV infection (33). To compare the affinities of the two DPP4s for viruses, we introduced graded doses of MERS S1-Fc proteins before and during VSVluc-MERS S transduction. While control N-CEACAM-Fc proteins (23) had no effect on transduction (data not shown), the S1-Fc proteins blocked transduction into Hu and Hu(b4-5) DPP4-positive cells, and with equal effectiveness (Fig. 1D). These analyses further demonstrated that S1-Fc 50% inhibitory concentrations (IC_{50}) were ~10 nM for both receptors. These ~10 nM affinity measurements were similar to the recently-reported Biacore determination of 17.6 nM affinity between human DPP4 and S1 (26).

Chimeric animal DPP4 receptors. These results from comparisons of Hu and Hu(b4-5) DPP4s engendered confidence that animal blade 4-5 regions, placed into the Ms DPP4 context, would reflect the complete animal DPP4s, at least with respect to MERS-CoV entry. Therefore, we proceeded with additional blade 4-5 replacements from other animals. For this study, we focused on DPP4s from indigenous Middle East animals that are considered

to be potential carriers of MERS-CoV. This included Dubai camels, from which we obtained the complete DPP4 cDNA sequence by RT-PCR and RACE. The camel DPP4 sequence was deposited in NCBI Gene Bank (accession # KJ002534) and was also compared with other animal DPP4s in a phylogenetic analysis (Fig. 2). The comparisons also included Pipistrelle bats, one of ~ 20 bat genera residing in Saudi Arabia. We note, however, that Pipistrellis kuhlii is the native Saudi Arabian species, while Pipistrellis pipistrellis is the bat DPP4 that we evaluated.

DPP4 blade 4-5 amino acid sequences from these animals diverge increasingly from humans in the order shown in Fig. 3: horses, camels, goats, bats, and then mice. With respect to the 14 residues contacting S proteins at < 3.6 angstroms ((27) and Fig. 3, arrows), horses have zero, camels two, goats and bats three, and mice five residues diverging from humans. Of note, K392 in blade 6 is close to MERS-CoV S1 in the co-complex structure (27). While blades 4-5 make the key contacts, it is possible that this residue, which also differs among species, could have an additional small effect on MERS-CoV binding.

All of the chimeric DPP4s sensitized DBT cells to VSVluc-MERS S transduction, but to varying levels (Fig. 4A). Human, horse and camel receptors were similarly effective, while goat and bat conferred significantly lower susceptibilities. These trends were also identified in results of authentic MERS-CoV infections (Fig. 4B). These trends did not arise from relative under-expression of the goat and bat DPP4 chimeras, as assessed by western immunoblotting (Fig. 4C). Notably, relative to the transduction assay results, the infection assays revealed far more prominent differences in the receptors' ability to sensitize cells (note that Fig. 4A and 4B y-axes are linear and logarithmic, respectively). This may reflect the fact that the transductions are necessarily single-cycle processes, while the 2-day infections involve multiple cycles of virus entry, release and re-entry, with each entry step being influenced by receptor abundance and affinity. Cumulative low-efficiency entry steps will multiply to create greater end-stage differences in authentic MERS-CoV yields.

JVI Accepts published online ahead of print

S protein affinities for DPP4 receptors. Cell-surface receptor levels and receptor affinities for viruses both contribute to sensitize for infection (34). Cell-surface receptor levels were assessed by flow cytometry, using antibodies to the extracellular FLAG epitope tags. Consistent with the western blot analyses (Fig. 4C), the results (Fig. 5) demonstrated that all chimeric receptors were expressed similarly on surfaces, with minor differences perhaps reflecting slight variations in the ~ 50% efficient plasmid DNA transfections. These results indicated that the reduced susceptibilities of goat and bat DPP4$^+$ cells did not result from diminished surface expression but rather from reduced affinities for MERS-CoV. The same DPP4$^+$ transfectants, assessed in parallel for S1-Fc binding, revealed quite similar S1 associations for all of the receptors except for bat and mouse. Notably, the similar S1 associations were observed amongst fairly divergent receptors.

While flow cytometry results revealed some S-protein affinity differences between the animal DPP4s, they did not provide quantitative binding data, and therefore we adopted the more sensitive approach of measuring affinities via S1-Fc-mediated blockade of MERS S pseudotype transduction. To this end, animal DPP4$^+$ transfectants were incubated with serial dilutions of S1-Fc, then challenged with VSVluc-MERS S. These experiments revealed that the human DPP4 chimeras had the highest affinities of ~ 10 nM for S proteins, with affinities being modestly lower for horse and camel receptors (Fig. 6). In four of four separate experiments, the S1-Fc affinities for Hu(b4-5) exceeded that of Hs(b4-5) and Cm(b4-5) DPP4 chimeras, however, the modest differences between these S1-Fc affinities were not statistically significant. Gt(b4-5), however, had significantly lower affinities of ~ 40 nM, while Bt(b4-5) receptors bound so weakly with S1-Fc that an accurate affinity determination was not obtained by this method (Fig. 6). These quantitative data concurred with the flow cytometric determinations (Fig. 5), and, in part, with DPP4 phylogenetic relationships (Fig. 2).

Role of TMPRSS2 proteases. In addition to S-binding receptors, S-cleaving proteases are principal host factors determining the efficiency of CoV entry (35). Indeed, the cell-surface serine protease TMPRSS2 can augment MERS-CoV infection by up to 100-fold (18, 19). To evaluate the role of TMPRSS2 in relation to DPP4 affinities for MERS-CoV, target cells were

JVI Accepts published online ahead of print

transfected with DNAs encoding both DPP4 and TMPRSS2, or with DPP4 and the control, catalytically-inactive TMPRSS2 (S441A) (36). The catalytically-inactive S441A TMPRSS2 DNA was indistinguishable from empty vector DNA and had no effect on subsequent MERS S-mediated transductions (data not shown). However, relative to the S441A mutant control conditions, TMPRSS2 significantly promoted MERS S-mediated transduction into all of the DPP4$^+$ cells, except those expressing mouse DPP4 (Fig. 7A). We noted a trend in which transduction into cells with relatively low-affinity receptors (Bt(b4-5) and Gt(b4-5)) were augmented by TMPRSS2 more substantially than the corresponding transductions into cells with higher-affinity receptors. Specifically, transduction into Bt(b4-5) and Gt(b4-5) receptor-positive cells was augmented by WT TMPRSS2 ~ 3.6 times more than the corresponding transduction into Cm(b4-5), Hs(b4-5) and Hu(b4-5) DPP4$^+$ cells. These intriguing findings demanded further investigation by TMPRSS2 titration. In the context of the far less adhesive Bt(b4-5) DPP4, TMPRSS2 stimulated virus entry approximately 10-fold (from ~2 to ~20-fold above background levels), while the TMPRSS2 stimulation was a less pronounced ~ 5-fold in the human DPP4 context (Fig. 7B). These were statistically significant differences as assessed by Student's t-test. Notably, by western blotting, we detected relatively constant DPP4 levels with increasing TMPRSS2 (Fig. 7B, bottom panels). TMPRSS2 was not readily detectable by western blotting at the plasmid input doses used (data not shown). However, as it is known that TMPRSS2 proteolyzes the SARS-CoV receptor, angiotensin converting enzyme 2 (21), and augments SARS pseudovirus entry (37), we further investigated DPP4 proteolysis at higher TMPRSS2 levels, and in human 293 cells. In these experiments, human DPP4 was clearly diminished with increasing TMPRSS2, similar to the receptor for SARS-CoV, but only at supraphysiologic TMPRSS2 levels (Fig. 7C). In sum, the main conclusion from these studies involving TMPRSS2, one of the principal MERS-CoV activating proteases, is that cells bearing receptors with low affinities for MERS-CoV will be rendered far more susceptible to infection if the appropriate proteolytic environments are in place.

Discussion

MERS-CoV preferentially infected cells expressing human DPP4, and its S1 domain bound to human DPP4 with higher affinity than to any of the other orthologous animal DPP4s. Thus it is possible that the MERS-CoVs (2012 and 2013 isolates), even with their limited residence in human hosts, are modestly "human-adapted". We suggest that the proximal source of the human-adapted MERS-CoV includes animals whose DPP4 proteins bind to MERS-CoV at near human DPP4 affinity. These animals are likely to maintain a MERS-CoV population that include variants with relatively high affinities for human receptors and thus become the founders that intrude into the human population. Our results suggest that camels and horses can harbor these human founder viruses. Goats and bats may be less prominent hosts for "human" MERS-CoVs, as their DPP4s are less adherent to the human MERS-CoV. However, a very recent report documenting susceptibility of two goat cell lines to MERS-CoV (38) makes it clear that goats cannot be excluded from animals potentially transmitting the virus to humans. Definitive exclusion from the MERS-CoV transmission processes applies to mice, and also ferrets, as a recent publication demonstrated that ferret DPP4 did not bind MERS S1 or support MERS-CoV infection (39). Quite likely there are several mammals entirely refractory to MERS-CoV binding and thus resistant to infection.

The affinity of the MERS-CoV S RBD for human DPP4 is ~ 17 nM (26). This value is ~ 10 times lower than SARS-CoV S RBD for human ACE2 (40). These findings suggest that the MERS-CoV could further adapt to the human DPP4, in the same ways that SARS-CoV adapted to humans. Indeed, the presumed animal precursors of human SARS-CoVs have affinities for ACE2 in the ~ 20-100 nM range (40), and the higher ~ 2 nM affinities of human-adapted SARS-CoV are considered to be central contributors to epidemic potential (41, 42). Thus careful monitoring of human and animal MERS-like CoV spike RBD changes is critical for assessing the likelihood of epidemic spread.

JVI Accepts published online ahead of print

421 It is notable, however, that there appears to be limited diversity in human MERS-CoVs.
422 Nearly identical MERS-CoVs have apparently transmitted from animal to human on more
423 than one occasion and in more than one geographic location (15). This observation is most
424 consistent with the notion that a single animal species, harboring MERS-CoV populations of
425 restricted genomic diversity, served as the reservoir for all human transmission thus far.
426 Furthermore, once in humans, while there is evidence of some genetic drift, there are no
427 changes in the MERS CoV spike RBDs (15). Even in virus isolates from patients with co-
428 morbidities that impaired anti-viral immune responses, and in whom virus might be
429 expected to persist, there is no evidence for changes in the MERS-CoV S RBD. While this
430 apparent genetic stability may simply reflect the small number of human infections and the
431 limited analysis of virus isolates, it is also possible that there is little selective force for
432 change at the level of virus-receptor binding.
433
434 A genetically stable MERS-CoV RBD suggests that binding affinity to the DPP4 receptor
435 may not be the most critical factor for adaptation to new species. MERS-CoV may have
436 stably adapted to an affinity range (~ 10 to ~ 20 nM) that allows for relatively similar
437 binding strength to many different animal DPP4s, i.e., human, camel and horse, and
438 consequent facile transfer between species. This affinity range, however, makes MERS-CoV
439 considerably less adherent than human SARS-CoV for its human ACE2 receptors. It is
440 possible that affinity requirements relate to virus entry events following receptor binding.
441 For SARS-CoV, endocytosis typically precedes S protein proteolysis and tethering of virus
442 to cells via S protein fusion machinery (43, 44). A durable virus:receptor connection may
443 therefore be necessary to maintain SARS-CoV on cells throughout endocytosis, or at least
444 until its S proteins refold into "fusion-intermediate" forms that directly connect the viral
445 and cellular membranes in a receptor-independent fashion. By contrast, the MERS-CoV,
446 appears to more rapidly adopt the fusion-intermediate, membrane-tethering forms at the
447 target cell plasma membrane, and thus may not require such long-lasting association with
448 receptors. This notion is supported by the fact that, unlike SARS-CoV (45), MERS-CoV
449 infection is quite sensitive to a membrane-impermeant inhibitory peptide that targets the
450 fusion intermediate forms (46). Additionally, MERS-CoV infection is remarkably increased
451 by TMPRSS2, a cell surface protease that quite likely cleaves and exposes S protein fusion

452 machinery immediately after receptor binding (19). Our results show that the weakly-
453 adhesive goat and bat DPP4s were especially assisted by TMPRSS2 (Fig. 7A and B),
454 suggesting that a low-affinity receptor can sensitize cells to infection as long as there are
455 protease co-factors available to cleave viral spikes and permit their transitions into
456 membrane fusion-active conformations.
457
458 While no MERS-CoV RBD mutations have been detected, adaptations in its membrane
459 fusion machinery have been repeatedly observed (15, 30). With the caveat of quite limited
460 data on MERS-CoV diversity, we suggest that the selective forces in MERS-CoV are at the
461 level past RBD interaction, and that the MERS-CoV has adapted to a more immediate cell
462 surface proteolysis, which does not demand this sort of stable association with receptors.
463 Indeed, high-affinity receptor interaction may not be a requisite feature of all CoV
464 infections. More relevant to infection may be the host cell proteases and the fusion
465 activation process. These views are consistent with previous hypotheses that enveloped
466 virus:receptor affinities adapt to the minimum levels sufficient to allow for the next
467 membrane fusion stage (34).

Figure legends

Fig. 1: *Properties of Hu and Hu(b4-5) DPP4s.* (A) DPP4 includes a transmembrane anchor (residues 7-28), a propeller ectodomain (54-497) and a protease ectodomain (508-766). Exchangeable blades 4-5 comprise residues 194-350. Hu and Ms DPP4s are in black and grey, respectively. (B) Mouse DBT cells were transfected with pcDNA3.1 (empty vector, EV) Hu, Ms, or Hu(b4-5) DPP4s, then transduced one day later with VSVluc-MERS S. At 16 h post-transduction, luminescence values (RLU) were measured and plotted. (C) Mouse DBT cells were transfected and infected one day later with MERS-CoV (MOI = 1). Secreted viruses were collected after 2 days and infectivities (PFU/ml) were determined by titration on Vero cell indicators. The hatched horizontal line indicates the lower limit of assay sensitivity. (D) Mouse DBT cells were transfected, and after one day, exposed to the indicated doses of MERS S1-Fc. After 1h at 37°C, VSVluc-MERS S were inoculated, with MERS S1-Fc concentrations remaining the same. At 16 h post-transduction, luminescence values were measured and the relative transduction values were quantified. The concentration of MERS S1-Fc at the IC_{50} value reflects the affinity of MERS S for the DPP4 receptors. In all data sets, the error bars indicate the standard errors of means from triplicate values. Each experiment was repeated twice.

Fig. 2: *Camel DPP4 sequence and phylogenetic relationships with other animal DPP4s.* The complete camel DPP4 open reading frame is deposited in NCBI Gene Bank; accession number KJ002534. Camel DPP4 was compared with the indicated animal DPP4 protein sequences using Molecular Evolutionary Genetics Analysis (MEGA; www.megasoftware.net) to generate the neighbor-joined phylogenetic tree. Numbers at each node are bootstrap values calculated from 500 trees, and represent the percentage of trees that resolved clades at the indicated endpoints. The scale bar indicates the relationship between line lengths and sequence dissimilarities (0.05 = 5 / 100 amino acid divergence). Asterisks denote the animal DPP4s evaluated in this report.

JVI Accepts published online ahead of print

Fig. 3: *Alignment of DPP4 blade 4-5 regions.* The human and animal DPP4 sequences are arranged in order of increasing divergence from human blades 4-5. Light grey highlighting denotes divergent amino acids. Underlined regions denote the conserved terminal residues comprising the junctions between animal blades 4-5 and the mouse DPP4. The arrows and associated numbers at the top point to residues that, in human DPP4, interface closely with the MERS S protein.

Fig. 4: *Transduction and infection of animal DPP4 – positive cells.* (A) DPP4-transfected DBT cells were transfected with the indicated DPP4s, transduced one day later with VSVluc-MERS S, and luciferase accumulations determined 16 h later. Standard errors are shown; n = 6. Statistical significance tests were performed by Student t-test. Data shown are representative of five independent results. (B) DBT cells were infected with MERS-CoV and infectivity in media quantified by plaque assay on Vero cells. The hatched horizontal line indicates the lower limit of assay sensitivity. Standard errors are shown; n = 3. Statistical significance tests were performed by Student t-test. (C) DPP4-transfected DBT cells were lysed at one day post-transfection (the time of pseudovirus and virus inoculation). DPP4 and actin proteins were visualized by immunoblotting.

Fig. 5: *Relative levels of anti-FLAG antibody and MERS S1-Fc binding to cells.* DBT cells transfected with pcDNA3.1 (EV), or with pCMV6-DPP4 chimeras, were incubated with anti-FLAG antibodies (1:500), or with 50 nM S1-Fc, for 1h at 4°C, and analyzed by flow cytometry. . The bars in each panel indicate positive cell windows, and the numbers under the bars indicate the percentage of anti-FLAG antibody and MERS S1-Fc positive cells. Positive cell percentages, after background subtraction, are listed to the right of the figure.

Fig. 6: *Transduction blockade by MERS S1-Fc*. DBT cells were transfected with DPP4 chimeras, incubated with the indicated concentrations of MERS S1-Fc for 1h at 37°C, and transduced with VSVluc-MERS-S. Luminescence values were measured 16 h later. Data were normalized to transduction in the absence of S1-Fc. The concentrations of S1-Fc at each IC_{50} reflect the affinities of MERS spikes for the different DPP4 receptors. The experiment was repeated four times with similar results. Error bars indicate the standard

JVI Accepts published online ahead of print

errors of means from triplicate values. Student's t-tests were used to assess significance of differences between human and animal DPP4 data; n.s. = not significant.

Fig. 7: *Effect of TMPRSS2 on MERS S-mediated transduction*. (A) DBT cells were co-transfected with the indicated DPP4 chimeras and either wild type (WT) or catalytically-inactive (S441A) TMPRSS2 plasmids, at 1 : 0.1 DPP4 : TMPRSS2 DNA ratios. After one day, cell subsets were transduced with VSVluc-MERS-S and luciferase values determined 16 h later. (B) DBT cells were transfected with Hu(b4-5) or Bt(b4-5) DPP4 chimeras, in conjunction with increasing amounts of wild type (WT) or catalytically-inactive (S441A) TMPRSS2 plasmids. After one day, cell subsets were transduced with VSVluc-MERS-S and luciferase values determined 16 h later. The dotted line designates the basal transduction level into MsDPP4 transfected cells. Holm-Sidak Student's t-tests were used to reveal the significance of the relative differences between transduction levels in the presence of S441A and WT TMPRs; p-values are indicated. To obtain the images beneath the graph, the luciferase-containing lysates were subjected to electrophoresis and the DPP4 and actin proteins visualized by western blotting. (C) 293T cells were transfected with HuDPP4 (1 ug), in conjunction with the indicated TMPRSS2 doses. After one day, the HuDPP4, TMPR and actin proteins in cell lysates were visualized by western blotting. The uncleaved (inactive) TMPRSS2 zymogen has a molecular weight of ~ 60 kDa and the proteolytically-active (WT) TMPRSS2 has ~ 25 kDa molecular weight.

SUMMARY

The recently reported Middle East respiratory syndrome coronavirus (MERS-CoV) is phylogenetically closely related to the bat coronaviruses (BatCoVs) HKU4 and HKU5. However, the evolutionary pathway of MERS-CoV is still unclear. A receptor binding domain (RBD) in the MERS-CoV envelope-embedded spike protein specifically engages human CD26 (hCD26)to initiate viral entry. The high sequence identity in the viral spike protein prompted us to investigate if HKU4 and HKU5 can recognize hCD26 for cell entry. We found that HKU4-RBD, but not HKU5-RBD, binds to hCD26, and pseudotyped viruses embedding HKU4 spike can infect cells via hCD26 recognition. The structure of the HKU4-RBD/hCD26 complex revealed a hCD26-binding mode similar overall to that observed for MERS-RBD. HKU4-RBD, however, is less adapted to hCD26 than MERS-RBD, explaining its lower affinity for receptor binding. Our findings support a bat origin for MERS-CoV and indicate the need for surveillance of HKU4-related viruses in bats.

INTRODUCTION

Coronaviruses (CoVs)are a group of enveloped, single-stranded RNA viruses taxonomically affiliated with the *Coronaviridae* family (Lai et al., 2007). Based on genotypic and serological characteristics, coronaviruses are further classified into four species: *Alpha*, *Beta*, *Gamma* (King et al., 2012), and *Deltacoronavirus* (Woo et al., 2009). Both alpha (alphaCoVs) and betacoronaviruses (betaCoVs) can cause human diseases (Lai et al., 2007). Most human infections related to alpha and betaCoVs, such as coronaviruses NL63, 229E, OC43, and HKU1 (reviewed in Wevers and van der Hoek, 2009), which commonly manifest as self-limiting common cold-like illnesses, though more severe diseases can develop in children, the elderly, and immunocompromised patients (Chiu et al., 2005; Gorse et al., 2009; Jean et al., 2013; Jevšnik et al., 2012). BetaCoVs, however, can also be life threatening and have pandemic potential (Ksiazek et al., 2003; Zaki et al., 2012). In 2003, the severe acute respiratory syndrome coronavirus (SARS-CoV), a lineage B betaCoV (Lu and Liu, 2012), caused >8,000 infections and >800 deaths worldwide (WHO, 2004). In 2012, another lineage C betaCoV named the Middle East respiratory syndrome coronavirus (MERS-CoV) (King et al., 2012) initially emerged in Saudi Arabia (Bermingham et al., 2012; Zaki et al., 2012) and then spread to other countries in the Middle East, Europe, Asia, and the US, leading to 701 confirmed cases as of June 16th, 2014 (WHO, 2014) with a fatality rate of approximately 35%. These unexpected outbreaks highlight the public health significance of betaCoVs, especially those in lineages B and C.

In addition to MERS-CoV, lineage C betaCoVs include two other important members: the bat coronaviruses (BatCoVs) HKU4 and HKU5 (Lu and Liu, 2012). These viruses were first identified as genomes in 2006 in lesser bamboo bats

(*Tylonycteris pachypus*) and Japanese pipistrelles (*Pipistrellus abramus*), respectively (Woo et al., 2006), and remain circulating in bats (Lau et al., 2013). Bats have been implicated as the largest reservoir of alpha and betaCoVs (Li et al., 2005b; Woo et al., 2012) and play pivotal roles in interspecies transmission of coronaviruses. This is best exemplified by SARS-CoV, which was recently shown to originate from Chinese horseshoe bats (Ge et al., 2013) and likely transmitted directly to humans (Ge et al., 2013) or through an intermediate host such as the palm civet (Guan et al., 2003). The emergent MERS-CoV might also be of bat origin, with gene fragments being identified in bats from both Saudi Arabia (Memish et al., 2013) and Africa (Ithete et al., 2013) that are nearly identical to those of MERS-CoV in sequence. Despite the fact that the BatCoVs HKU4 and HKU5 are bat derived, the potential of both viruses evolving for human adaptation cannot be excluded because of their close phylogenetic relationship with MERS-CoV (Lau et al., 2013; Lu and Liu, 2012; van Boheemen et al., 2012). Nevertheless, such presumptions are largely based on their genomic features and phylogenetic status (Lau et al., 2013; Woo et al., 2006, 2007).

Virus infections initiate with the binding of viral particles to host surface cellular receptors. Identification of the functional receptors represents a central issue in studying viral pathogenesis. Several host peptidases, including aminopeptidase N (Delmas et al., 1992; Yeager et al., 1992) and angiotensin converting enzyme 2 (hACE2)(Hofmann et al., 2005; Li et al., 2003), are utilized by coronaviruses for cell entry. A timely study on MERS-CoV identified a third peptidase recognized by coronaviruses: dipeptidyl peptidase 4 (DPP4 or CD26) (Raj et al., 2013). This enzyme is a type II transmembrane protein contributing to the regulation of various physiological processes (Gorrell et al., 2001) and is "hijacked" by MERS-CoV to infect humans. This work pioneered the study on lineage C betaCoVs for potential cellular receptors. However, it remains unknown which molecules can be recognized by BatCoVs HKU4 and HKU5.

The receptor binding of coronaviruses is mediated by the spike (S) protein embedded in the viral envelope (Lai et al., 2007). In most cases, S is further cleaved by host proteases into S1 and S2 subunits that function to engage receptors and mediate membrane fusion, respectively (Lai et al., 2007). High sequence identities (>50%) in S have been observed between BatCoV HKU4/HKU5 and MERS-CoV (Lau et al., 2013), raising the possibility that these two viruses may use human CD26 (hCD26) as a receptor.

We previously delineated the molecular basis of MERS-CoV binding to hCD26. The S1 domain responsible for hCD26 recognition is located in a C-terminal 240-residue receptor binding domain (RBD)that is composed of a core and an external subdomain (Lu et al., 2013). The latter engages the receptor and is therefore also designated as the receptor binding motif (RBM) (Lu et al., 2013). Despite the overall high sequence identities in S, amino acid variance in the RBD region, especially in the RBM region, is still obvious among BatCoV HKU4, HKU5, and MERS-CoV. Investigation of the hCD26-binding potential of BatCoVs HKU4 and HKU5 is therefore a key to understanding the biology of these bat-derived viruses, their potential threat to human health, and the evolutionary pathway of MERS-CoV.

In this study, we demonstrated that the RBD domain of BatCoV HKU4 (HKU4-RBD), but not the equivalent domain of BatCoV HKU5 (HKU5-RBD), can bind to hCD26. The binding affinity between HKU4-RBD and hCD26 was determined by surface plasmon resonance (SPR) to be within the micromolar range. Despite the observed lower affinity compared to that between the MERS-CoV RBD (MERS-RBD) and hCD26, we found that pseudoviruses containing BatCoV HKU4 S can infect human Huh7 cells via hCD26. The findings provided solid evidence that BatCoV HKU4 recognizes hCD26 as a cellular receptor, indicating its potential for adaptation to infect humans. We further solved the complex structure of HKU4-RBD bound to hCD26 to delineate the basis of receptor recognition. Our structural analysis and mutagenesis also demonstrated a similar hCD26-binding mode between BatCoV HKU4 and MERS-CoV, but the details of variant amino acid interactions responsible for the differences in binding affinity are distinct. Our work also supports the notion that MERS-CoV most likely originated from bats.

RESULTS

HKU4-RBD, but Not HKU5-RBD, Binds to hCD26

Our previous study determined the hCD26-interacting region as an RBD spanning amino acids 367–606 of the MERS-CoV S (Lu et al., 2013). The phylogenetic relatedness between BatCoV HKU4/HKU5 and MERS-CoV (Figure 1A) prompted us to further investigate the equivalent RBD regions (S amino acids 372–611 for BatCoV HKU4, HKU4-RBD; and 375–604 for BatCoV HKU5, HKU5-RBD) in these bat-derived viruses for their potential to bind hCD26. A recent phylogenetic analysis of 13 BatCoV HKU4 and 15 BatCoV HKU5 strains revealed that the S gene of MERS-CoV is more closely related to BatCoV HKU4 than to BatCoV HKU5 (Lau et al., 2013). Using only the RBD amino acids, a concise phylogenetic tree was constructed, and a sequence alignment comparison was performed among BatCoV HKU4, HKU5, MERS-CoV, and SARS-CoV. Consistently, BatCoV HKU4 clustered with MERS-CoV with high bootstrap support, together joining BatCoV HKU5 to form an evolutionary branch distant from SARS-CoV (Figure 1A). At the sequence level, MERS-RBD exhibits identity to HKU4-RBD slightly higher than HKU5-RBD does (54.4% versus 52.9%). Nevertheless, the pairwise alignment clearly showed two marked deletions located in a region corresponding to the external subdomain of MERS-RBD in HKU5-RBD, but not in HKU4-RBD (Figure 1B). According to our previous study (Lu et al., 2013), this subdomain is responsible for receptor recognition. Therefore, we hypothesized that BatCoV HKU4 stands a better chance than BatCoV HKU5 of engaging hCD26.

Thus, we prepared the individual Fc fusion RBD proteins and tested their binding avidities to human hepatoma Huh7 cells (CD26-expressing) via flow cytometry. Consistent with previous reports (Raj et al., 2013), Huh7 cells express abundant hCD26 protein on their membrane surface (Figure 2A). MERS-RBD, as a natural viral ligand of hCD26, avidly binds to Huh7 cells. HKU4-RBD, but not HKU5-RBD, also bound to Huh7 cells (Figure 2B). Compared to MERS-RBD, however, an evidently smaller fluorescence shift was observed for HKU4-RBD, indicating a lower binding potency than MERS-RBD. An hCD26-specific antibody rather than an isocontrol immunoglobulin G (IgG) blocked the Huh7 surface attachment by HKU4-RBD (Figure 2C). The observed Huh7 binding was also inhibited by the soluble

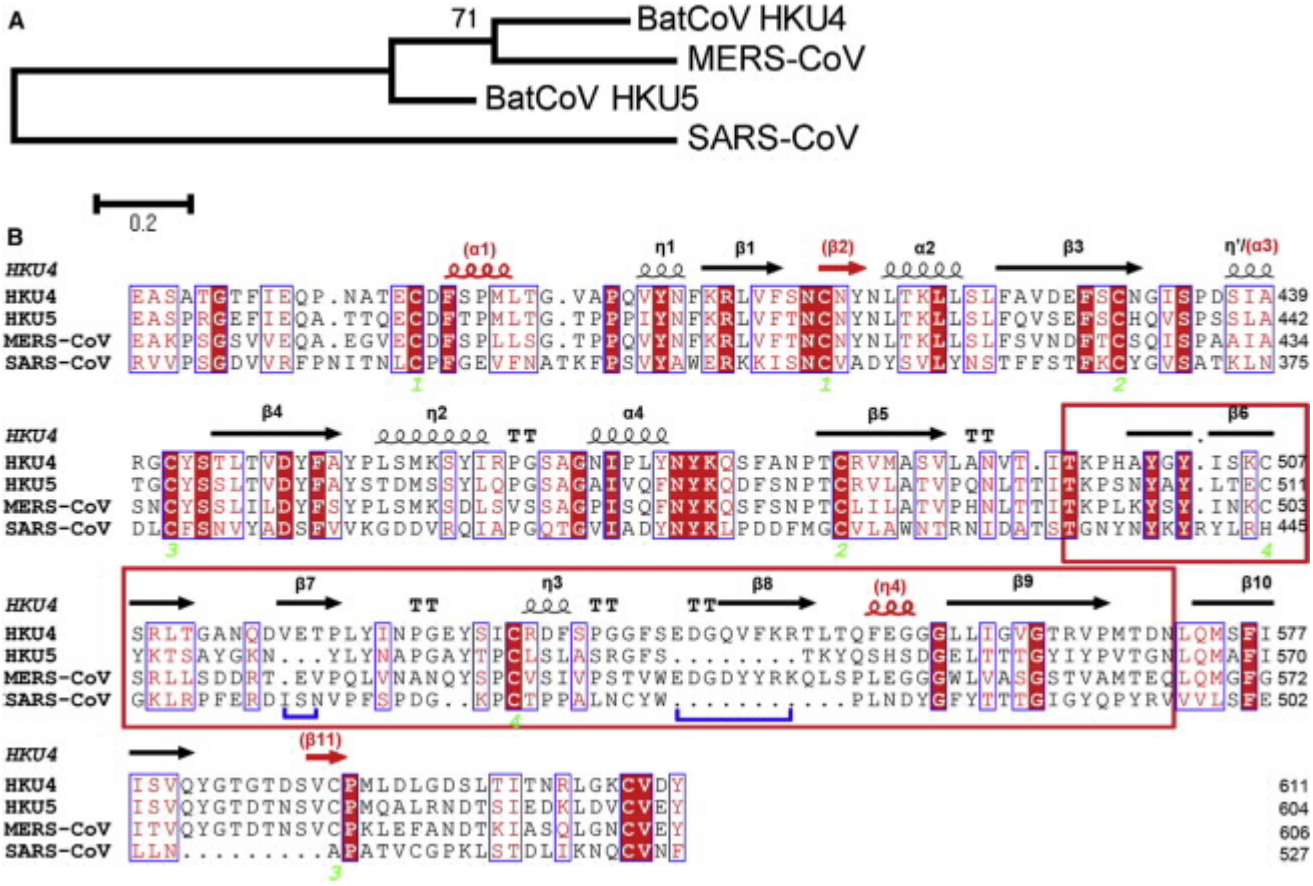

Figure 1. Comparison of the HKU4-RBD, HKU5-RBD, MERS-RBD, and SARS-RBD Sequences

(A) Phylogenetic tree generated using MEGA (Tamura et al., 2013) with the indicated RBD sequences.

(B) Structure-based sequence alignment. The secondary structure elements are defined based on an ESPript (Gouet et al., 1999) algorithm and are labeled as in a previous report on the MERS-RBD structure (Lu et al., 2013). Spiral lines indicate a or 3_{10} helices, while arrows represent b strands. Helices a1 and h4 and strands b2 and b11 are not preserved in the HKU4-RBD structure and are marked in red. The element equivalent to the MERS-RBD helix a3 exhibits characteristics of a 3_{10} helix in HKU4-RBD and is therefore labeled as h^0. The external subdomain is highlighted by enclosure with a red box. The two deletions in HKU5-RBD are marked with blue lines. The Arabic numerals 1–4 indicate cysteine residues that pair to form disulfide bonds. See also Figure S3.

ectodomain protein of hCD26, but not by the extracellular fragment of the SARS-CoV receptor hACE2 (Figure 2D). We also utilized the hCD26-negative BHK cell line in the binding assay. As expected, surface binding to BHK cells could only be observed for HKU4-RBD and MERS-RBD after transfection of the cells with an hCD26-expressing plasmid (Figures 2E–2H). Taken together, these results clearly demonstrated that BatCoV HKU4, unlike its close relative BatCoV HKU5, is capable of binding to hCD26 via the spike-RBD region.

The Interaction between HKU4-RBD and hCD26 Is Specific but of Low Affinity

We next set out to characterize the interaction between HKU4-RBD and hCD26 using real-time biophysical binding assays. The proteins prepared from insect cells were purified to homogeneity (Figure S1, available online) and subjected to SPR experiments. As assay controls, MERS-RBD and SARS-RBD were found to bind potently to their respective canonical receptors (Figures 3A and 3B). HKU4-RBD interacted with hCD26, but not with hACE2 (Figures 3C and 3D). However, in contrast to the control pairs showing slow on and off rates, the Biacore binding profile between HKU4-RBD and hCD26 revealed fast association/dissociation kinetics. The equilibrium dissociation constant (K_D) of HKU4-RBD binding to hCD26 was calculated to be 35.7 mM (Figures 3C and S2), which is approximately three orders of magnitude lower than that of MERS-RBD to hCD26 (Lu et al., 2013). Though HKU5-RBD behaved similarly to its HKU4 homolog protein by gel filtration (Figure S1), no hCD26 binding was observed (Figure 3E), which is consistent with our flow cytometric assays (Figures 2B and 2F).

Cell Infection of BatCoV HKU4 Pseudoviruses Is Mediated by hCD26

With evidence of binding between HKU4-RBD and hCD26, we then tested the potential of this human surface molecule to function as a receptor for BatCoV HKU4. Lentiviral particles pseudotyped with either the BatCoV HKU4 or the MERS-CoV S were individually prepared in 293T cells. The successful incorporation of the viral S protein into the pseudovirus envelope was ascertained by western blotting using a monoclonal antibody

recognizing a FLAG epitope engineered at the S C terminus (Figure 4A). In accordance with a previous report (Gierer et al., 2013), the majority of the MERS-CoV S protein was proteolytically cleaved (Figure 4A). In marked contrast, however, BatCoV HKU4 S remained largely intact (Figure 4A), displaying a pattern similar to that of SARS-CoV (Moore et al., 2004; Simmons et al., 2004).

The viral infection mediated by BatCoV HKU4 S was then tested in Huh7 cells. With a pseudotyped vector encoding luciferase, the infection efficiency was determined by quantifying luciferase activities in the cell lysates. As a positive control, pseudoparticles bearing the MERS-CoV S protein robustly infected Huh7 cells, showing an 400-fold increase in the luciferase signal as compared to particles bearing no S protein. However, no evident cell infection was observed for the BatCoV HKU4 pseudoviruses (Figure 4B).

According to previous studies on other coronaviruses (reviewed in Simmons et al., 2013), proteolytic separation of the S protein into functional S1 and S2 subunits by host cell proteases is a prerequisite to subsequent membrane fusion. Noting the inefficient S proteolysis in the BatCoV HKU4 pseudoviruses above, we hypothesized that in vitro treatment of the virus particles with proteases such as trypsin might activate the S protein, enabling viral entry into the cells upon receptor recognition. Therefore, the harvested BatCoV HKU4 pseudovirus particles were treated with various concentrations of trypsin (2.5–40 mg/ml), incubated with fetal bovine serum to inactivate the trypsin, and then used to infect Huh7 cells. Proteolysis of the S protein was observed in a concentration-dependent manner for the pseudoviruses (Figure 4A). Accordingly, significant increases (>150-fold) in the luciferase activity were recorded for pseudoviruses pretreated with 10, 20, and 40 mg/ml of trypsin, demonstrating successful entry into the cells (Figure 4B). Then, pseudoviruses digested with 10 mg/ml trypsin were used in the subsequent antibody blocking assays. As expected, a concentration-dependent inhibition of cell infection was observed using the hCD26 antibody that specifically blocked the Huh7 surface attachment of HKU4-RBD (Figure 4C). Therefore, we provided direct evidence that pseudoviruses bearing BatCoV HKU4 S infect human cells via hCD26 recognition.

Complex Structure between HKU4-RBD and hCD26

We further used cocrystallography to study the molecular basis of binding between HKU4-RBD and hCD26. The two purified proteins were mixed in vitro to allow the formation of heterocomplexes, and we managed to solve the structure at a resolution of 2.6 Å (Table S1). In the crystallographic asymmetric unit, HKU4-RBD and hCD26 were observed to form two 1:1 binding

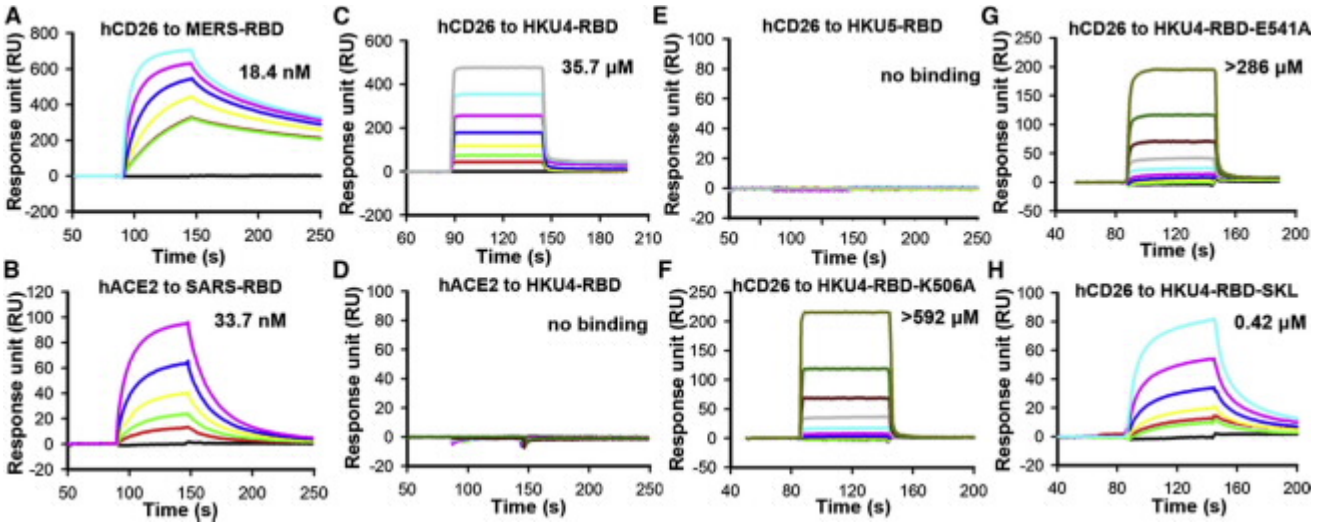

Figure 3. Specific Interaction between HKU4-RBD and hCD26 Characterized by SPR

(A–H)The indicated wild-type or mutant RBD proteins were immobilized on the chip and tested for binding with gradient concentrations of hCD26 or hACE2. The binding profiles are shown.

(A)hCD26 binding to MERS-RBD. (B)hACE2 binding to SARS-RBD. (C)hCD26 binding to HKU4-RBD. (D)hACE2 binding to HKU4-RBD. (E)hCD26 binding to HKU5-RBD. (F)hCD26 binding to HKU4-RBD-K506A. (G)hCD26 binding to HKU4-RBD-E541A. (H)hCD26 binding to HKU4-RBD-SKL, a triple mutant of S540W, K547R, and L558W. The dissociation constants were calculated to be 35.7 and 0.42 mM for the hCD26/HKU4-RBD and hCD26/HKU4-RBD-SKL pairs, respectively, and >400 mM for the hCD26/HKU4-RBD-K506A and hCD26/HKU4-RBD-E541A pairs. See also Figures S1 and S2.

complexes that are related by a two-fold axis (Figure 5A). These two complexes are of essentially the same structure, showing a root-mean-square deviation (rmsd) of 0.18 Å for all Ca pairs. For hCD26, clear electron densities could be traced for 727 amino acids from R40 to P766. As observed in previous reports (Engel et al., 2003), this human enzyme folds into two structural domains: an a/b hydrolase domain and an eight-bladed b-propeller domain. hCD26 utilizes its propeller blades IV and V to recognize HKU4-RBD (Figures 5A and 5B). The two hCD26 molecules in the asymmetric unit were assembled into a dimer in the structure, with each protomer engaging one HKU4-RBD via its propeller. This leads to an overall U-shaped structure very similar to that observed for the MERS-RBD/hCD26 complex (Lu et al., 2013).

In the complex structure, HKU4-RBD contains 208 consecutive density-traceable residues, spanning T386 to L593. The folded structure comprises a core subdomain located distally from the engaging hCD26 and an external subdomain recognizing blades IV and V of the receptor propeller (Figure 5B). The core subdomain involves a five-stranded b sheet (b1, b3, b4, b5, and b10) forming a "nucleus" in the center, several helices (a helices a2 and a4, and 3_{10} helices h1, h^0, and h2) decorating the center sheet on the exterior, and three disulfide bonds (C388/C412, C430/C483, and C442/C590) stabilizing the subdomain structure in the interior. The N and C termini are in close proximity, extending away from the bound receptor. The external subdomain is a strand-dominated structure with four anti-parallel b strands (b6–b9) and exposes a flat sheet-face for receptor engagement. An extra disulfide bond (C507/C531) located in this external region links helix h3 to strand b6 (Figures 1B and 5B).

As expected, this BatCoV HKU4 viral ligand exhibits significant structural homology to its MERS-CoV homolog, in agreement with the >50% sequence identity between the two molecules (Figure 1). Superimposition of the HKU4-RBD structure onto a previously reported MERS-RBD structure (Protein Data Bank [PDB]: 4KQZ) revealed an rmsd of 1.1 Å for 194 equivalent Ca atoms. In comparison to MERS-RBD, the majority of the secondary structure elements are well preserved in HKU4-RBD. The latter, however, lacks an a helix (a1) and two small strands (b2 and b11) in its core subdomain and is devoid of a 3_{10} helix (h4) in the external subdomain. In addition, the helix preceding strand b3 exhibits characteristics of a 3_{10} helix (h^0) in HKU4-RBD, rather than being a-helical (a3) as in MERS-RBD (Figures 1 and S3).

Atomic Details at the Binding Interface between HKU4-RBD and hCD26

In the complex structure, large surface areas (968.7 $Å^2$ in HKU4-RBD and 1,033.9 $Å^2$ in hCD26) are buried by the two binding entities. Therefore, we scrutinized this extended buried surface to identify key amino acids involved in complex formation. Residues located within the van der Waals (vdw) contact distance (4.5 Å resolution cutoff) between HKU4-RBD and hCD26 were selected (Table S2), and a series of hydrophilic amino acids located along the interface were found to form a solid network of H bond and salt bridge interactions (Figures 5B and 5C). These strong polar contacts include the HKU4-RBD residue K506 interacting with the receptor amino acids T288 and A289, N514 and Q515 with R317, D516 with Y322, E541 and D542 with K267, and K547 with I295 (Figure 5C). In addition, several residues (such as Y460 located in helix h2 of the RBD core subdomain) were further shown to contribute to the receptor binding by providing multiple vdw contacts (Table S2). It is notable that K506 and E541 of the viral ligand afforded both side-chain H bond and

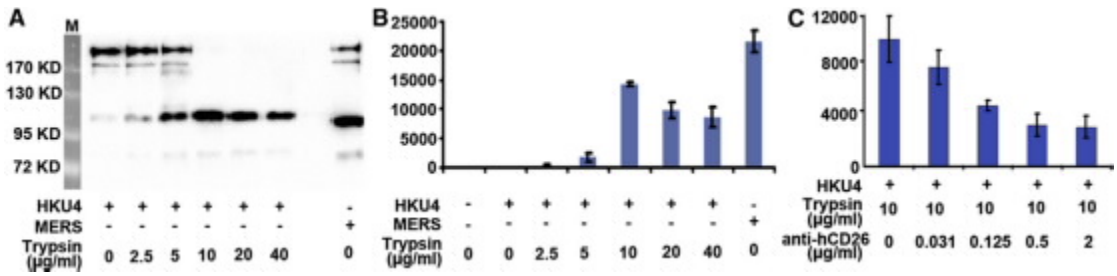

Figure 4. Huh7 Infection by Lentiviral Particles Pseudotyped with BatCoV HKU4 S

(A) Proteolytic processing of the embedded BatCoV HKU4 S by trypsin. The HKU4 pseudovirus was treated with trypsin at the indicated concentrations and characterized with an antibody recognizing a FLAG epitope engineered at the S C terminus. The untreated MERS pseudovirus was included as a reference control.

(B) A Huh7 cell infection assay with the indicated pseudoviruses.

(C) An antibody blocking assay using HKU4 pseudoviruses treated with 10 mg/ml trypsin and an anti-hCD26 antibody. The recorded fluorescence intensities were plotted as histograms, and the error bars represent ± SD for triplicate experiments.

multi-vdw interactions in this network (Table S2). Thus, these residues were individually mutated to alanine, and the resultant HKU4-RBD mutants were tested for receptor binding using SPR assays. The calculated K_Ds for the two mutants binding to hCD26 were >400 mM, which is an 10-fold decrease in binding affinity compared to that of the wild-type protein (Figures 2F, 2G, and S2), demonstrating their important roles in receptor recognition. Interestingly, these two amino acids are conserved between HKU4-RBD and MERS-RBD (Figure 1B) and are also involved in the binding of the MERS-CoV ligand to hCD26 (Lu et al., 2013).

In addition to the aforementioned contact network, extra HKU4-RBD/hCD26 interactions involve a small hydrophobic patch (Figure 5D) and a sugar-mediated engagement (Figure 5E). The former is located in the proximity to a bulged hCD26 helix, which packs amino acids A291, L294, and I295 against RBD residues L510 and I560; the latter consists of a carbohydrate moiety linked to hCD26 N229 and amino acids E541 and Q544 in HKU4-RBD, which together form two H bonds.

Variant Amino Acid Interaction Details with hCD26 between HKU4-RBD and MERS-RBD

Overall, the HKU4-RBD/hCD26 structure solved in this study is very similar to the previously reported structure of MERS-RBD bound to hCD26. The two complex structures can be superimposed onto each other well, except for two interstrand loops (the b6/b7 and b8/b9 loops) in the RBD, which are distinctly oriented between the two viral ligands (Figure 6A). Despite variance in sequence, HKU4-RBD and MERS-RBD engage the same IV and V blades of the hCD26 b-propeller, demonstrating an overall similar recognition mode for hCD26 between BatCoV HKU4 and MERS-CoV.

We next compared the receptor binding details between the two viruses by characterizing the vdw contacts for each RBD residue along the binding interface. In both HKU4-RBD and MERS-RBD, a limited number of intermolecule contacts are contributed by the core subdomain residues, such as those located in the h2 (e.g., HKU4-Y460 and MERS-D455) and a4 (e.g., HKU4-N468 and MERS-P463) helices. These amino acids are adapted for hCD26 in HKU4-RBD slightly better than for that in MERS-RBD. For example, both HKU4-Y460 and HKU4-N468 provide more vdw contacts than the equivalent residues in MERS-RBD (Figures 6B and 6C).

In contrast to the core subdomain, with only limited contributions to hCD26 engagement, the majority of the ligand/receptor intermolecule contacts are provided by the amino acids located in the RBD external subdomain. Most HKU4 residues in this region contact hCD26 less efficiently than the corresponding MERS-RBD amino acids. Among these, the S540/W535 and K547/R542 pairs in the b8 strand and the L558/W553 pair in the b9 strand are most evident, each showing 20–30 contact differences (Figures 6B and 6C). Reminiscent of the low binding affinity of HKU4-RBD to hCD26, these three residues in HKU4-RBD were mutated to the MERS-RBD amino acids, and the resultant mutant protein was tested for receptor binding by SPR. The calculated dissociation constant for this triple mutant was 0.42 mM, indicating that its binding affinity is 100-fold greater than that of the wild-type parental protein. In addition, the mutation also shifted the binding kinetics from a fast-on/fast-off mode, as observed for the wild-type HKU4-RBD, to a slow-on/slow-off mode, as observed for the MERS-RBD (Figures 2H and S2). We believe that the resultant introduction of extra vdw contacts and hydrophobic interactions by substituting these three residues in HKU4-RBD with more hydrophobic amino acids (e.g., tryptophan) led to the change in the binding kinetics. A similar phenomenon of altered K_{on} and/or K_{off} rates resulting from changes in hydrophobic interaction has also previously been observed in other protein interactions (Weihofen et al., 2004).

DISCUSSION

Entry into susceptible host cells is the first step in the virus life cycle, and each entry process starts with receptor recognition. Identification of the cellular receptors for a virus is therefore a key question in viral pathogenesis studies. The BatCoVs HKU4 and HKU5 represent two important bat-derived coronaviruses closely related to MERS-CoV (Lau et al., 2013; van Boheemen et al., 2012). In this study, we performed a functional assay to identify potential receptors for these viruses. We found that HKU4-RBD, a protein domain spanning residues 372–611 of the BatCoV HKU4 S, but not the equivalent S region of BatCoV

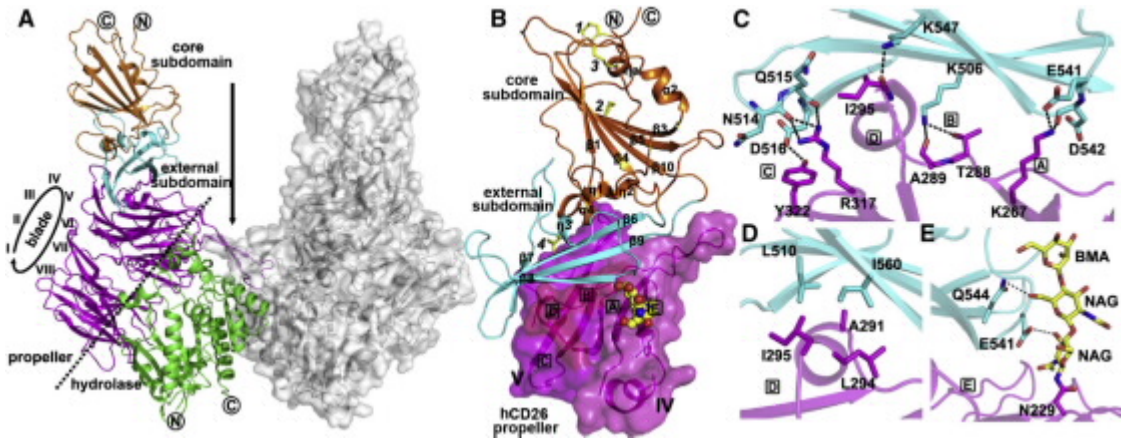

Figure 5. The Complex Structure of HKU4-RBD Bound to hCD26

(A) The overall structure. The two 1:1 complexes related by a two-fold axis (vertical arrow) are shown in cartoon and surface representations, respectively. The core and external subdomains of HKU4-RBD and the b-propeller and hydrolase domains of hCD26 are individually labeled and highlighted in orange, cyan, magenta, and green, respectively. The propeller blades (I–VIII)and the protein N/C termini are marked.

(B) A magnified view of the HKU4-RBD structure and the ligand/receptor interface. The secondary structure elements are specified by ESPript and labeled for the viral ligand. Yellow sticks marked with Arabic numbers indicate disulfide bonds. For the receptor, only propeller blades IV and V that engage HKU4-RBD are shown, using a surface representation.

(C–E) The important contact sites are marked with boxed letters A–E and are further delineated for interaction details as follows. (C) A solid network of H bond and salt bridge interactions. (D) A small patch of hydrophobic interactions. (E) Extra H bond contacts contributed by a carbohydrate moiety linked to hCD26 N229. The residues involved and the carbohydrates referred to are shown and labeled. See also Tables S1 and S2.

HKU5, binds to hCD26. In addition, the complex structure of HKU4-RBD bound to hCD26 was solved, demonstrating a receptor recognition mode similar to that observed for MERS-RBD, though with variant amino acid interaction details and a low binding affinity. We further showed that lentivirus particles pseudotyped with BatCoV HKU4 S could infect Huh7 cells via engagement of hCD26. Taken together, we provide the comprehensive data showing that hCD26 is also a functional receptor for the bat-derived HKU4 coronavirus. In support of this, a similar study of the functional reactivity of BatCoV HKU4 S for hCD26 was recently reported online (Yang et al., 2014) during the revision of our manuscript.

Coronavirus S proteins are among the typical class I membrane fusion proteins (Gao, 2007; Harrison, 2008; Xu et al., 2004a, 2004b). Activation of the subsequent membrane fusion process requires, in most cases, proteolysis of the fusion proteins by host cell proteases. This proteolytic process either occurs during or after maturation of the viruses, such as with murine hepatitis virus (MHV) (Frana et al., 1985) and MERS-CoV (Gierer et al., 2013), or occurs during viral entry, such as with SARS-CoV (Simmons et al., 2013). When we analyzed the lentivirus particles, the pseudotyped BatCoV HKU4 S was predominantly uncleaved. Accordingly, we initially were unable to observe any infection of Huh7 cells by the HKU4 pseudoviruses. However, by mimicking the maturation process of MERS-CoV, we showed that treatment of the pseudoviruses with trypsin enabled hCD26-mediated Huh7 infection. These results demonstrated that engagement of a receptor by, and proteolytic activation of, the envelope S protein remain two prerequisite factors for BatCoV HKU4 infection, as with other coronaviruses (Simmons et al., 2013). By identifying hCD26 as a functional receptor for BatCoV HKU4, the spatiotemporal processing of its S protein to allow subsequent membrane fusion remains an unresolved issue that should be further explored in the future.

Our results should also shed light on virus isolation. Since the first identification of the full-length HKU4 genome in bats in 2006 (Woo et al., 2006), culturing of the viruses has been unsuccessful. Further trials should consider cell lines expressing hCD26 but displaying variant proteases (e.g., cathepsin L, furin/furin-like proteases, HAT, and TMPRSS2) that are commonly involved in the processing of coronavirus spikes (Simmons et al., 2013). Alternatively, including small amounts of trypsin during viral culturing may facilitate the viral infection and thereby progeny virus production.

The previous SARS epidemic and the recent emergence of MERS-CoV in the Middle East serve as a constant reminder of the importance of identifying potential newly emerging coronaviruses in their natural animal reservoirs. Bats are natural reservoirs of many alphaCoVs and betaCoVs, which provide viral genes for the genesis of newly emerging coronaviruses with interspecies transmission potential. Phylogenetic dating suggests three suspected interspecies jumps of animal betaCoVs into humans, two of which (the SARS-CoV and MERS-CoV) are very likely of bat origin (Ge et al., 2013; Ithete et al., 2013; Li et al., 2005b; Memish et al., 2013) and were circulating in bats before they "jumped" to an intermediate host (e.g., civets for SARS-CoV and dromedary camels for MERS-CoV) and/or to humans (Ge et al., 2013; Guan et al., 2003; Haagmans et al., 2014; Reusken et al., 2013). A recent study demonstrates the circulation of BatCoV HKU4 in bats in the past years (Lau et al., 2013). With the data in this study, we found that BatCoV HKU4 has evolved to utilize hCD26 as a functional receptor and therefore gained one of the key factors sufficing for interspecies transmission and human infection. This highlights the necessity for a

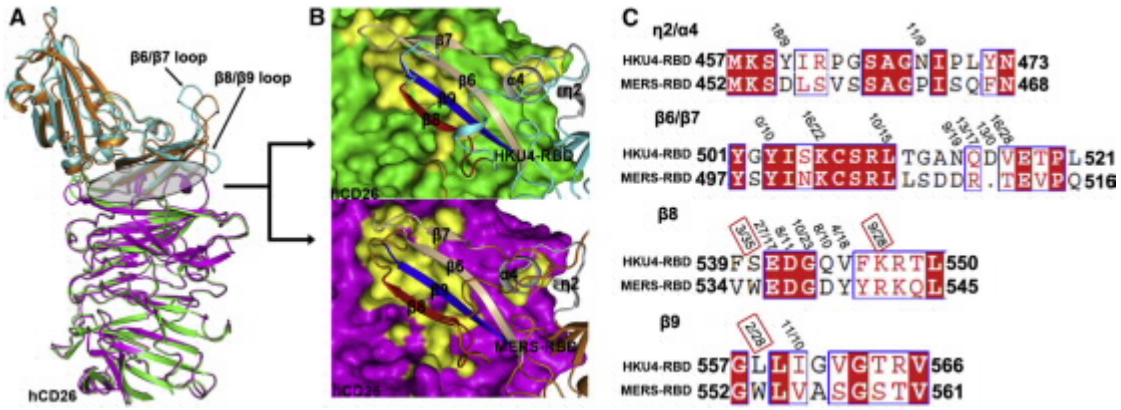

Figure 6. Comparison of the HKU4-RBD/hCD26 and MERS-RBD/hCD26 Pairs for Their Binding Modes and the Interaction Details

(A) Overall similar receptor binding mode between HKU4-RBD and MERS-RBD. Superimposition of the structure of HKU4-RBD (cyan) bound to hCD26 (green) and a complex structure of MERS-RBD (orange) with hCD26 (magenta). The loops exhibiting variant conformations are highlighted.

(B) A magnified view of the ligand/receptor (RBD in cartoon and hCD26 in surface) interface in the two binding pairs. The elements located within the vdw contact distance from the receptor are highlighted for the h2-a4 region (gray) in the core subdomain, and the b6-b7 (tint), b8 (red), and b9 (blue) strands in the external subdomain. Top: the HKU4-RBD/hCD26 structure. Bottom: the MERS-RBD/hCD26 structure.

(C) Better hCD26 adaptation in MERS-RBD than in HKU4-RBD. For each element specified in (B), the amino acid sequences were aligned between HKU4-RBD and MERS-RBD. The number pairs listed above the sequence highlight the differences in vdw contacts. For clarity, only those providing R 10 intermolecule contacts are labeled. The S540/W535, K547/R542, and L558/W553 pairs showing the most contact differences are marked with red boxes.

surveillance program to monitor HKU4 circulation in bats. Special attention should be paid to virus variants incorporating mutations in S that would increase their affinity for hCD26 and/or confer susceptibility to host protease cleavage.
